c. Extracting by news media does not constitute prior publication unless all vital tables and pertinent conclusions are involved or unless such publication was actively solicited by the authors.

Legal considerations require letters of permission from authors and publishers for use of illustrations or quotations originally appearing elsewhere, and also written permission for use of photographs of identifiable patients. Identifying information, such as names, initials, hospital numbers, and dates, must be avoided.

When experimentation involving human subjects is reported, an appropriate statement regarding informed consent should be made.

Case reports should include only significant data. Laboratory findings should be restricted to those pertinent to the discussion.

Symbols used for respiratory physiology should follow Fed. Proc. 9:602, 1950.

Explanation of abbreviations and symbols used within the text should be added as a footnote.

Example: torr: Unit of pressure of 1 mm. of mercury at 0° C. and standard gravity.

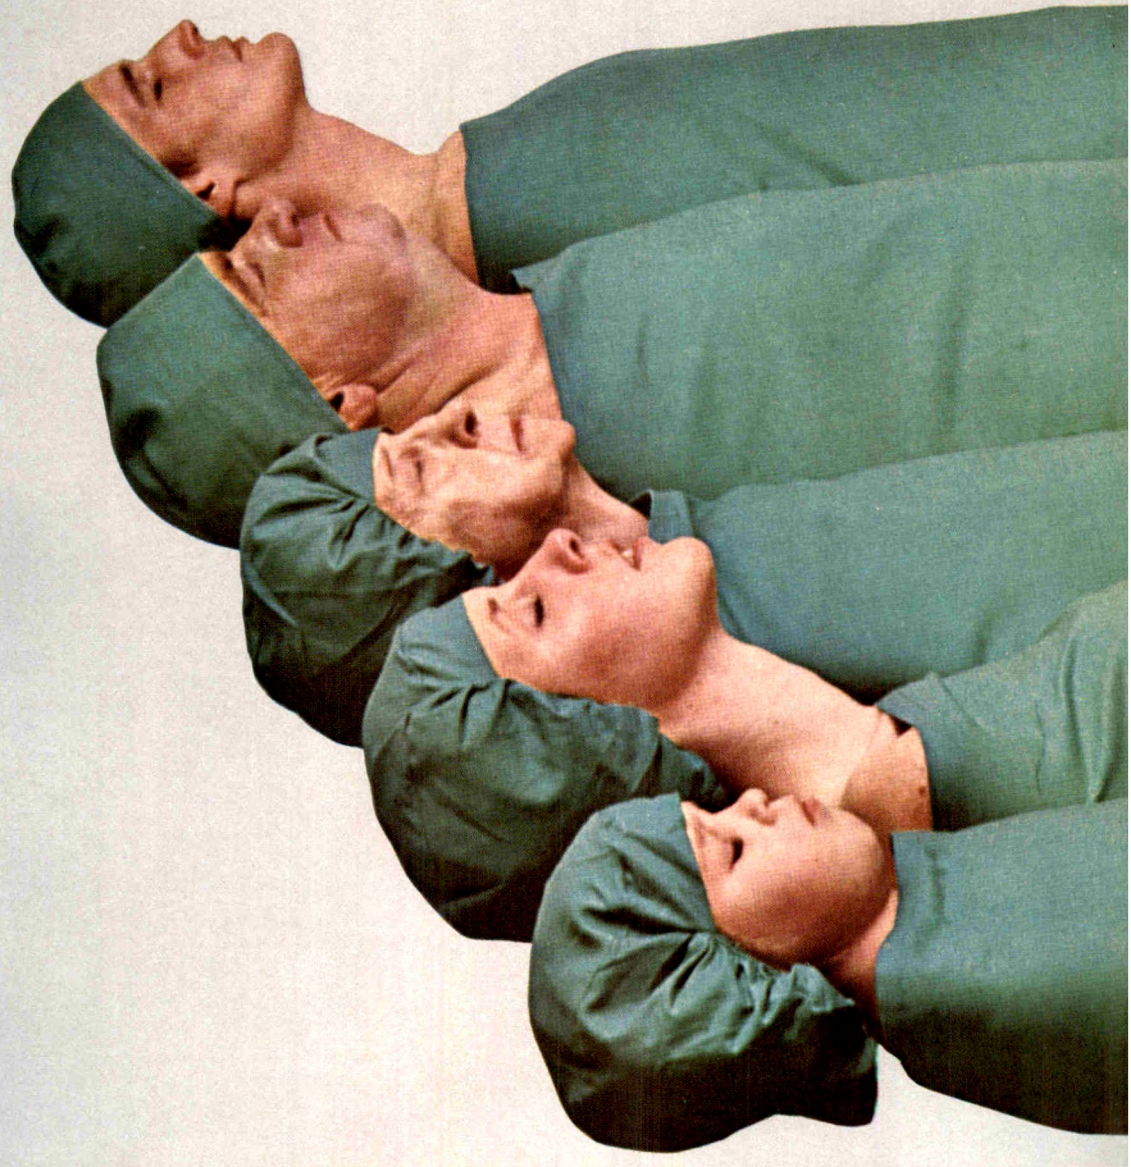
Clinically proven
nondepolarizing muscle relaxant

PAVULON®
pancuronium bromide

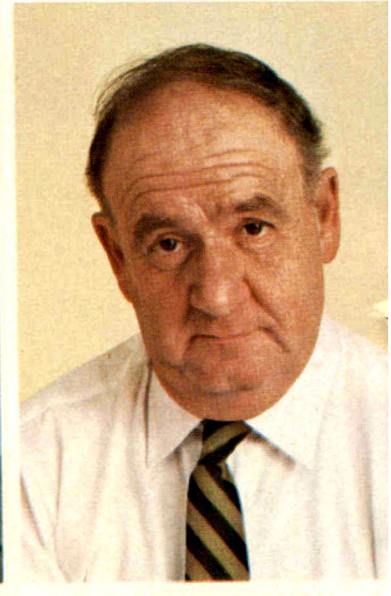
for many patients
for many reasons



Please turn page for full prescribing information

An unusually fast-acting nondepolarizing blocking agent [1-5]

PAVULON®
pancuronium bromide



for many patients for many reasons

in pediatric surgery[6-12]

Pavulon® has been used with satisfactory results in pediatric patients undergoing elective surgery[11], abdominal surgery[7] and cardiovascular surgery[8]. Dose response studies indicate that, except for neonates, dosage is the same as for adults. In neonates, a test dose of 0.02 mg/kg is recommended to determine responsiveness.

in geriatric surgery[13]

Pavulon® can be considered a preferred relaxant for major surgical procedures in the aged patient because of the relative absence of significant side effects.

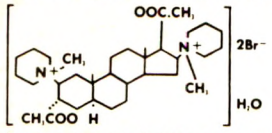
in the high risk patient[2-5, 14-18]

Pavulon® is often preferred for poor risk patients[5,14,16] especially those with asthma or chronic bronchitis[2,14,16,17], cardiovascular disease[4,5,16,18] and patients undergoing abdominal, thoracic or other major surgery[2,5], including open heart surgery[15]. Caution should be exercised, however, in the presence of renal disease since a major portion of the administered drug is excreted unchanged in the urine.

PAVULON® (pancuronium bromide)

THIS DRUG SHOULD ONLY BE ADMINISTERED BY ADEQUATELY TRAINED INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS, AND HAZARDS.

DESCRIPTION: Pavulon (pancuronium bromide) is the aminosteroid 2 beta, 16 beta-dipiperidine-5 alpha-androstane-3 alpha, 17 beta-diol diacetate dimethobromide. It has the following structural formula:



ACTIONS: Pavulon is a non-depolarizing neuromuscular blocking agent possessing all of the characteristic pharmacological actions of this class of drugs (curariform) on the myoneural junction.

Pavulon is approximately 5 times as potent as d-tubocurarine chloride.

The onset and duration of action of Pavulon is dose dependent. With the administration of 0.04 mg. per kg. the onset of action, as measured by a peripheral nerve stimulator, is usually within 45 seconds, and its peak effect is usually within 4½ minutes; recovery to 90% of control twitch height usually takes place in less than one hour. Larger doses, more suitable for endotracheal intubation, such as 0.08 mg. per kg. of Pavulon have an onset of action of about 30 seconds, and a peak effect within 3 minutes. Supplemental incremental doses of Pavulon, following the initial dose, slightly increase the magnitude of blockade, and significantly increase the duration of the blockade.

Pavulon has little effect upon the circulatory system. The most frequently reported observation is a slight rise in pulse rate.

Human histamine assays, and clinical observations, as well as in *vivo* guinea pig testing, and in *vitro* mast cell testing, indicate that histamine release rarely, if ever, occurs.

Pavulon is antagonized by acetylcholine, anticholinesterases, and potassium ion. Its action is increased by inhalational anesthetics such as halothane, diethyl ether, and methoxyflurane, as well as quinine, magnesium salts, hypokalemia, some carcinomas, and certain antibiotics such as neomycin, streptomycin, kanamycin, and bacitracin. The action of Pavulon may be altered by dehydration, electrolyte imbalance, acid-base imbalance, renal disease, and concomitant administration of other neuromuscular agents.

Pavulon has no known effect on consciousness, the pain threshold, or cerebration.

INDICATIONS: Pavulon is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may also be employed to facilitate the management of patients undergoing mechanical ventilation.

CONTRAINDICATIONS: Pavulon is contraindicated in patients known to be hypersensitive to the drug or to the bromide ion.

WARNINGS: PAVULON SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS, WHO ARE FAMILIAR WITH ITS ACTIONS AND THE POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND REVERSAL AGENTS ARE IMMEDIATELY AVAILABLE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR CONTROL RESPIRATION.

In patients who are known to have myasthenia gravis small doses of Pavulon may have profound effects. A peripheral nerve stimulator is especially valuable in assessing the effects of Pavulon in such patients.

USAGE IN PREGNANCY: The safe use of pancuronium bromide has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards. There are insufficient data to support safe use of Pavulon in obstetrics, so such use is not recommended.

PRECAUTIONS: Although Pavulon has been used successfully in many patients with pre-existing pulmonary, hepatic, or renal disease, caution should be exercised in these situations. This is particularly true of renal disease since a major portion of administered Pavulon is excreted unchanged in the urine.

ADVERSE REACTIONS: Neuromuscular: The most frequently noted adverse reactions consist primarily of an extension of the drug's pharmacological actions beyond the time period needed for surgery and anesthesia. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle relaxation resulting in respiratory insufficiency or apnea. Inadequate reversal of the neuromuscular blockade by anticholinesterase agents has also been observed with Pavulon (pancuronium bromide) as with all curariform drugs. These adverse reactions are managed by manual or mechanical ventilation until recovery is judged adequate.

Cardiovascular: A slight increase in pulse rate is frequently noted.

Gastrointestinal: Salivation is sometimes noted during very light anesthesia, especially if no anticholinergic premedication is used.

Skin: An occasional transient rash is noted accompanying the use of Pavulon.

Respiratory: One case of wheezing, responding to deepening of the inhalational anesthetic, has been reported.

DRUG INTERACTION: The intensity of blockade and duration of action of Pavulon is increased in patients receiving potent volatile inhalational anesthetics such as halothane, diethyl ether, enflurane, and methoxyflurane. No increase in intensity of blockade or duration of action of Pavulon is noted from the use of thiobarbiturates, narcotic analgesics, nitrous oxide, or droperidol.

Prior administration of succinylcholine, such as that used for endotracheal intubation, enhances the relaxant effect of Pavulon and the duration of action. If succinylcholine is used before Pavulon, the administration of Pavulon should be delayed until the succinylcholine shows signs of wearing off.

DOSAGE AND ADMINISTRATION: Pavulon should be administered only by or under the supervision of experienced clinicians. DOSAGE MUST BE INDIVIDUALIZED IN EACH CASE. The dosage information which follows has been derived from dose-response studies based on body weight and is intended to serve as a guide only. Since potent inhalational agents or prior administration of succinylcholine enhance the intensity of blockade and duration of Pavulon (see DRUG INTERACTION), these factors should be taken into consideration in selection of initial and incremental dosage.

In adults the initial intravenous dosage range is 0.04 to 0.1 mg. per kg. Later incremental doses starting at 0.01 mg. per kg. may be used. These increments slightly increase the magnitude of the blockade, and significantly increase the duration of blockade, because a significant number of myoneural junctions are still blocked when there is clinical need for more drug.

If Pavulon is used to provide skeletal muscle relaxation for endotracheal intubation, doses of 0.06 to 0.1 mg. per kg. are recommended. Conditions satisfactory for intubation are usually present within 2 to 3 minutes. The ability of the anesthetist to intubate with Pavulon (pancuronium bromide) improves with experience.

Dosage in Children; Dose-response studies in children indicate that, with the exception of neonates, dosage requirements are the same as for adults. Neonates are especially sensitive to non-depolarizing neuromuscular blocking agents, such as Pavulon, during the first month of life. It is recommended that a test dose of 0.02 mg. per kg. be given first in this group to measure responsiveness.

MANAGEMENT OF PROLONGED NEUROMUSCULAR BLOCKADE: Residual neuromuscular blockade beyond the time period needed for surgery and anesthesia may occur with Pavulon as with other neuromuscular blockers. This may be manifested by skeletal muscle weakness, decreased respiratory reserve, low tidal volume or apnea. A peripheral nerve stimulator may be used to assess the degree of residual neuromuscular blockade. Under such circumstances the primary treatment is manual or mechanical ventilation and maintenance of a patent airway until complete recovery of normal respiration is assured. Regonol® (pyridostigmine bromide) or neostigmine, in conjunction with atropine, will usually antagonize the skeletal muscle relaxant action of Pavulon. These should be accompanied by or preceded by injection of atropine sulfate to minimize the incidence of cholinergic side effects, notably excessive secretions and bradycardia. Satisfactory reversal can be judged by adequacy of skeletal muscle tone, and by adequacy of respiration. A peripheral nerve stimulator may also be used to monitor restoration of twitch height. Failure of prompt reversal (within 30 minutes) may occur in the presence of extreme debilitation, carcinomatosis, and with concomitant use of certain broad spectrum antibiotics, or anesthetic agents and adjuncts which enhance neuromuscular blockade or cause respiratory depression of their own. Under such circumstances the management is the same as that of prolonged neuromuscular blockade; ventilation must be supported by artificial means until the patient has resumed control of his respiration. Prior to the use of reversal agents, reference to the specific package insert of the reversal agents should be made.

CAUTION: Federal law prohibits dispensing without prescription.

HOW SUPPLIED:

2 ml. ampuls—2 mg./ml.—box of 25
5 ml. ampuls—2 mg./ml.—box of 25
10 ml. multiple dose vials—1 mg./ml.—box of 25

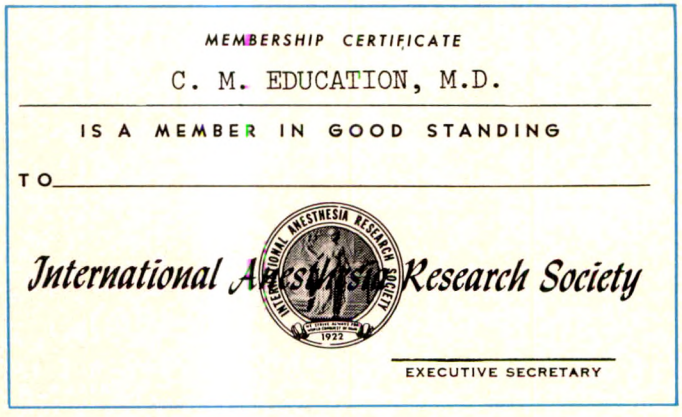
I. A. R. S. MEMBERSHIP

For Your In-training and Continuing Medical Education



MEMBERSHIP CERTIFICATE

C. M. EDUCATION, M.D.

IS A MEMBER IN GOOD STANDING

TO

International Anesthesia Research Society

EXECUTIVE SECRETARY

The International Anesthesia Research Society is a non-profit, scientific and educational corporation of the State of Ohio founded in 1922 "To Foster Progress and Research in Anesthesia." To this end it performs two functions: (1) It publishes a bi-monthly journal, "ANESTHESIA and ANALGESIA . . . Current Researches"; and (2) It sponsors an annual scientific "Congress" meeting which meets the criteria for Category 1 credit toward the AMA Physicians Recognition Award.

Membership in the IARS is voluntary; it is also separate and distinct from membership in any other local, state or national anesthesia organization.

MEMBERSHIP - ASSOCIATE MEMBERSHIP

MEMBERSHIP is open to individuals with doctorate degrees, licensed to practice in the medical, dental, osteopathic or veterinary medicine professions (i.e., MD, MB, DDS, DMD, DO, DMV); and to individuals with doctorate degrees (Ph.D.) in any scientific discipline, engaged in academic, private or commercial research.

ASSOCIATE MEMBERSHIP is open to individuals in the allied health professions, duly certified by their professional accrediting organization as nurse anesthetists (CRNA), physician assistants-anesthesia (PA-Anesth.), inhalation therapists (ARIT) or respiratory technicians (CRTT).

DUES are $25 per year for Members and Associate Members, and include a subscription to ANESTHESIA and ANALGESIA . . . Current Researches. Members are also entitled to reduced registration fee at IARS annual scientific meetings.

EDUCATIONAL MEMBERSHIP

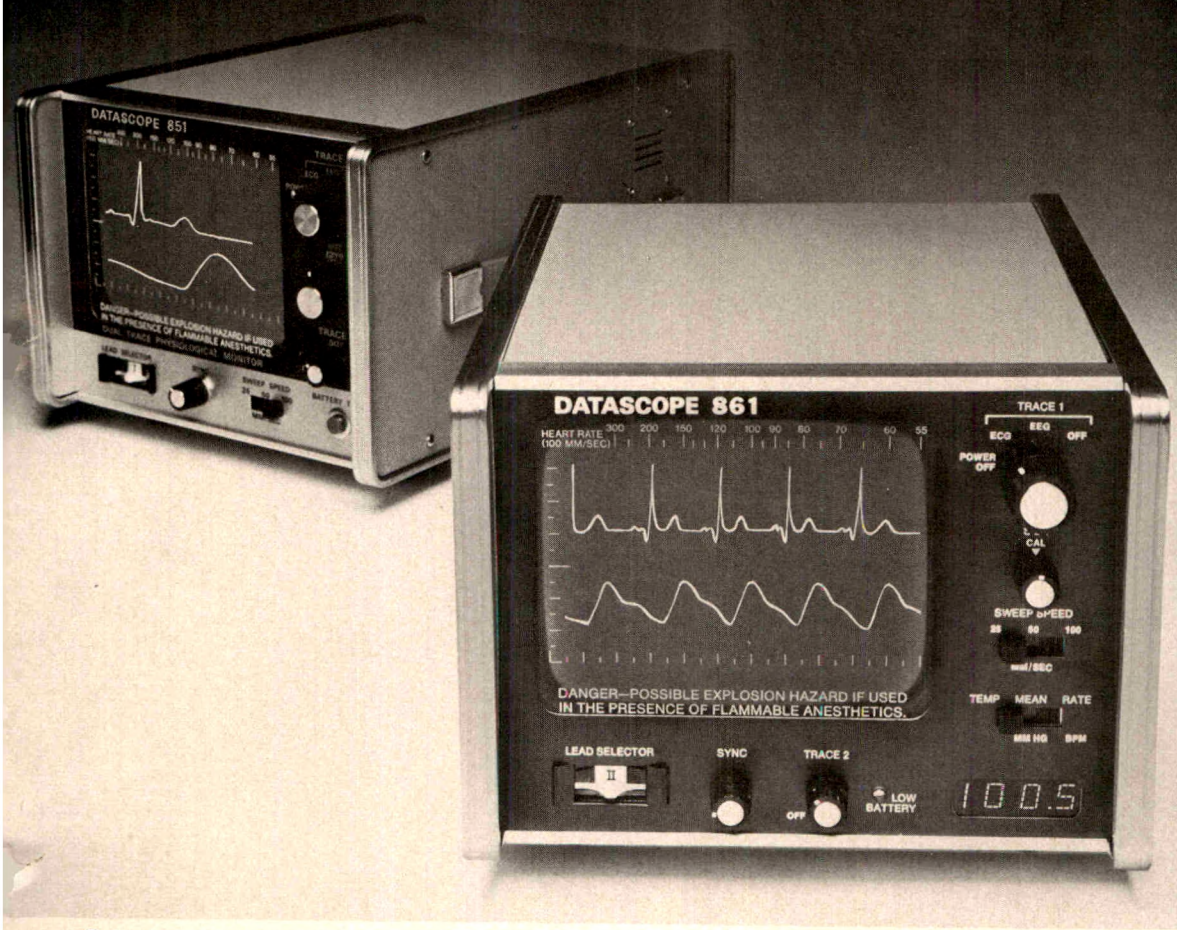
EDUCATIONAL MEMBERSHIP is open to interns and residents in anesthesiology training programs; registered nurses enrolled in nurse anesthesia schools; students in inhalation or respiratory therapy training programs, or in physician assistant anesthesia programs.

The official Educational Membership application blank must be completed by the individual applicant, and signed by his or her training program director.

Dues are $25 for a single, two-year period during the member's anesthesia training period, and include a two-year subscription to ANESTHESIA and ANALGESIA . . . Current Researches. Educational Members are entitled to complimentary registration at IARS annual scientific meetings.

Application forms are available from Cleveland business office. Program Directors are invited to obtain a supply of Educational Membership applications for their students in training.

THE MOST POPULAR MONITORS MADE. MADE EVEN BETTER.



For some time now, our monitors have been selected for use in surgery by more medical people than any other battery-powered monitors in the world. Because we give you more of what you want in a monitor than any other monitors in the world.

However, this didn't stop us from improving them.

Our new Datascope 851 and 861 will now give you heart rate not only from ECG, but also from pulse or blood pressure.

And both monitors will give you 2 traces. So you can monitor ECG (or EEG) and pulse simultaneously.

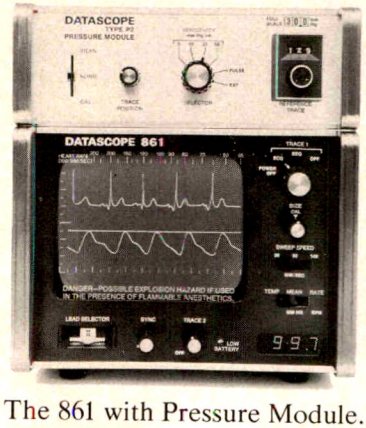
And both give you beat by beat synchronization†. So a single ECG complex shows up with each full sweep.

The 861 does even more. It monitors body temperature. On a digital read-out. And this same digital display will give you heart rate when you want it; or mean blood pressure when you are using the 861 with our Pressure Module.

For all the things our 851 and 861 do, they're surprisingly portable. And they offer longer battery-operating time than any other monitors. In some cases, actually twice as long.

Will they continue to be the most popular monitors made? More so.

For further information about our new 851, 861, or our Pressure Module, write Datascope Corp., 580 Winters Ave., Paramus, NJ 07652.



The 861 with Pressure Module.

THE DATASCOPE 851/861

†U.S. PATENT NO. 3457452

take the **Excessive Anxiety** out of **Anesthesi**

Vistaril I.M. (hydroxyzine HCl) helps allay the anxiety that may complicate premedication, induction and recovery room emergence.

It has no significant depressant effects on respiratory or circulatory function and often reduces postoperative emesis.

Vital signs are seldom impaired. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage.

And, because it may enhance the effect of injectable analgesics, requirements of narcotic and nonnarcotic analgesics, such as meperidine, morphine sulfate and pentazocine, may be reduced.

Vistaril I.M. is physically compatible with most commonly used analgesics, and can be mixed with them in the same syringe.

Alone, or as an adjunct for use with injectable analgesics, the maximum recommended dosage of Vistaril I.M. is 100 mg. While the analgesic dosage needed will usually be reduced, the actual dosage of Vistaril I.M. should be titrated against the individual patient's clinical response.

Vistaril® I.M.
(hydroxyzine HCl)
100 mg./2 ml., 50 mg./ml. and 25 mg./ml. Vials and Isojects®

Pfizer

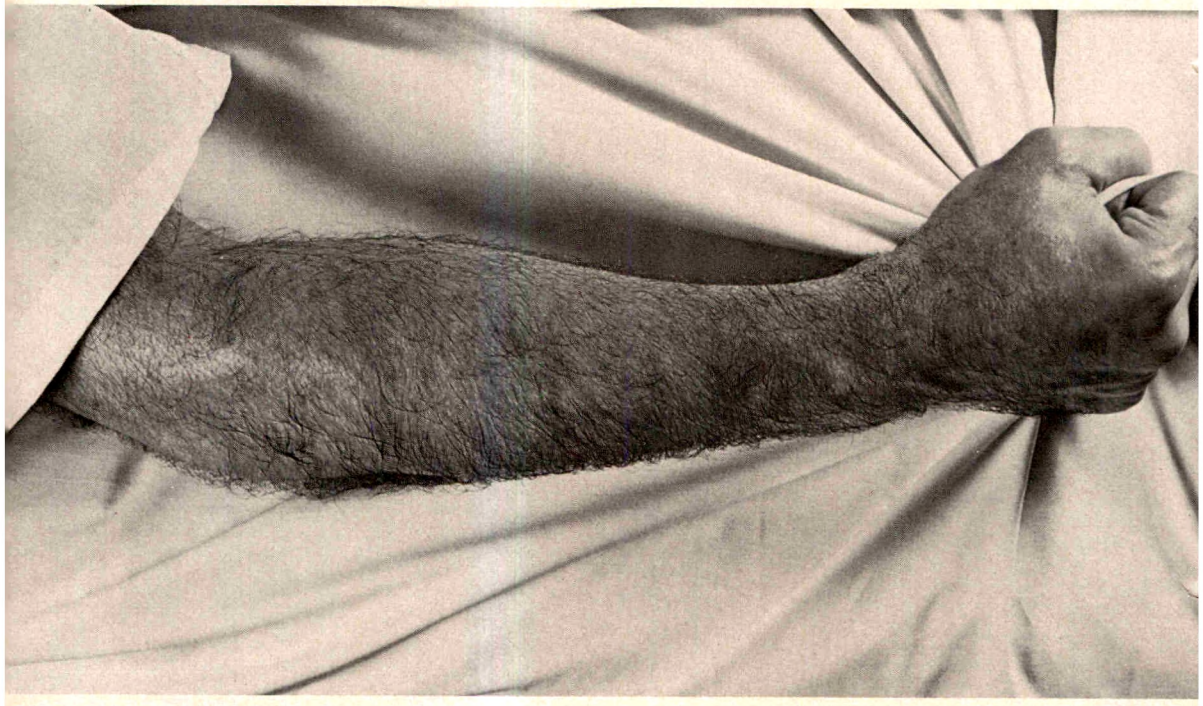
Vistaril® I.M.
(hydroxyzine HCl)

100 mg./2 ml., 50 mg./ml. and 25 mg./ml.
Vials and Isojects®

Calm Before Anesthesia... In Recovery



Brief Summary
VISTARIL® (hydroxyzine hydrochloride) Intramuscular Solution
For Intramuscular Use Only

Contraindications: Hypersensitivity to hydroxyzine. The solution for intramuscular use *must not* be injected subcutaneously, intra-arterially, or intravenously.

Hydroxyzine, when administered to the pregnant mouse, rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Clinical data in human beings are inadequate. Until adequate data are available to establish safety in early pregnancy, hydroxyzine is contraindicated during this period.

Precautions: *Hydroxyzine may potentiate the action of central nervous system depressants such as narcotics and barbiturates.* In conjunctive use, dosage for these drugs should be decreased as much as 50%. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery. The usual precautions for intramuscular injection should be followed; soft-tissue reactions have rarely been reported when proper technique has been used. Hydroxyzine intramuscular solution should be injected well within the body of a relatively large muscle. In adults, the preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus), or the mid-lateral thigh. In children, preferably the mid-lateral muscle of the thigh. In infants and small children, the upper outer quadrant of the gluteal region should only be used when necessary, as in burn patients, in c to minimize the possibility of damage to the sciatic nerve. The deltoic area should be used only if well developed, such as in certain adults older children, and only with caution to avoid radial nerve injury. Injections should not be mac'e in the lower and middle thirds of the upper arm. Aspiration is necessary to help avoid intravascular inject

Adverse Reactions: Drowsiness may occur; if so, it is usually transit and may disappear in a few days of continued therapy or upon dosa reduction. Dryness of the mouth may occur with higher doses. Involu tary motor activity, including rare instances of tremor and convulsion has been reported, usually with higher than recommended dosage.

Supply: Vistaril (hydroxyzine HCl) Intramuscular Solution: 25 mg./m 10 ml. vial; 50 mg./ml.—2 ml. and 10 ml. vial; Isoject®, 25 mg./ml. ar 50 mg./ml., 1 ml. fill; 100 mg./2 ml., 2 ml. fill.

CLASSIFIED ADVERTISING

ANESTHESIOLOGIST — markedly expanding academic medical center located in attractive Midwestern setting requires additional senior and junior faculty; Board certification and teaching experience necessary; salary from $45,000-$75,000 with extraordinary fringe benefit program. Inquiries with curriculum vitae to Box 5-76-B in care of I.A.R.S.

ANESTHESIOLOGIST: Board certified/eligible to join newly formed group of anesthesiologists and nurse anesthetists in New Orleans. Fee for service private practice at 650-bed general hospital and newly opened Pediatric hospital. Write or call Metropolitan Anesthesia Associates, 4520 Melpomene, New Orleans, La. 70185. (504) 822-9331.

ANESTHESIOLOGIST—to join staff in new 400+ bed university affiliated teaching hospital in large metropolitan area. Candidates must be licensed or eligible for licensure in the state of Minnesota at the time they are accepted for employment. Salary commensurate with experience. For further information contact:

Irving Greenfield, Chief of Service
Dept. of Anesthesia
Hennepin County Medical Center
5th and Portland
Minneapolis, MN 55415

ADMINISTRATIVE-TEACHING POSITION WANTED: CRNA with seven years clinical, teaching and administrative experience, plus masters degree. Prefer teaching hospital and authority equivalent to responsibility. Salary important, not hours. For resumé contact: Box 3-76-C in care of I.A.R.S.

ANESTHESIOLOGIST—Position available for Board Certified or eligible Anesthesiologist in an ambulatory surgical facility. Competitive salary with liberal fringe benefits offered. For details, please call D. L. Henderson, M.D., at 318-233-5025, or send vitae to Surgery Center, Inc., 1101 South College Road, Suite 100, Lafayette, Louisiana 70501.

FACULTY POSITIONS

Department of Anesthesiology, Charity Hospital, New Orleans, affiliated with LSU and Tulane Medical Schools, has three faculty positions open for board certified/eligible anesthesiologists at Associate-Assistant Professor, Instructor levels. Duties involve teaching, research, clinical supervision. Salaries negotiable. Send inquiries and curriculum vitae to: M. Naraghi, M.D., Director, Department of Anesthesiology, Charity Hospital, New Orleans, Louisiana 70140.

PEDIATRIC ANESTHESIOLOGY RESIDENCY

Childrens Hospital of Los Angeles

Three-phase program: Clinical, Academic, Investigative, emphasizing practical aspects of anesthesiology related to infants and children.

AMA approval for third-year residency. Positions available from two months to one year.

Apply: George B. Lewis, Jr., M.D.
Head, Division of Anesthesiology
Childrens Hospital of Los Angeles
4650 Sunset Boulevard
Los Angeles, California 90054
Phone (213) 660-2450, Ext. 2262

POSITION WANTED BY CRNA: Experience and masters degree. Seeks position as director of nurse anesthesia school or division. Resumé on request. Reply: Box 3-76-D in care of I.A.R.S.

FACULTY POSITIONS

Department of Anesthesiology, University of Louisville School of Medicine, has faculty positions open for board certified/eligible anesthesiologists. One position reserved for those with special interest in obstetrical anesthesia; work involves teaching, research and/or coordination of clinical activities. Send inquiries and curriculum vitae to K. P. Geevarghese, M.D., P.O. Box 1055, Louisville, Kentucky 40201. An equal opportunity, affirmative action employer.

Young bd. elig. married with no military obligation. 3 year major university training including faculty experience. Particularly qualified in regional anesthesia. Can share cardiac and respiratory consults. Excellent references. Desires Western U.S. Write Box 5-76-A in care of I.A.R.S.

NEBRASKA Opportunity for Anesthesiologist in 450-bed acute care, teaching hospital affiliated with two medical schools; must be board certified or eligible, salary commensurate with education and experience. An equal opportunity employer. Contact J. J. Matoole, M.D., Chief of Staff, Veterans Administration Hospital, 4101 Woolworth Avenue, Omaha, Nebraska 68105. (402) 346-8800, Ext. 442.

ANESTHESIOLOGIST, FFARCS, age 31, 6½ years experience in England and Holland, ECFMG and US Immigration visa; seeks challenging position academic or multispecialty clinic. Contact: V. S. Joshi, 2 Castelmorelaan, Maastricht, Holland.

A mainstay of modern anesthesia

- As an adjunct to general anesthesia
- As a supplement to regional anesthesia
- Used without a general anesthetic in certain diagnostic procedures

INNOVAR® injection is available for use only upon direction of a physician.

Special educational material available

A Programmed Instruction Manual on the chemistry, pharmacology and clinical applications of INNOVAR injection and its components is available from McNeil Laboratories. For further information, please write: Product Director, INNOVAR injection, McNeil Laboratories, Inc., Fort Washington, Pa. 19034.

© McN 1975

For prescribing information including Contraindications, Warnings, Precautions and Adverse Reactions, please turn page.

Innovar® injection

The two components of INNOVAR® injection, fentanyl and droperidol, have different pharmacologic actions. Before administering INNOVAR injection, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action.

DESCRIPTION

Each cc. contains (in a 1:50 ratio):

Fentanyl ..... 0.05 mg.
as the citrate

Warning: May be habit forming

Droperidol ..... 2.5 mg.
Lactic acid for adjustment of pH to 3.5± 0.3

FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY

Protect from Light

ACTIONS INNOVAR injection is a combination drug containing a narcotic analgesic, fentanyl, and a neuroleptic (major tranquilizer), droperidol. The combined effect, sometimes referred to as neuroleptanalgesia, is characterized by general quiescence, reduced motor activity, and profound analgesia; complete loss of consciousness usually does not occur from use of INNOVAR injection alone. The incidence of early postoperative pain and emesis may be reduced.

A. Fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. Fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. Fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays, and skin wheal testing in man, as well as *in vivo* testing in dogs indicate that histamine release rarely occurs with fentanyl.

Fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours. Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics, it may be considerably longer than the analgesic effect.

B. Droperidol produces marked tranquilization and sedation. It also produces an antiemetic effect as evidenced by the antagonism of apomorphine in dogs. It potentiates other CNS depressants. It also produces mild alpha adrenergic blockade, peripheral vascular dilatation and reduction of the pressor effect of epinephrine. Droperidol can produce hypotension and decreased peripheral vascular resistance. It may decrease pulmonary arterial pressure (particularly if it is abnormally high). It may reduce the incidence of epinephrine-induced arrhythmias but it does not prevent other cardiac arrhythmias. The onset of action is from three to ten minutes following intravenous or intramuscular administration. The full effect, however, may not be apparent for 30 minutes. The duration of the sedative and tranquilizing effects generally is two to four hours. Alteration of consciousness may persist as long as 12 hours. This is in contrast to the much shorter duration of action of fentanyl.

INDICATIONS INNOVAR injection is indicated to produce tranquilization and analgesia for surgical and diagnostic procedures. It may be used as an anesthetic premedication, for the induction of anesthesia, and as an adjunct in the maintenance of general and regional anesthesia. If the supplementation of analgesia is necessary, SUBLIMAZE® (fentanyl) injection alone rather than the combination drug INNOVAR injection should usually be used.

CONTRAINDICATIONS INNOVAR injection should not be used in patients who are hypersensitive to either component.

WARNINGS PATIENTS WHO HAVE RECEIVED *INNOVAR* INJECTION SHOULD BE UNDER APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

The respiratory depressant effect of narcotics persists longer than their measured analgesic effect. When used with INNOVAR injection, the total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, be used initially in reduced doses, as low as 1/4 to 1/3 those usually recommended.

INNOVAR injection may cause muscle rigidity, particularly involving the muscles of respiration. This effect is due to the fentanyl component and is related to the speed of injection. Its incidence can be reduced by the use of slow intravenous injection. Once the effect occurs it is managed by the use of assisted or controlled respiration and by a neuromuscular blocking drug, if necessary.

FLUIDS AND OTHER COUNTERMEASURES TO MANAGE HYPOTENSION SHOULD ALSO BE AVAILABLE.

Drug Dependence: *Fentanyl, the narcotic analgesic component, can produce drug dependence of the morphine type and therefore has the potential for being abused.*

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl, in this regard, has not been established, the use of INNOVAR injection or SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: INNOVAR injection should be used with caution in patients who may be particularly susceptible to respiratory depression such as comatose patients who may have a head injury or brain tumor. In addition, these drugs may obscure the clinical course of patients with head injury.

Usage in Children: The safety of INNOVAR injection in children two years of age or younger has not been established.

Usage in Pregnancy: The safe use of INNOVAR injection has not been established with respect to possible adverse effects upon fetal development.

Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects therefore, safety for the infant in obstetrics has not been established.

PRECAUTIONS *The initial dose of INNOVAR injection should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and some peridural anesthetics, can alter respiration by blocking intercostal nerves, and can cause peripheral vasodilatation and hypotension because of sympathetic blockade. Through other mechanisms (see Actions) fentanyl and droperidol also depress respiration and blood pressure. Therefore, when INNOVAR injection is used to supplement these forms of anesthesia, the anesthetist must be familiar with the physiological alterations involved, and be prepared to manage them in the patients selected for this form of anesthesia.

The droperidol component of INNOVAR injection may decrease pulmonary arterial pressure. This fact should be considered by those who conduct diagnostic or surgical procedures where interpretation of pulmonary arterial pressure measurements might determine final management of the patient.

Vital signs should be monitored routinely.

INNOVAR injection, and SUBLIMAZE fentanyl, should be used with caution in patients with chronic obstructive pulmonary disease, patients with decreased respiratory reserve, and others with potentially compromised ventilation. In such patients narcotics may additionally decrease respiratory drive and increase airway resistance. During anesthesia this can be managed by assisted or controlled respiration. Postoperatively respiratory depression caused by narcotic analgesics can be reversed by narcotic antagonists (levallorphan, nalorphine, and naloxone); consult individual prescribing information before using.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, and general anesthetics) have additive or potentiating effects with INNOVAR injection. When patients have received such drugs, the dose of INNOVAR injection required will be less than usual. Likewise, following the administration of INNOVAR injection the dose of other CNS depressant drugs should be reduced.

INNOVAR injection should be administered with caution to patients with liver and kidney dysfunction because of the importance of these organs in the metabolism and excretion of drugs.

If hypotension occurs, the possibility of hypovolemia should be considered and managed with appropriate parenteral fluid therapy. Repositioning the patient to improve venous return to the heart should be considered when operative conditions permit. It should be noted that in spinal and peridural anesthesia, tilting the patient into a head down position may result in a higher level of anesthesia than is desirable, as well as impair venous return to the heart. Care should be exercised in the moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus these other countermeasures do not correct the hypotension, then the administration of pressor agents other than epinephrine should be considered. Epinephrine may paradoxically decrease the blood pressure in patients treated with INNOVAR injection due to the alpha-adrenergic blocking action of droperidol.

The fentanyl component may produce bradycardia, which may be treated with atropine; however, INNOVAR injection should be used with caution in patients with cardiac bradyarrhythmias.

When the EEG is used for postoperative monitoring, it may be found that the EEG pattern returns to normal slowly.

ADVERSE REACTIONS The most common serious adverse reactions reported to occur with INNOVAR injection are respiratory depression, apnea, muscular rigidity, and hypotension; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have been observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with anti-parkinson agents.

Other adverse reactions that have been reported are dizziness, chills and/or shivering, twitching, blurred vision, hyperactivity on induction, laryngospasm, transient hypertension, nausea and emesis, diaphoresis, emergence delirium, and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression).

Postoperative drowsiness is also frequently reported.

OVERDOSAGE ***Manifestations:*** The manifestations of INNOVAR injection overdosage are an extension of its pharmacologic actions.

Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered. A specific narcotic antagonist such as nalorphine, levallorphan or naloxone should be available for use as indicated to manage respiratory depression caused by the narcotic component fentanyl. This does not preclude the use of more immediate countermeasures. Consult the package inserts for the individual narcotic antagonists for details about use.

HOW SUPPLIED INNOVAR® injection is supplied in 2 cc. (**NDC** 0045-0280-20) and 5 cc. (**NDC** 0045-0280-50) ampuls, in packages of 10.

IMPORTANT: Complete dosage information is available in insert which accompanies each package (or on request). The drug is available only upon direction of a physician.

PROFESSIONAL INSTRUMENTS COMPANY MODEL NS-2 * PERIPHERAL NERVE STIMULATOR

MONITORS EFFECTS OF SKELETAL MUSCLE RELAXANTS ON THE NEUROMUSCULAR JUNCTION, DETECTING ABNORMAL RESPONSE TO MUSCLE RELAXANTS AND DISTINGUISHES BETWEEN DEPOLARIZING AND NON-DEPOLARIZING BLOCKADE.

THE MODEL NS-2

- ☐ **DELIVERS** STIMULI AT 5 SECOND INTERVALS. ONE OR FIFTY PULSES-PER-SECOND MAY BE SELECTED BY MOMENTARY PUSH-BUTTON SWITCHES.
- ☐ **OUTPUT** IS A MONOPHASIC SQUARE WAVE PULSE HAVING A RISE AND FALL TIME OF LESS THAN ONE MICROSECOND. AMPLITUDE OF PULSE IS LINEARLY ADJUSTABLE.
- ☐ **SOLID STATE**, RUGGED, BATTERY POWERED, PORTABLE AND LIGHTWEIGHT. THE USE OF INTEGRATED CIRCUITS ENSURES MAXIMUM RELIABILITY.
- ☐ **IT IS** THE RESULT OF AN AGGRESSIVE, CONTINUING RESEARCH AND DEVELOPMENT PROGRAM IN NERVE STIUMLATORS AND OTHER ELECTRONIC PRODUCTS BY PROFESSIONAL INSTRUMENTS COMPANY.

Ref: Corneal Injuries During General Anesthesia, Anesthesia and Analgesia, Vol. 54, No. 4, July-August, 1975

Protect patients' eyes with OPTI-GARD™

Why tape eyelids shut and risk skin abrasion, loss of eyelashes, and contact dermatitis? Dupaco Opti-Gard,™ for use during general anesthesia and post-op recovery, effectively and comfortably helps prevent corneal abrasion, lacerations, and scleral hemorrhage. Opti-Gard™ also protects against blood, fluid, or other foreign materials entering the eyes . . . a vital consideration in ENT, head, or neck surgery. Sterile packaged and boxed in convenient dispenser, Opti-Gard™ clear plastic protective covers come with self adhesive foam cushion. **Send for free sample.**

DUPACO INCORPORATED

P.O. Box 98, San Marcos, Ca. 92069

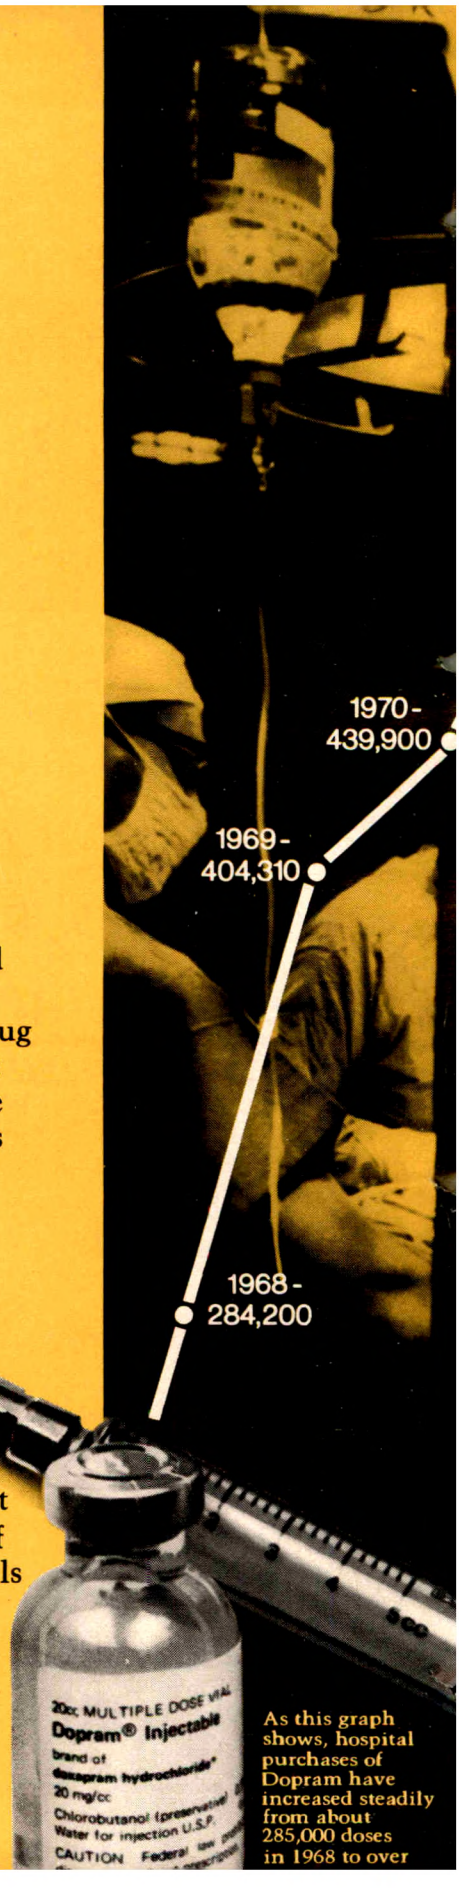
In all types of hospitals across the United States, its usage grows–

Dopram®
Injectable
(doxapram HCl)

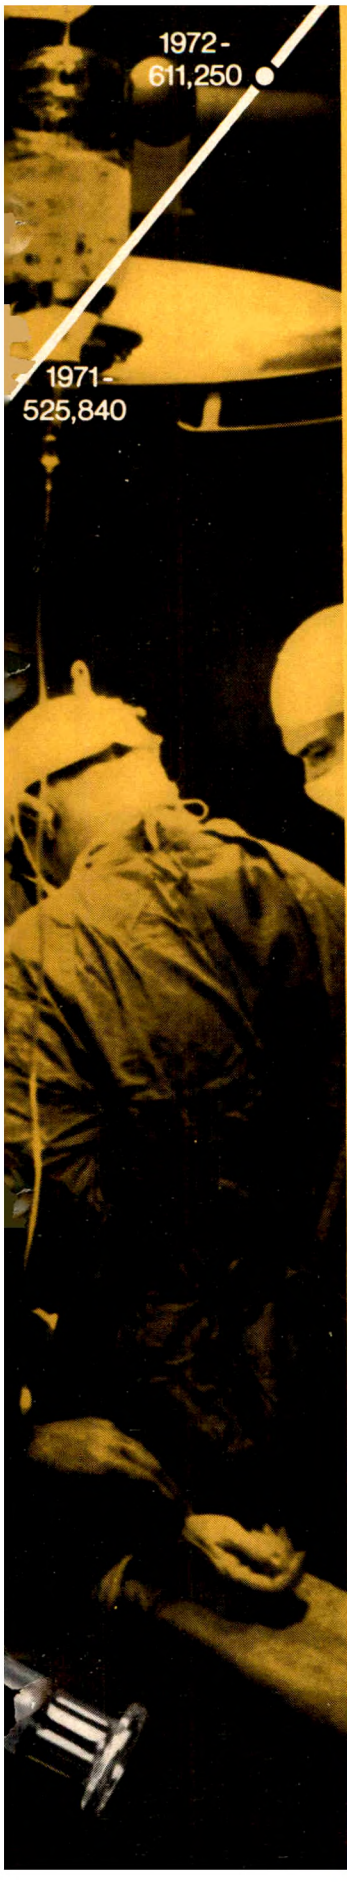
Seven years ago, A. H. Robins introduced Dopram, a unique respiratory stimulant developed in the company's research laboratories. What made this drug so useful to the anesthesiologist was its ability to rapidly restore the respiratory drive in patients with drug-induced post anesthetic depression.

Usage of Dopram has been steadily increasing each year, until today it has become a very important drug in the armamentarium of more than 1,500 hospitals of all types in all 50 states, the District of Columbia, and a number of foreign countries. These hospitals purchased more than 600,000 doses in 1972 alone.

Dopram–an important drug in anesthesiology. Try it for sighs!



As this graph shows, hospital purchases of Dopram have increased steadily from about 285,000 doses in 1968 to over



Indications

1. To stimulate respiration in patients with drug induced post-anesthetic respiratory depression or apnea other than that due to muscle relaxant drugs.
2. To pharmacologically stimulate deep breathing in the so-called "stir-up" regimen in the post-operative patient. Simultaneous administration of oxygen is desirable.
3. To hasten arousal and return of protective pharyngeal and laryngeal reflexes.
4. To aid in the differential diagnosis of post-anesthetic respiratory depression. Failure to adequately stimulate respiration suggests residual muscle relaxant effect.
5. To stimulate respiration, hasten arousal and to encourage the return of laryngopharyngeal reflexes in patients with mild to moderate respiratory and CNS depression due to drug overdosage.

Contraindications—Epilepsy and other convulsive states: incompetence of the ventilatory mechanism due to muscle paresis, flail chest, pneumothorax, airway obstruction, and extreme dyspnea; severe hypertension and cerebrovascular accidents; hypersensitivity.

Doxapram is not recommended for patients 12 years of age or under because studies to evaluate its safety and efficacy have not been performed.

Warnings—Doxapram is an analeptic agent; it is neither an antagonist to muscle relaxant drugs nor a specific narcotic antagonist. Since doxapram has an acid pH, it should not be mixed with alkaline solutions such as thiopental sodium.

Since narcosis may recur after stimulation with doxapram, care should be taken to maintain close observation until the patient has been fully alert for 1/2 to 1 hour. (Duration of drug 5-12 minutes.)

Doxapram is an adjunct to well-accepted supportive measures and resuscitative techniques. It may not stimulate adequate spontaneous breathing or provide sufficient arousal in patients who are severely depressed with CNS depressant drugs.

When doxapram is administered to postoperative patients or to patients in a state of narcosis with chronic pulmonary insufficiency, oxygen should be administered concomitantly. Failure to do so may result in further oxygen debt and more severe dyspnea due to the increased work of breathing.

Doxapram should be administered with great care and only under close supervision to patients with cerebral edema, bronchial asthma, severe tachycardia, cardiac arrhythmia, cardiac disease, hyperthyroidism and pheochromocytoma.

Usage in pregnancy

No adequate clinical studies have been performed to determine the safe use of doxapram in pregnancy. Until further clinical experience has been obtained, the physician must weigh the need against possible risks in using the drug in pregnant patients or in women of child-bearing potential.

Precautions—Recommended dosages of doxapram should be employed and maximum total dosages should not be exceeded. In patients with advanced pulmonary disease with hypoxemia, marked respiratory stimulation increases the work of breathing and may, thus, increase oxygen consumption and carbon dioxide production.

With excessive dosage, hyperventilation induced by doxapram may lead to respiratory alkalosis and hypocapnia with tetany and, theoretically, apnea.

An adequate airway is essential. In order to avoid side effects, it is advisable to use the minimum effective dosage. Monitoring of the blood pressure and deep tendon reflexes is recommended to prevent overdosage.

It is desirable that blood gases (P_{O_2} P_{CO_2} O_2 saturation) be monitored to assess the effectiveness of respiratory stimulation.

Intravenous barbiturates, oxygen and resuscitative equipment should be readily available to manage overdosage manifested by excessive central nervous system stimulation. Slow administration of the drug and careful observation of the patient during administration and for some time subsequently are advisable to insure restoration of the protective reflexes. The possibility of post-stimulation respiratory depression must be kept in mind. In patients who have been lightly curarized, doxapram may temporarily mask the residual effects of muscle relaxant drugs.

Doxapram should be administered cautiously to patients receiving sympathomimetic or monoamine oxidase inhibiting drugs, since a synergistic pressor effect may occur. It should likewise be used with care in post-operative patients with marked dyspnea due to obstructive pulmonary emphysema, acute or chronic asthma, profound metabolic disorders, severe to moderately severe hypertension, increased cerebrospinal fluid pressure, head injury and acute agitation.

Since doxapram may stimulate basal gastric secretion, it should be used with care in patients with peptic ulcer disease and in patients undergoing gastric surgery.

Vascular extravasation or use of a single injection site over an extended period should be avoided since either may lead to thrombophlebitis.

Hypocapnia accompanying forced ventilation is a potent stimulus to cerebral vasoconstriction; it may be postulated that some element of risk may exist from reduced cerebral blood flow following prolonged and intensive hyperventilation.

Since an increase in epinephrine release has been noted with doxapram, it is recommended that initiation of therapy with this respiratory stimulant be delayed for at least 10 minutes following the discontinuance of anesthetics known to sensitize the myocardium to catecholamines, such as halothane and cyclopropane.

As with other intravenous preparations, all precautions should be taken during administration of doxapram to insure that injection is made directly into a suitable vein; extravasation, and inadvertent intra-arterial injection should be avoided.

Adverse reactions—The following adverse reactions have been reported: *Central and Autonomic Nervous Systems.* Hyperactivity feeling of warmth, sweating, muscle tremor, clonus, increased deep tendon reflexes, dizziness, muscle spasticity, pyrexia, confusion, paresthesia, pupillary dilatation, pilomotor erection, headache, bilateral babinski, fasciculation and carpopedal spasm. A grand mal seizure occurred 95 minutes after drug administration in a known epileptic patient who was on anticonvulsant medication.

Respiratory. Cough, dyspnea, laryngospasm bronchospasm and hiccough.

Cardiovascular. Hypertension, sinus tachycardia, bradycardia, extrasystoles, lower T-waves, premature ventricular contractions, irregular heart rhythm, tightness in chest. Although a mild to moderate increase in blood pressure is not infrequent, such an increase may occasionally be of concern in hypertensive patients.

Gastrointestinal. Nausea and/or vomiting, salivation, stimulation of lower bowel, sour taste.

Genitourinary. Urinary retention, stimulation of urinary bladder with spontaneous voiding.

Miscellaneous. Pruritus, thrombophlebitis.

Laboratory Determinations. A decrease in hemoglobin, hematocrit, or red blood cell count has been observed in postoperative patients. In the presence of pre-existing leukopenia, a further decrease in WBC was observed following anesthesia and treatment with doxapram hydrochloride. Elevation of BUN and albuminuria have been observed.

In some of the cases cited above, the patients had received multiple drugs concomitantly, thus preventing an absolute judgment as to the role of doxapram in these reactions.

Dosage—For complete information concerning dosage and administration see package insert.

Supply—Dopram (doxapram hydrochloride) is available in 20 cc rubber-stoppered vials containing 20 mg/cc, with chlorobutanol 0.5% as the preservative.

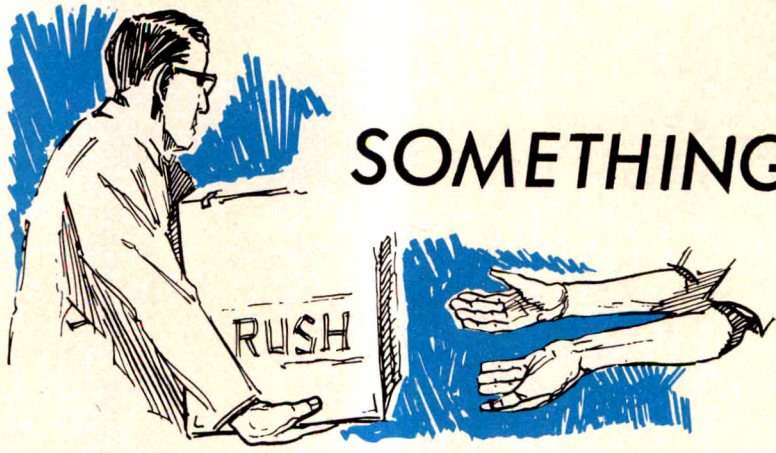
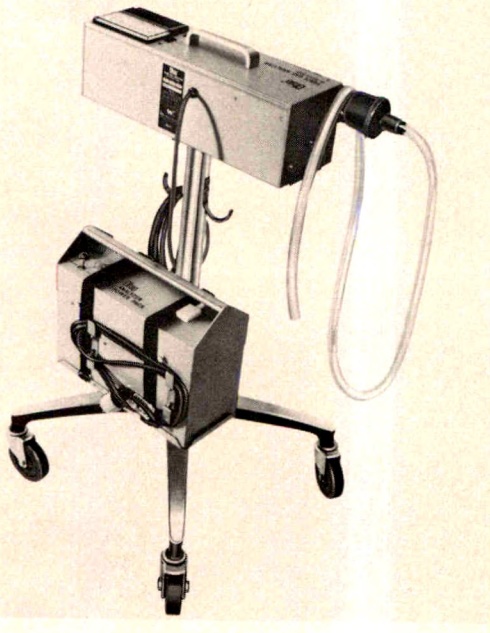
A·H·ROBINS



SOMETHING NEW



Ohio Medical Products, Madison, Wisconsin, has available an instrument for ambient air contamination analysis known as the OHIO Trace Gas Analyzer. It is designed to provide rapid and continuous measurement of nitrous oxide pollution in operating rooms and elsewhere. It can be employed to test exhaust systems for escaping nitrous oxide, and to detect equipment leakage both through time period analysis of ambient conditions as well as source identification.

★ ★ ★

Informatics Inc., Woodland Hills, California, a world leader in computer services, has just released two new brochures describing its extensive, computerized medical information data base, Excerpta Medica On-Line (EMOL) Service.

This EMOL Service resulted from a cooperative agreement between the Excerpta Medica Foundation, long a major source for the dissemination of medical information to the world's health care professionals, and Informatics Inc.

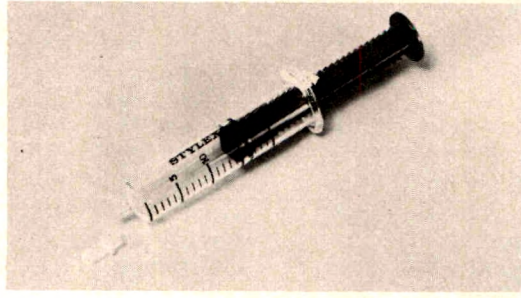
EMOL provides extensive coverage of the world's biomedical literature and offers instant retrieval capability on a retrospective or continuing basis, thus permitting researchers, clinicians, program administrators, pharmaceutical manufacturers access to the bibliographic material through a simple typewriter-like computer terminal that can be used in any office or laboratory.

Columbus Instruments International Corporation, Columbus, Ohio, presents their "CARDIOTHERM-500." It automatically measures and tracks blood temperature via the same thermistor catheter which is used for thermodilution curve sensing. It also automatically measures and tracks the indicator temperature. The only parameter left for manual entry is the volume of indicator. Any volume can be entered on the digital dial—0 to 10 mL in increments 0.01 mL.

The "CARDIOTHERM-500" is rechargeable battery-operated and, using a special power-saving circuit, the battery will last for 100 cardiac output measurements independent of the time of use.

★ ★ ★

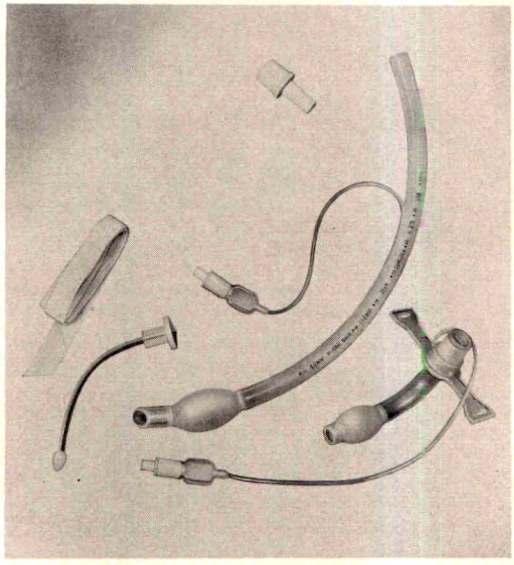
Pharmaseal, Glendale, California, has a new 10 cc medication device which features a special ratchet plunger design that eliminates the numerous problems that may arise, eg, when disconnetcing syringes from IV lines, or the need for check valves, slide clamps and tubes. Also, Stylox's ratchet design means you can inject incremental doses precisely.



★ ★ ★

Shiley Laboratories, Inc., Irvine, California, announces their new disposable radiopaque tracheostomy tube, with a new thin-walled, high volume low pressure cuff and a new pressure relief valve to prevent tracheal damage due to cuff overinflation. The relief valve prevents internal cuff pressures in excess of 25 mmHg by venting off excess air.

Additional features of the new tracheostomy tube include an inner cannula with locking 15 mm connector, easily removed and cleaned to maintain a patent airway without changing the entire tube, and a swivel neck plate for maximum comfort and conformity to individual neck anatomies. The obturator is tapered to simplify insertion and minimize trauma.



Medical Engineering Corporation, Racine, Wisconsin, has available the "Surgitek® Silicone Anesthesia Tubes" with the exclusive Surgitek® low trauma cuff. The all-silicone tube is soft, pliable, and is claimed to be more comfortable for the patient, and much less likely to cause necrosis. The Surgitek® tubes may be steam or gas sterilized.

★ ★ ★

Wolff Industries, San Marino, California, have a new product, the MR-81 Physiological Data Tape Recorder. Eight channels of physiological data may be recorded on a compact cassette.

This instrument finds use in recording a wide variety of physiological parameters such as ECG, EEG, blood pressure, blood flow, pulse wave forms and heart sounds. The MR-81 Recorder utilizes both FM and PPM modulation technics. Additionally, one channel may be temporarily interrupted with voice comments by using the press-to-talk microphone that is furnished.

★ ★ ★

A three channel electrocardiograph capable of producing a complete 12-lead electrocardiogram in 10 seconds is now available from the Burdick Corporation, Milton, Wisconsin. The Burdick model EK-6 simultaneously records three leads, offering physicians and technicians maximum accuracy and diagnostic data while maintaining the simplicity and ease of operation of single channel ECGs.

It is suitable for use in hospitals, multiphasic screening centers, physician offices, or any other facility where there is daily need for specific, accurate, electrocardiographic service.

★ ★ ★

Advanced Instrumentation Corporation, Middleton, Wisconsin, has a new blood pressure monitor which is noninvasive, nonocclusive, atraumatic and offers continuous pressure readout in addition to continuous pulse pressure recording or CRT display. A small force transducer held in place on the wrist with a Velcro strip provides input data to this new Model ML-10.

THE VULNERABLE EYE.

Lacri-Lube® protects the vulnerable eye of the anesthetized patient.

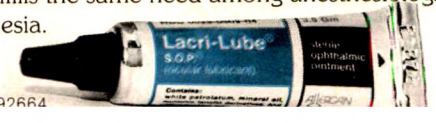
The under-protected eye is threatened during general anesthesia. Tape alone can leave your patient's eye vulnerable to dehydration and corneal erosion. And with medicated ointments, you unnecessarily risk allergic reactions and possible long-term sensitization.

Lacri-Lube meets your need for a safer, more sophisticated method of protecting and lubricating the eye. Either on its own or as an adjunct to taping. It's the first non-medicated, sterile ophthalmic ointment specifically designed to lubricate and protect the eye—and do nothing more.

In fact, ophthalmologists have established Lacri-Lube as their lubricant-protectant of choice whenever an eye is jeopardized by exposure or dehydration. And the rapid increase in its surgical use indicates that Lacri-Lube fulfills the same need among anesthesiologists.

Lacri-Lube is the ophthalmic for anesthesia.

When you consider the alternatives, you can't make a better choice.



ALLERGAN
Irvine, CA 92664

ANTILIRIUM
(Physostigmine Salicylate)

REVERSES MOST POST-OPERATIVE DELIRIUM AND PROLONGED SOMNOLENCE

Before prescribing, please consult complete product information, a summary of which follows:

ACTION: ANTILIRIUM (physostigmine salicylate) is a salicylic acid derivative of an alkaloid extracted from seeds of Physostigma Venenosum (calabar bean). The action of the parasympathetic nerves is intermediated by the formation of acetylcholine at the peripheral end of these nerves. Physostigmine inhibits the destructive action of cholinesterase and thereby prolongs and exaggerates the effect of the acetylcholine.

Physostigmine contains a tertiary amine and easily crosses the blood brain barrier, while neostigmine contains a quaternary amine and is not capable of crossing the structure. This may explain why neostigmine does not cause reversal of anticholinergic-induced delirium while physostigmine does.

INDICATIONS: TO REVERSE THE TOXIC EFFECTS UPON THE CENTRAL NERVOUS SYSTEM CAUSED BY DRUGS IN CLINICAL OR TOXIC DOSAGES CAPABLE OF PRODUCING ANTICHOLINERGIC POISONING.

SEVERE ANTICHOLINERGIC POISONING MAY PRODUCE: COMA, MEDULLARY PARALYSIS AND DEATH.

CENTRAL TOXIC EFFECTS MAY INCLUDE: HALLUCINATIONS, DELIRIUM, DISORIENTATION, ANXIETY AND HYPERACTIVITY.

Dramatic reversal within minutes of coma, hallucinations, and other signs can be expected if the diagnosis is correct and the patient has not suffered anoxia or other insult. Therapeutic doses may be necessary at intervals as life-threatening signs recur. Physostigmine is destroyed in the body in 60 to 120 minutes.

CONTRAINDICATIONS: Physostigmine should not be used in the presence of asthma, gangrene, diabetes, cardiovascular disease, mechanical obstruction of the intestines or urogenital tract or any vagotonic state, and in patients receiving choline esters or depolarizing neuromuscular blocking agents.

WARNING: If excessive symptoms of salivation, emesis, urination and defecation occur, the use of ANTILIRIUM should be terminated. If excessive sweating or nausea occur, the dosage should be reduced.

Intravenous administration should be at a slow, controlled rate, no more than 1 mg. per minute (see dosage). Rapid administration can cause bradycardia, hypersalivation leading to respiratory difficulties and possibly convulsions.

An overdosage of ANTILIRIUM can cause a cholinergic crisis.

PRECAUTIONS: Because of the possibility of hypersensitivity in an occasional patient, atropine sulfate injection should always be at hand since it is an antagonist and antidote for physostigmine.

ADMINISTRATION AND DOSAGE: The usual adult dose of ANTILIRIUM is 0.5 to 2.0 mg. intramuscularly or intravenously. Intravenous administration should be at a slow, controlled rate of no more than 1 mg. per minute. It may be necessary to repeat dosages of 1 mg. to 4 mg. at intervals as life threatening signs such as arrhythmias, convulsions and deep coma recur.

IN ALL CASES OF POISONING, THE USUAL SUPPORTIVE MEASURES SHOULD BE UNDERTAKEN.

SUPPLIED: 2 ml. ampules containing: PHYSOSTIGMINE SALICYLATE 1 mg. per ml. Packed 12 ampules per box.

NDC 0456-1037-12

CAUTION: Federal law prohibits dispensing without prescription.

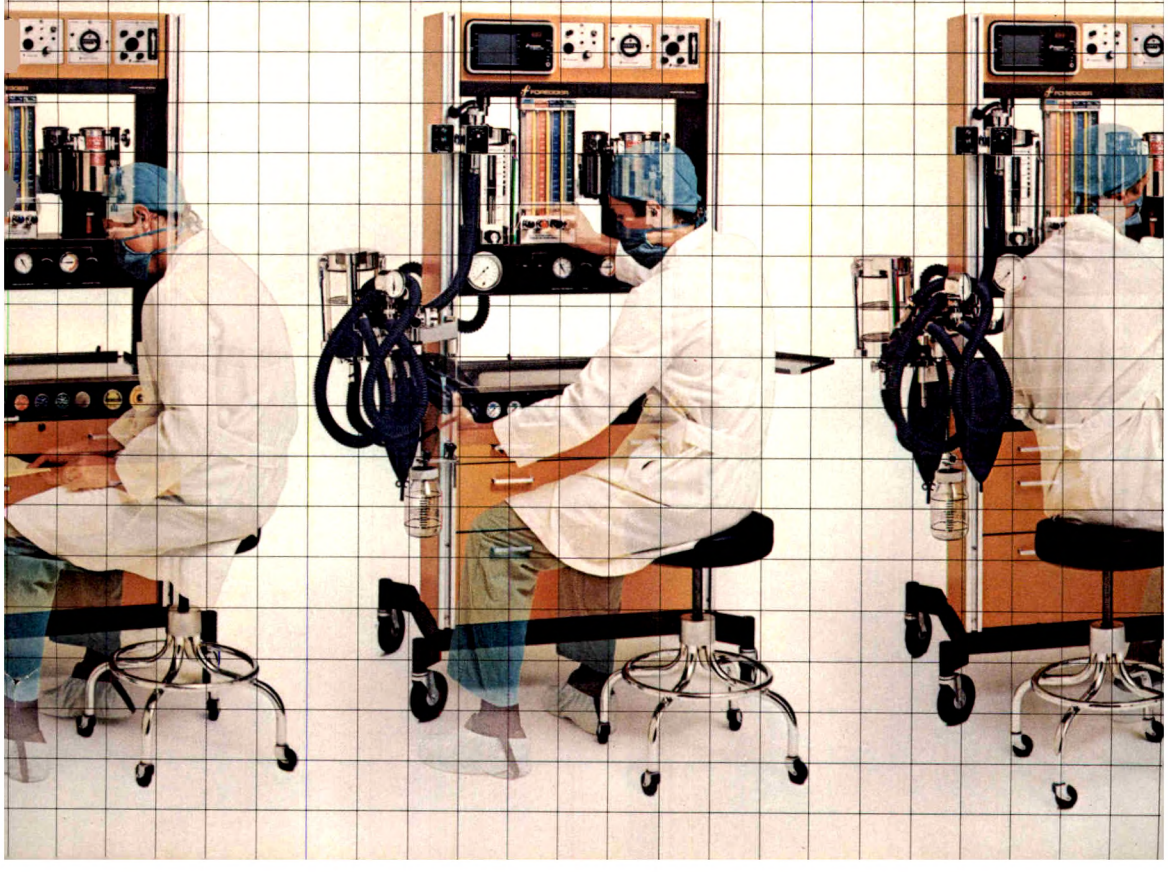
1304 ASHBY ROAD • ST. LOUIS, MISSOURI 63132 • (314) 997-6650

Introducing The Human-Engineered Anesthesia Control Center.

The FOREGGER® 710



The FOREGGER 710

Anesthesia Control Center.

Unlike Anything You've Ever Seen.

Think of what it is like using a typical anesthesia machine. Now, look at the new FOREGGER 710 Anesthesia Control Center. Notice the completeness, compactness, accessibility and visibility of the components. Everything is in one place, within reach . . . without dangling wires and add-on components. That's why we call it the FOREGGER 710 Anesthesia Control Center.

Unlike existing anesthesia machines, the FOREGGER 710 Anesthesia Control Center is human engineered. The design revolves around you. All of the controls for both fixed and movable components are operated from a comfortable, working position. And this ease of control is complemented by the latest innovations in anesthesia equipment design.

Take, for instance, the unique rotating Vaporizer Turret. It accommodates up to three vaporizers, including the Foregger Copper Kettle® Vaporizer and Foregger Direct Reading Vaporizers. When the Turret is locked into place, there is no doubt which vaporizer is in circuit. Possible contamination from anesthetic agents contained in the other vaporizers is eliminated.

Then there are the Direct Reading Vaporizers designed for the administration of a specific liquid anesthetic, over a wide range of temperatures and flow rates. The Copper Kettle Vaporizer, on the other hand, affords you constant and precise control in both increments and decrements, while providing simple and accurate administration of an anesthetic agent.

There's also a built-in Anesthesia Ventilator that features fluidic circuitry, independent controls, and a mode selector switch that enables you to transfer from ventilator to bag without changing tubes or adjusting the pressure relief valve. It gives you the convenience of easy readouts and the efficiency of direct control. And it's easy to clean.

Storage is human-engineered too! Cabinetry in the new FOREGGER 710 Anesthesia Control Center combines linear designed storage with easy accessibility and large capacity.

The Monitoring System, which provides a wide range of physiological monitoring capability, is located where you need it during procedures. Easy to see and reach, it includes a physiological monitor (ECG, EEG, temperature, pulse rate, and pressure), an Oxygen Analyzer, Ventilator Disconnect Alarm, and an Elapsed Timer.

In addition, the FOREGGER 710 Anesthesia Control Center has a built-in Oxygen Start, which automatically shuts off all other gases when the oxygen flow is reduced to a predetermined level. Plus, four parallel accessory tracks to mount and adjust FOREGGER 710 Anesthesia Control Center accessories. All of which add another dimension to overall flexibility.

And that's where you should place the new FOREGGER 710 Anesthesia Control Center. Over all. In capabilities. Flexibilities. And human engineering. Take a look at its other unlike features and we think you'll agree . . . The FOREGGER 710 Anesthesia Control Center is unlike anything you have seen before. For more information about what human engineering with everything in one place can mean to you, fill out and return the attached card.

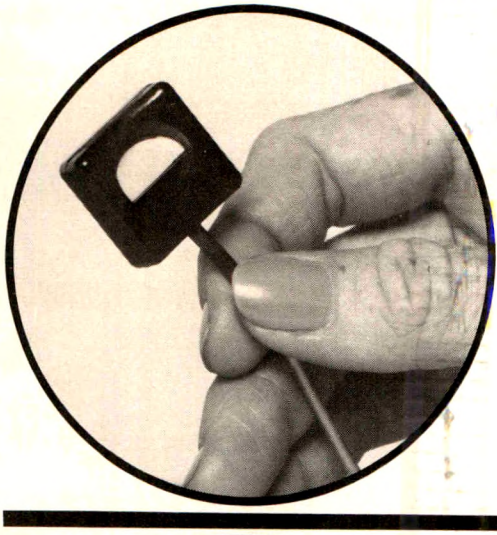
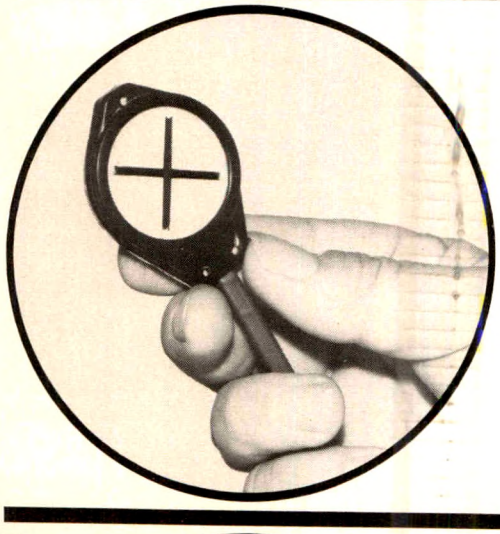
VERSATONE® MULTI-PURPOSE DOPPLER INSTRUMENT



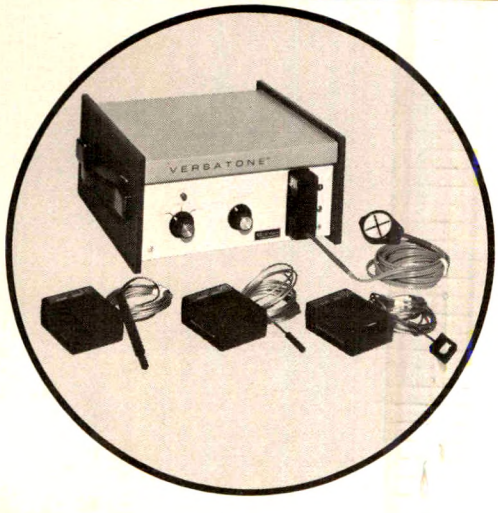
FOR MONITORING DOPPLER SOUNDS OF BLOOD FLOW AND TO TAKE DOPPLER SYSTOLIC BLOOD PRESSURE

This sensitive Doppler probe is easy to tape in position for non-invasive detection and monitoring of arterial blood flow during surgery. Used with an occlusive cuff and manometer, systolic blood pressures may be obtained even on infants and hypotensive patients.



FOR EARLY DETECTION OF VENOUS AIR EMBOLISM

This sensitive wide-angle Doppler probe is particularly well suited for the detection of venous air emboli which may occur during neurosurgical procedures performed with the patient in the upright position. It also detects motion of the heart muscle, heart valves and blood flow.



VERSATONE D8 DOPPLER

The Model D8 VERSATONE Doppler instrument is designed to use interchangeable probes of various frequencies and configurations. It is powered by a rechargeable battery and has a built-in loudspeaker. Options include an electrocautery sensor and cut-out, a molded earset for private listening, and a chart recording circuit. The two probes shown above are particularly useful to the anesthesiologist. Two sizes of pencil shaped probes are also available. These are useful for intraoperative assessment of flow in exposed vessels, as well as for transcutaneous flow detection.

ANECTINE
(succinylcholine chloride)
For controlled muscle relaxation adjunctive to anesthesia:

FLO-PACK® for prolonged relaxation

- instant-mix sterile powder interfaces with all major parenteral systems (vacuum or nonvacuum)
- each unit complete—no needle or syringe needed
- retains potency indefinitely
- no refrigeration required
- unbreakable, sterile plastic injection units of 500 and 1,000 mg

INJECTION for short-term relaxation

- a product of choice for intubation and other short procedures
- unique square bottle and bright yellow label for positive identification
- ready for immediate use
- 20 mg per cc . . . in 10 cc multidose vials
- flip-top cap for easy opening
- single or multiple use

ANECTINE®
(succinylcholine chloride)
THE LONG AND SHORT of surgical muscle relaxation

THIS DRUG SHOULD BE USED ONLY BY INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS AND HAZARDS.

DESCRIPTION: Anectine brand Succinylcholine Chloride is an ultra short-acting depolarizing type muscle relaxant. Chemically it is a di-quaternary base consisting of the di-chloride salt of the di-choline ester of succinic acid. It is a white, odorless, slightly bitter powder and very soluble in water. The drug is unstable with alkaline solutions, but relatively stable in acid solutions depending upon the concentration of the solution and the storage temperature. While solutions of succinylcholine chloride are sterilized by autoclaving, they should, nevertheless, be stored under refrigeration to preserve their potency.

INDICATIONS: Succinylcholine chloride is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may be employed to reduce the intensity of muscle contractions of pharmacologically or electrically induced convulsions.

CONTRAINDICATIONS: Succinylcholine is contraindicated for persons with a known hypersensitivity to the drug.

WARNINGS:

WARNING: SUCCINYLCHOLINE SHOULD BE USED ONLY BY THOSE SKILLED IN THE MANAGEMENT OF ARTIFICIAL RESPIRATION AND ONLY WHEN FACILITIES ARE INSTANTLY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND FOR PROVIDING ADEQUATE VENTILATION OF THE PATIENT, INCLUDING THE ADMINISTRATION OF OXYGEN UNDER POSITIVE PRESSURE AND THE ELIMINATION OF CARBON DIOXIDE.. THE CLINICIAN MUST BE PREPARED TO ASSIST OR TO CONTROL RESPIRATION.

Succinylcholine should not be mixed with short-acting barbiturates in the same syringe, or administered simultaneously during intravenous infusion through the same needle. Solutions of succinylcholine have an acid pH whereas those of barbiturates are alkaline in reaction. Depending upon the resultant pH of a mixture of solutions of these drugs, either free barbituric acid may be precipitated or succinylcholine hydrolyzed.

Usage in Pregnancy. The safe use of succinylcholine has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards.

PRECAUTIONS: Low levels of, or abnormal variants of plasma cholinesterase may be associated with prolonged respiratory depression or apnea following the use of succinylcholine. Low levels of plasma cholinesterase may occur in patients with severe liver disease or cirrhosis, severe anemia, malnutrition, severe dehydration, changes in body temperature, exposure to neurotoxic insecticides or those receiving antimalarial drugs. Succinylcholine should be administered with extreme care to such patients and dosage should be minimal. If low plasma cholinesterase activity is suspected, a small test dose of from 5 to 10 mg of succinylcholine may be administered, or relaxation may be produced by the cautious administration of a 0.1% solution of the drug by intravenous drip. Drugs which either inhibit plasma cholinesterase, such as neostigmine or phospholine iodide, or compete with succinylcholine for the enzyme, as does intravenous procaine, should not be given concurrently with succinylcholine.

Succinylcholine should be administered with great caution to patients with severe burns, those recovering from severe trauma, those suffering from electrolyte imbalance, those receiving quinidine, those who have been digitalized recently or who may have digitalis toxicity as serious cardiac arrhythmias or cardiac arrest may result. Great caution should be observed also in patients with pre-existing hyperkalemia or who are paraplegic, have suffered spinal neuraxis injury, or have degenerative or dystrophic neuromuscular disease, as such patients tend to become severely hyperkalemic when succinylcholine is given.

When succinylcholine is given over a prolonged period of time, the characteristic depolarization block of the myoneural junction may change to a non-depolarizing block which results in prolonged respiratory depression or apnea. Under such circumstances, small repeated doses of neostigmine may possibly act as an antagonist. A peripheral nerve stimulator (e.g., the Wellcome Peripheral Nerve Stimulator) may be used to ascertain the type of neuromuscular blockade. If a depolarization block is present both fast (tetanic) and slow (twitch) rates of nerve stimulation are well sustained, and post-tetanic facilitation is absent. If a non-depolarizing block is present there is post-tetanic facilitation and "fade" of successive stimuli on both fast (tetanic) and slow (twitch) rates of nerve stimulation.

Succinylcholine should be used with caution during ocular surgery and in patients with glaucoma. The drug should be employed with caution in patients with fractures or muscle spasm as the muscle fasciculations may cause additional trauma. Muscle fasciculations and hyperkalemia may be reduced by administering a small dose of a non-depolarizing relaxant. If other relaxants are to be used during the same procedure, the possibility of a synergistic or antagonistic effect should be considered.

During the past few years, reports have called attention to a fulminant syndrome, malignant hyperthermia, observed during anesthesia. Its etiology is not fully understood. Malignant hyperthermia occurs in genetically prone individuals of all ages and both sexes receiving potent anesthetics such as halothane, methoxyfluothane, cyclopropane and diethyl ether. It appears to develop irrespective of the concomitant use of a muscle relaxant, but may be triggered by succinylcholine. Because of the seriousness of this syndrome and the need for early effective treatment of the patient, it is suggested that the continuous monitoring of the temperature will serve as an aid to the early recognition of malignant hyperthermia.

ADVERSE REACTIONS: Adverse reactions consist primarily of an extension of the drug's pharmacological actions. Profound and prolonged muscle relaxation may occur, resulting in respiratory depression to the point of apnea. Hypersensitivity to the drug may exist in rare instances.

The following adverse reactions have been reported: bradycardia, tachycardia, hypertension, hypotension, arrhythmias, cardiac arrest, prolonged respiratory depression or apnea, hyperthermia, increased intraocular pressure, muscle fasciculation, postoperative muscle pain, myoglobinemia and excessive salivation.

MANAGEMENT OF ADVERSE REACTIONS: Apnea or prolonged muscle paralysis should be treated with controlled respiration.

The use of neostigmine to reverse a non-depolarization block is a medical decision which must be made upon the basis of the individual clinical pharmacology and the experience and judgment of the clinician. When neostigmine is used atropine should also be administered.

SUPPLIED: Injection, Multi-dose vials, 20 mg cc, 10 cc, boxes of 12 vials. Flo-Pack® Sterile Powder 500 mg and 1,000 mg, boxes of 12.

This valve makes no difference-except to the atmosphere

Whatever your anaesthesia equipment, so long as it has a BS or ISO standard breathing circuit, there's a place for the new anti-pollution valve – the first element in Medishield's complete theatre pollution control system.

It uses the same well-proven spring and disc principle as your existing valve (but offers less resistance); it introduces no new controls; demands nothing new of the anaesthetist; changes nothing except the theatre conditions.

The swivel-head nozzle permits convenient positioning and with the two metre flexible hose attached conducts anaesthetic pollutants to floor level. Using the new Medishield pollution control system currently being developed it will be possible to extend the valve for remote venting to atmosphere.

The PSI 5000 Recorder is a portable, battery operated, self-contained unit for use in most heart, lung, and blood pressure measurements. The PSI 5000 meets AHA specifications for electrocardiography, assuring superior performance in any application requiring high frequency response. The pen stylus is held in a stress-free mount on a titanium arm to provide exceptional life. It is capable of sustaining up to 1000 G's acceleration. A fully charged battery will provide up to four hours continuous operation.

When to use the word Phär′mȧ·sēal.

For components, features, "performance" in single-use anesthesia trays, just say the word.

The trays you've counted on from the start now offer you even more to go on.

Back in 1963 we introduced the world's first single-use, regional anesthesia trays.

Today, with a record of safe performance difficult to equal, we offer you an even wider selection of components and features—just as difficult to match—in spinal, caudal and epidural trays.

All with our all-new spinal needle. The needle that's been called the cleanest spinal needle yet. The one with a cannula with almost uncanny smoothness, a cartridge pack with an exceptional point protector, a matched-ground point, metal hub and more.

Trays that offer you a new fenestrated drape with its own adhesive tabs.

A large, moisture-resistant hospital wrap with a new "wrinkle" for better procedure.

Plus, a specially designed introducer needle, a clear 5-cc. Stylex® syringe, a unique aseptic transfer carton...and a variety of other first-quality components and drugs.

But see for yourself what we're talking about. See the trays with performance you can count on. For samples, just call or write.

You know the word to use.

If You're Confused About O.R. Pollution, **Cut It Out.**

Get a compilation of data on the problems of trace anesthetic gas and OR pollution control. Send for our Positive Response Program.

Besides reports and studies to help you put the problem in perspective, our "PRP" plan of action provides an up-to-date look at our products which help you detect and scavenge trace gas in your OR. Key to our program is the Foregger 410 N_2O Trace Gas Monitor, a basic requirement for any efficient trace gas monitoring program. It's designed to provide rapid and continuous sampling of the OR air you breathe.

The machine has two sensing modes—Monitor (0-100 ppm) and Leak Test (0-1,000 ppm). The first mode continuously monitors the ambient air through the gas inlet of the machine. The second permits probing of local concentrations and sounds a repetitive burst alarm as the gas concentration increases.

In short, the Foregger 410 N_2O Trace Gas Monitor is a logical first step in solving your OR pollution problem. And there's more. The Scaveng-OR™ Gas Evacuator System, the Protect-OR™ Filter, Wall Suction Systems, and Air-CARE™ Preventive Maintenance Service.

Based on current data, it's likely that routine monitoring of pollution levels and scavenging of waste anesthetic gases will soon be standard Operating Room procedure. We're ready to help you now.

Fill out this ad coupon or ask our Representative for a Foregger PRP Folder. You'll get the problem in perspective and a plan of action to help correct it.

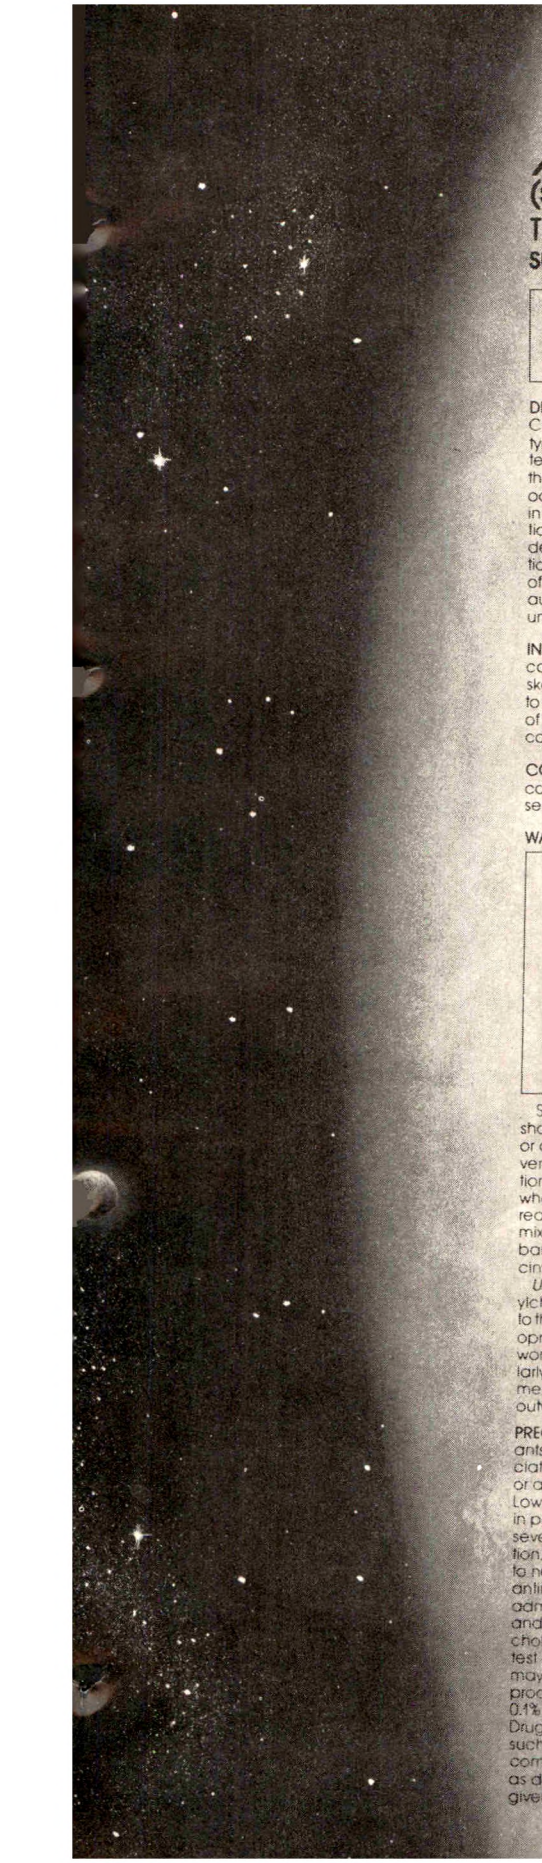
ANECTINE®
(succinylcholine chloride)
For controlled muscle relaxation adjunctive to anesthesia:

FLO-PACK® for prolonged relaxation

- instant-mix sterile powder interfaces with all major parenteral systems (vacuum or nonvacuum)
- each unit complete—no needle or syringe needed
- retains potency indefinitely
- no refrigeration required
- unbreakable, sterile plastic injection units of 500 and 1,000 mg

INJECTION for short-term relaxation

- a product of choice for intubation and other short procedures
- unique square bottle and bright yellow label for positive identification
- ready for immediate use
- 20 mg per cc . . . in 10 cc multidose vials
- flip-top cap for easy opening
- single or multiple use



ANECTINE®
(succinylcholine chloride)
THE LONG AND SHORT of surgical muscle relaxation

THIS DRUG SHOULD BE USED ONLY BY INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS AND HAZARDS.

DESCRIPTION: Anectine brand Succinylcholine Chloride is an ultra short-acting depolarizing type muscle relaxant. Chemically it is a di-quaternary base consisting of the di-chloride salt of the di-choline ester of succinic acid. It is a white, odorless, slightly bitter powder and very soluble in water. The drug is unstable with alkaline solutions, but relatively stable in acid solutions depending upon the concentration of the solution and the storage temperature. While solutions of succinylcholine chloride are sterilized by autoclaving, they should, nevertheless, be stored under refrigeration to preserve their potency.

INDICATIONS: Succinylcholine chloride is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may be employed to reduce the intensity of muscle contractions of pharmacologically or electrically induced convulsions.

CONTRAINDICATIONS: Succinylcholine is contraindicated for persons with a known hypersensitivity to the drug.

WARNINGS:

WARNING: SUCCINYLCHOLINE SHOULD BE USED ONLY BY THOSE SKILLED IN THE MANAGEMENT OF ARTIFICIAL RESPIRATION AND ONLY WHEN FACILITIES ARE INSTANTLY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND FOR PROVIDING ADEQUATE VENTILATION OF THE PATIENT, INCLUDING THE ADMINISTRATION OF OXYGEN UNDER POSITIVE PRESSURE AND THE ELIMINATION OF CARBON DIOXIDE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR TO CONTROL RESPIRATION.

Succinylcholine should not be mixed with short-acting barbiturates in the same syringe, or administered simultaneously during intravenous infusion through the same needle. Solutions of succinylcholine have an acid pH whereas those of barbiturates are alkaline in reaction. Depending upon the resultant pH of a mixture of solutions of these drugs, either free barbituric acid may be precipitated or succinylcholine hydrolyzed.

Usage in Pregnancy. The safe use of succinylcholine has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards.

PRECAUTIONS: Low levels of, or abnormal variants of plasma cholinesterase may be associated with prolonged respiratory depression or apnea following the use of succinylcholine. Low levels of plasma cholinesterase may occur in patients with severe liver disease or cirrhosis, severe anemia, malnutrition, severe dehydration, changes in body temperature, exposure to neurotoxic insecticides or those receiving antimalarial drugs. Succinylcholine should be administered with extreme care to such patients and dosage should be minimal. If low plasma cholinesterase activity is suspected, a small test dose of from 5 to 10 mg of succinylcholine may be administered, or relaxation may be produced by the cautious administration of a 0.1% solution of the drug by intravenous drip. Drugs which either inhibit plasma cholinesterase, such as neostigmine or phospholine iodide, or compete with succinylcholine for the enzyme, as does intravenous procaine, should not be given concurrently with succinylcholine.

Succinylcholine should be administered with great caution to patients with severe burns, those recovering from severe trauma, those suffering from electrolyte imbalance, those receiving quinidine, those who have been digitalized recently or who may have digitalis toxicity as serious cardiac arrhythmias or cardiac arrest may result. Great caution should be observed also in patients with pre-existing hyperkalemia or who are paraplegic, have suffered spinal neuraxis injury, or have degenerative or dystrophic neuromuscular disease, as such patients tend to become severely hyperkalemic when succinylcholine is given.

When succinylcholine is given over a prolonged period of time, the characteristic depolarization block of the myoneural junction may change to a non-depolarizing block which results in prolonged respiratory depression or apnea. Under such circumstances, small repeated doses of neostigmine may possibly act as an antagonist. A peripheral nerve stimulator (e.g., the Wellcome Peripheral Nerve Stimulator) may be used to ascertain the type of neuromuscular blockade. If a depolarization block is present both fast (tetanic) and slow (twitch) rates of nerve stimulation are well sustained, and post-tetanic facilitation is absent. If a non-depolarizing block is present there is post-tetanic facilitation and "fade" of successive stimuli on both fast (tetanic) and slow (twitch) rates of nerve stimulation.

Succinylcholine should be used with caution during ocular surgery and in patients with glaucoma. The drug should be employed with caution in patients with fractures or muscle spasm as the muscle fasciculations may cause additional trauma. Muscle fasciculations and hyperkalemia may be reduced by administering a small dose of a non-depolarizing relaxant. If other relaxants are to be used during the same procedure, the possibility of a synergistic or antagonistic effect should be considered.

During the past few years, reports have called attention to a fulminant syndrome, malignant hyperthermia, observed during anesthesia. Its etiology is not fully understood. Malignant hyperthermia occurs in genetically prone individuals of all ages and both sexes receiving potent anesthetics such as halothane, methoxyfluothane, cyclopropane and diethyl ether. It appears to develop irrespective of the concomitant use of a muscle relaxant, but may be triggered by succinylcholine. Because of the seriousness of this syndrome and the need for early effective treatment of the patient, it is suggested that the continuous monitoring of the temperature will serve as an aid to the early recognition of malignant hyperthermia.

ADVERSE REACTIONS: Adverse reactions consist primarily of an extension of the drug's pharmacological actions. Profound and prolonged muscle relaxation may occur, resulting in respiratory depression to the point of apnea. Hypersensitivity to the drug may exist in rare instances.

The following adverse reactions have been reported: bradycardia, tachycardia, hypertension, hypotension, arrhythmias, cardiac arrest, prolonged respiratory depression or apnea, hyperthermia, increased intraocular pressure, muscle fasciculation, postoperative muscle pain, myoglobinemia and excessive salivation.

MANAGEMENT OF ADVERSE REACTIONS: Apnea or prolonged muscle paralysis should be treated with controlled respiration.

The use of neostigmine to reverse a non-depolarization block is a medical decision which must be made upon the basis of the individual clinical pharmacology and the experience and judgment of the clinician. When neostigmine is used atropine should also be administered.

SUPPLIED: Injection, Multi-dose vials, 20 mg. cc, 10 cc, boxes of 12 vials. Flo-Pack® Sterile Powder 500 mg and 1,000 mg, boxes of 12.

Selected cases for Ketalar® (ketamine HCl injection)

(and a caution)

There are certain situations where the advantages of Ketalar suggest its serious consideration.

Four such hypothetical situations are detailed here. A fifth hypothetical case illustrates a situation in which Ketalar probably should be used only with caution.

Geriatric surgical procedure

Ketalar offers advantages in minor rectal surgery on elderly patients. When properly administered, Ketalar usually does not depress the patient's blood pressure or pulse rate, which can be a distinct advantage with any patient who is likely to develop hypotension. Further, emergence reactions normally are not a problem with patients in the older age group (over 65).

Severely burned patients

Patients with severe burns—and particularly children—are often excellent cases for Ketalar. In children, Ketalar offers rapid surgical anesthesia (generally within three to four minutes) at a range of 9 to 13 mg/kg, with the effect lasting from 12 to 25 minutes (the time intervals are for IM, not IV). Intramuscular administration avoids the possible difficulty in locating the vein in burn patients (particularly helpful in children where the veins are small). IM administration is also convenient and effective for repeated short-term anesthesia for such procedures as changing burn dressings, and skin grafts.

Manipulative diagnostic procedure

Ketalar facilitates diagnostic procedures in which the patient must be moved freely, and in which the maintenance of unaided respiration is essential. The pneumoencephalogram is an example. Once anesthesia is established, the patient can be transferred from a supine to an upright, supported position with ease since Ketalar maintains adequate unaided respiration, and there is minimal relaxation of the skeletal muscles.

Emergency room treatment

A good case for Ketalar can be made for use in accident victims with unknown medical histories brought to the emergency room. In the absence of positive medical history, Ketalar can be a useful agent because of its wide margin of safety. Consideration should be given to the effects of a significant increase in blood pressure, hypersensitivity to the drug, and an elevation in cerebrospinal fluid pressure. Ketalar also provides the benefit of rapid onset, and decreases the chance of aspiration because of active laryngeal-pharyngeal reflexes.

A caution:

Caution should be exercised when administering Ketalar to patients who are known to be alcoholics or who are acutely alcohol-intoxicated as such patients may be prone to untoward reactions.

Ketalar

(Ketamine HCl injection)

Brief summary of prescribing information.

SPECIAL NOTE

EMERGENCE REACTIONS HAVE OCCURRED IN APPROXIMATELY 12% OF PATIENTS.

THE PSYCHOLOGICAL MANIFESTATIONS VARY IN SEVERITY BETWEEN PLEASANT, DREAMLIKE STATES, VIVID IMAGERY, HALLUCINATIONS, AND EMERGENCE DELIRIUM. IN SOME CASES, THESE STATES HAVE BEEN ACCOMPANIED BY CONFUSION, EXCITEMENT, AND IRRATIONAL BEHAVIOR WHICH A FEW PATIENTS RECALL AS AN UNPLEASANT EXPERIENCE. THE DURATION ORDINARILY LASTS NO MORE THAN A FEW HOURS; IN A FEW CASES, HOWEVER, RECURRENCES HAVE TAKEN PLACE UP TO 24 HOURS POSTOPERATIVELY. NO RESIDUAL PSYCHOLOGICAL EFFECTS ARE KNOWN TO HAVE RESULTED FROM USE OF KETALAR.

THE INCIDENCE OF THESE EMERGENCE PHENOMENA IS LEAST IN THE YOUNG (15 YEARS OF AGE OR LESS) AND ELDERLY (OVER 65 YEARS OF AGE) PATIENT. ALSO, THEY ARE LESS FREQUENT WHEN THE DRUG IS GIVEN INTRAMUSCULARLY.

THESE REACTIONS MAY BE REDUCED IF VERBAL, TACTILE, AND VISUAL STIMULATION OF THE PATIENT IS MINIMIZED DURING THE RECOVERY PERIOD. THIS DOES NOT PRECLUDE THE MONITORING OF VITAL SIGNS. IN ADDITION, THE USE OF A SMALL HYPNOTIC DOSE OF A SHORT-ACTING OR ULTRASHORT-ACTING BARBITURATE MAY BE REQUIRED TO TERMINATE A SEVERE EMERGENCE REACTION. THE INCIDENCE OF EMERGENCE REACTIONS IS REDUCED AS EXPERIENCE WITH THE DRUG IS GAINED.

WHEN KETALAR IS USED ON AN OUTPATIENT BASIS, THE PATIENT SHOULD NOT BE RELEASED UNTIL RECOVERY FROM ANESTHESIA IS COMPLETE AND THEN SHOULD BE ACCOMPANIED BY A RESPONSIBLE ADULT.

INDICATIONS

Ketalar (ketamine HCl injection) is recommended:

1. as the sole anesthetic agent for diagnostic and surgical procedures that do not require skeletal muscle relaxation. Ketalar is best suited for short procedures but it can be used, with additional doses, for longer procedures;

2. for the induction of anesthesia prior to the administration of other general anesthetic agents;

3. to supplement low-potency agents, such as nitrous oxide.

CONTRAINDICATIONS

Ketamine hydrochloride is contraindicated in those in whom a significant elevation of blood pressure would constitute a serious hazard and those who have shown hypersensitivity to the drug.

WARNINGS

1. Ketalar should be used by or under the direction of physicians experienced in administering general anesthetics and in maintenance of an airway and in the control of respiration.

2. Cardiac function should be continually monitored during the procedure in patients found to have hypertension or cardiac decompensation.

3. Barbiturates and Ketalar, being chemically incompatible because of precipitate formation, *should not* be injected from the same syringe.

4. Prolonged recovery time may occur if barbiturates and/or narcotics are used concurrently with Ketalar.

5. Postoperative confusional states may occur during the recovery period.

6. Respiratory depression may occur with overdosage or too rapid a rate of administration of Ketalar, in which case supportive ventilation should be employed. Mechanical support of respiration is preferred to administration of analeptics.

Usage in Pregnancy

Since the safe use in pregnancy, including obstetrics (either vaginal or abdominal delivery), has not been established, such use is not recommended.

PRECAUTIONS

1. Because pharyngeal and laryngeal reflexes are usually active, Ketalar (ketamine HCl injection) should not be used alone in surgery or diagnostic procedures of the pharynx, larynx, or bronchial tree. Mechanical stimulation of the pharynx should be avoided, whenever possible, if Ketalar is used alone. Muscle relaxants, with proper attention to respiration, may be required in both of these instances.

2. Resuscitative equipment should be ready for use.

3. ***The incidence of emergence reactions may be reduced*** if verbal and tactile stimulation of the patient is minimized during the recovery period. This does not preclude the monitoring of vital signs (see Special Note).

4. The intravenous dose should be administered over a period of 60 seconds. More rapid administration may result in respiratory depression or apnea and enhanced pressor response.

5. In surgical procedures involving visceral pain pathways, Ketalar should be supplemented with an agent which obtunds visceral pain.

6. Use with caution in the chronic alcoholic and the acutely alcohol-intoxicated patient.

7. An increase in cerebrospinal fluid pressure has been reported following administration of ketamine hydrochloride. Use with extreme caution in patients with preanesthetic elevated cerebrospinal fluid pressure.

ADVERSE REACTIONS

Cardiovascular: Blood pressure and pulse rate are frequently elevated following administration of Ketalar. However, hypotension and bradycardia have been observed. Arrhythmia has also occurred.

Respiration: Although respiration is frequently stimulated, severe depression of respiration or apnea may occur following rapid intravenous administration of high doses of Ketalar (ketamine HCl injection). Laryngospasms and other forms of airway obstruction have occurred during Ketalar anesthesia.

Eye: Diplopia and nystagmus have been noted following Ketalar administration. It also may cause a slight elevation in intraocular pressure measurement.

Psychological: (See Special Note).

Neurological: In some patients, enhanced skeletal muscle tone may be manifested by tonic and clonic movements sometimes resembling seizures (see Dosage and Administration).

Gastrointestinal: Anorexia, nausea and vomiting have been observed; however this is not usually severe and allows the great majority of patients to take liquids by mouth shortly after regaining consciousness (see Dosage and Administration).

General: Local pain and exanthema at the injection site have infrequently been reported. Transient erythema and/or morbilliform rash have also been reported.

DOSAGE AND ADMINISTRATION

Preoperative Preparations:

1. While vomiting has been reported following Ketalar administration, airway protection is usually afforded because of active laryngeal-pharyngeal reflexes. However, since these reflexes may also be diminished by supplementary anesthetics or muscle relaxants, the possibility of aspiration must be considered. Ketalar is recommended for use in the patient whose stomach is not empty when, in the judgment of the practitioner, the benefits of the drug outweigh the possible risks.

2. Atropine, scopolamine, or other drying agent should be given at an appropriate interval prior to induction.

Dosage

As with other general anesthetic agents, the individual response to Ketalar (ketamine HCl injection) is somewhat varied depending on the dose, route of administration, and age of patient, so that dosage recommendation cannot be absolutely fixed. The drug should be titrated against the patient's requirements.

Onset and Duration:

Because of rapid induction following the initial intravenous injection, the patient should be in a supported position during administration.

The onset of action of Ketalar (ketamine HCl injection) is rapid; an intravenous dose of 2 mg/kg (1 mg/lb) of body weight usually produces surgical anesthesia within 30 seconds after injection, with the anesthetic effect usually lasting five to ten minutes. If a longer effect is desired, additional increments can be administered intravenously or intramuscularly to maintain anesthesia without producing significant cumulative effects.

Intramuscular doses, from experience primarily in children, in a range of 9 to 13 mg/kg (4 to 6 mg/lb) usually produce surgical anesthesia within three to four minutes following injection, with the anesthetic effect usually lasting 12 to 25 minutes.

Induction:

Intravenous Route: The initial dose of Ketalar administered intravenously may range from 1 mg/kg to 4.5 mg/kg (0.5 to 2 mg/lb). The average amount required to produce five to ten minutes of surgical anesthesia has been 2 mg/kg (1 mg/lb).

NOTE: The 100 mg/ml concentration (S-V 1585) of Ketalar, *should not* be injected intravenously without proper dilution. It is recommended the drug be diluted with an equal volume of either Sterile Water for Injection, USP, Normal Saline, or 5% Dextrose in Water.

Rate of Administration: It is recommended that Ketalar be administered slowly (over a period of 60 seconds). More rapid administration may result in respiratory depression and enhanced pressor response.

Intramuscular Route: The initial dose of Ketalar administered intramuscularly may range from 6.5 to 13 mg/kg (3 to 6 mg/lb). A dose of 10 mg/kg (5 mg/lb) will usually produce 12 to 25 minutes of surgical anesthesia.

Maintenance of Anesthesia:

Increments of one half to the full induction dose may be repeated as needed for maintenance of anesthesia. However, it should be noted that purposeless and tonic-clonic movements of extremities may occur during the course of anesthesia. These movements do not imply a light plane and are not indicative of the need for additional doses of the anesthetic.

It should be recognized that the larger the total dose of Ketalar (ketamine HCl injection) administered, the longer will be the time to complete recovery.

Supplementary Agents:

Ketalar is clinically compatible with the commonly used general and local anesthetic agents when an adequate respiratory exchange is maintained.

HOW SUPPLIED

Ketalar is supplied as the hydrochloride in concentrations equivalent to ketamine base.

N 0071-4581-15—Each 50-ml vial contains 10 mg/ml. Supplied in cartons of 10.

N 0071-4581-12—Each 20-ml vial contains 10 mg/ml. Supplied in cartons of 10.

N 0071-4582-10—Each 10-ml vial contains 50 mg/ml. Supplied in cartons of 10.

N 0071-4585-08—Each 5-ml vial contains 100 mg/ml. Supplied in cartons of 10.

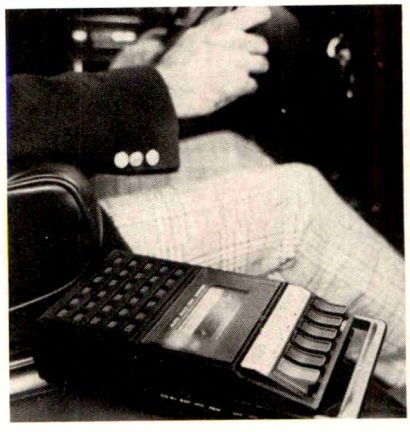
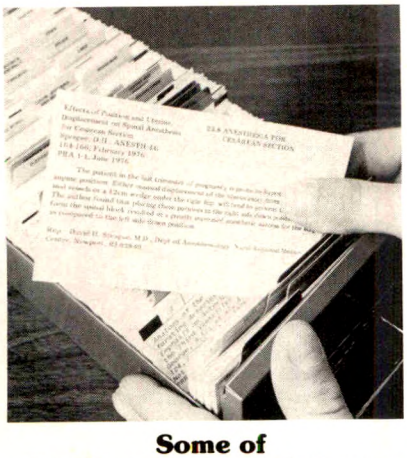
The Anesthesiologist: *You need to know it all... and now!*

Anesthesia cuts across the entire medical spectrum. And the very latest information is in the journals. But when can you find the time to read them? And even more important, to have the information at hand when you need it.

Practical Reviews can help!

Each month a group of outstanding anesthesiologists (plus distinguished guest commentators) picks the best of current information from the journals, boils it down to 3-4 minute segments and sends it to you on cassette tapes. Thus each month you get 20-25 digests of the newest and best in Anesthesiology. You can listen in any free time available, even in your car!





Information in seconds!

Best of all, each article is summarized on subject-indexed reference cards. Practical Reviews unique tab-filing system (also provided) makes instant retrieval possible. You build a library of vital information that is constantly being up-dated...automatically!

"This continuing medical education activity meets the criteria for hour-for-hour credit in Category I for the Physician's Recognition Award of the AMA."

Some of The Guest Commentators on The Practical Reviews Anesthesiology Team:

John Steinhaus, M.D.
Chairman, Department of Anesthesiology, Emory University

M. T. Jenkins, M.D.
Chief of Anesthesia, Parkland Memorial Hospital

Joachim Gravenstein, M.D.
Chairman of Anesthesiology, Case-Western Reserve School of Medicine

Robert M. Smith, M.D.
Director of Anesthesiology Children's Hospital of Boston

Joseph R. Artusio, Jr., M.D.
Chairman, Anesthesia, Cornell School of Medicine Anesthetist-in-Chief, New York Hospital

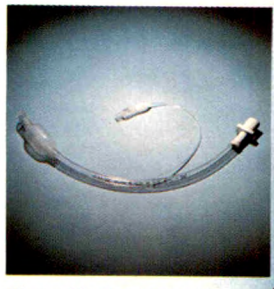
The anesthesia system without compromises is the one you design for yourself. Including Ohio keepables and disposables!

VORTEX™ Respiration Monitor measures tidal volumes continuously, totalizes to obtain minute volume.



Disposable Endotracheal Tubes, new, uncuffed or with anatomically designed cuffs for gentle seal. Unique inflation and pilot balloon assembly.

Disposable Anesthesia Breathing Circuit with conductive, cushioned masks in three sizes. Our bacteria filter-pathogen trap fits most anesthesia circuits.

OHIO Critical Care Ventilator with intermittent mandatory ventilation "engineered in." Assists ventilation in any interval from 5 to 100 seconds.

Anesthesia Ventilator, fluidically controlled for less maintenance. Precise and reliable. With a built-in gas evacuator. Ohio can also customize a gas evacuation interface to accommodate your disposal system.

O_2 Monitor with visual and audio alarms.

One system designed to suit all can't really satisfy everyone. Because somewhere along the line you have to compromise. Each of you has your own ideas about how best to provide excellence in patient care in your own operating theater. And each OR has its unique needs.

Most new systems begin with one of the four OHIO® anesthesia machines. Rugged. Practical. Versatile. Functional. Delivering your preference in anesthetic agents with accuracy and safety.

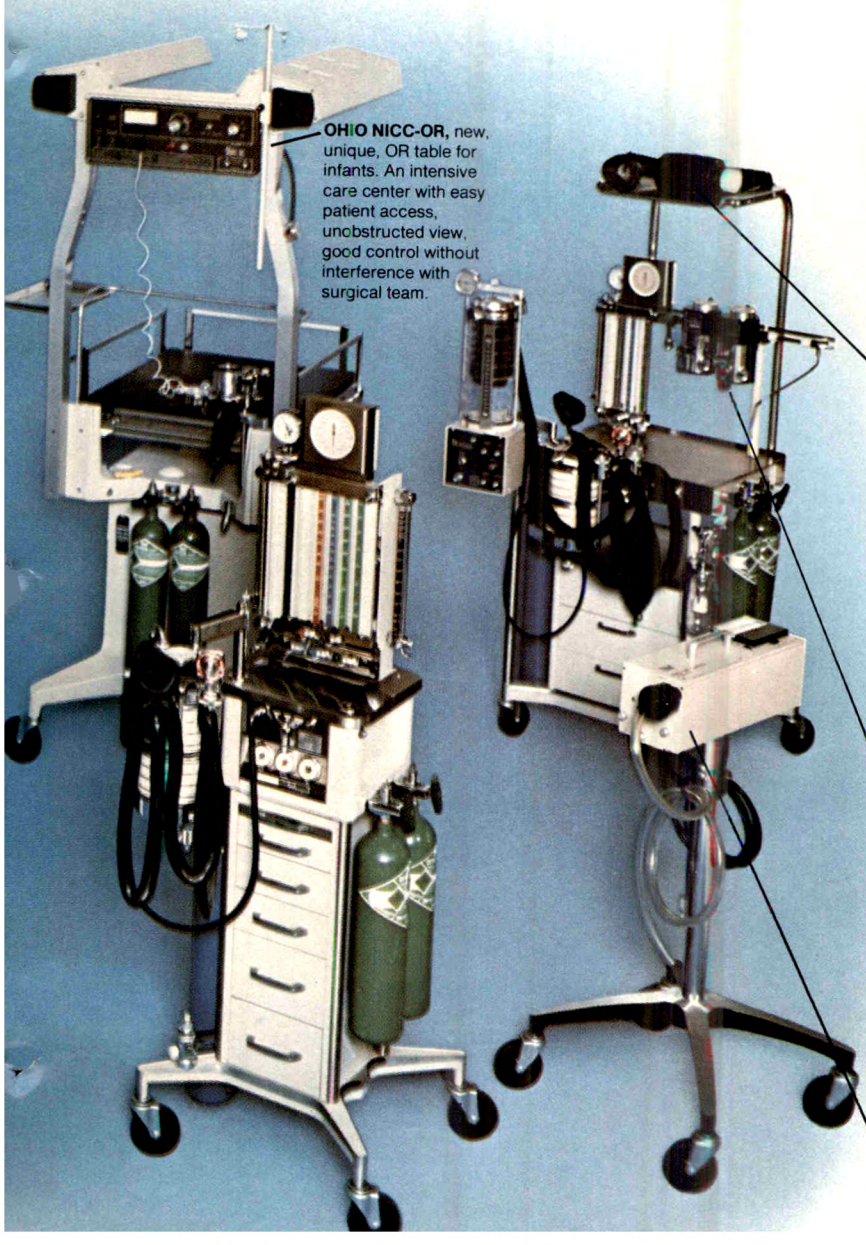
Then, your system grows to support your skills and techniques, as you add accessories and options from Ohio: Vaporizers, ventilators and absorbers, monitors, disposables, medical gases, and gas evacuation systems. And we always have more on the way.

You can depend on over 100 factory-trained Ohio servicemen and six service centers in the U.S. and Canada to keep your anesthesia equipment performing. Plus a knowledgeable sales staff.

Send for information. Or send for your salesman. Ohio will help you develop a reliable, sophisticated anesthesia system. One you can build on when future technologies develop. So, you'll never have to compromise in caring for your patients.

Ohio Medical Products AIRCO®

3030 Airco Drive, P.O. Box 7550, Dept. 305
Madison, Wisconsin 53707



OHIO NICC-OR, new, unique, OR table for infants. An intensive care center with easy patient access, unobstructed view, good control without interference with surgical team.

HOPE® II resuscitator with a new valve and the facility to administer enriched oxygen concentrations.

OHIO Calibrated Vaporizer, new, easy-to-use, temperature and flow compensated with excellent low-flow performance.

New Trace Gas Analyzer detects and measures the concentration of nitrous oxide in the operating room atmosphere; alerting OR personnel to leak sources.

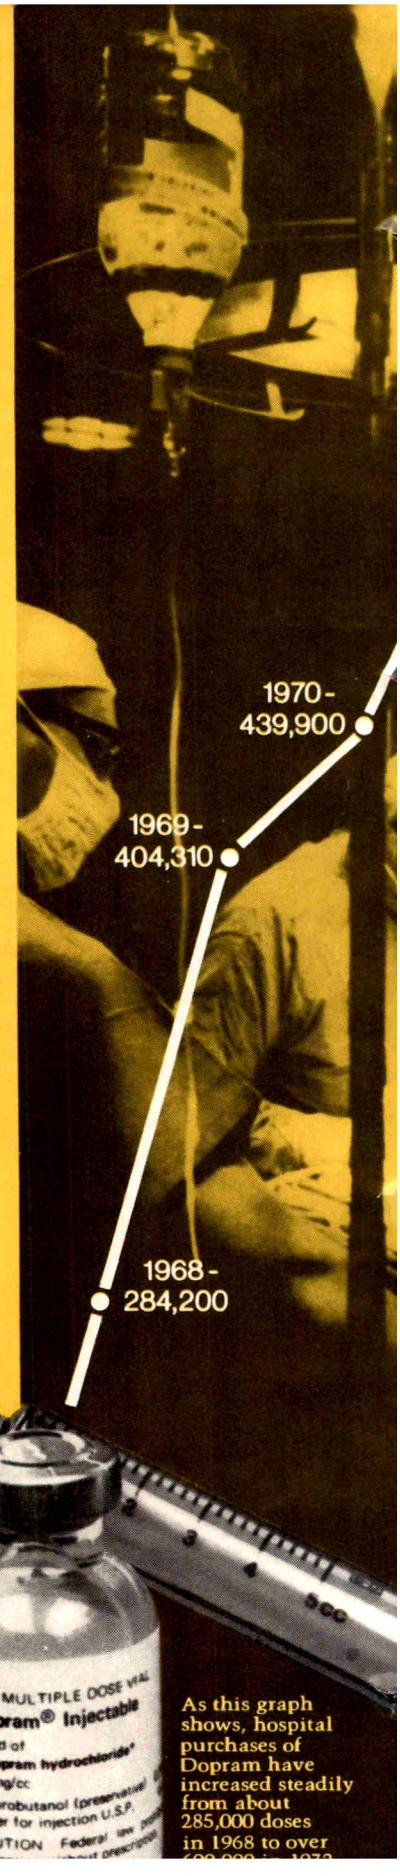
In all types of hospitals across the United States, its usage grows–

Dopram®
Injectable
(doxapram HCl)

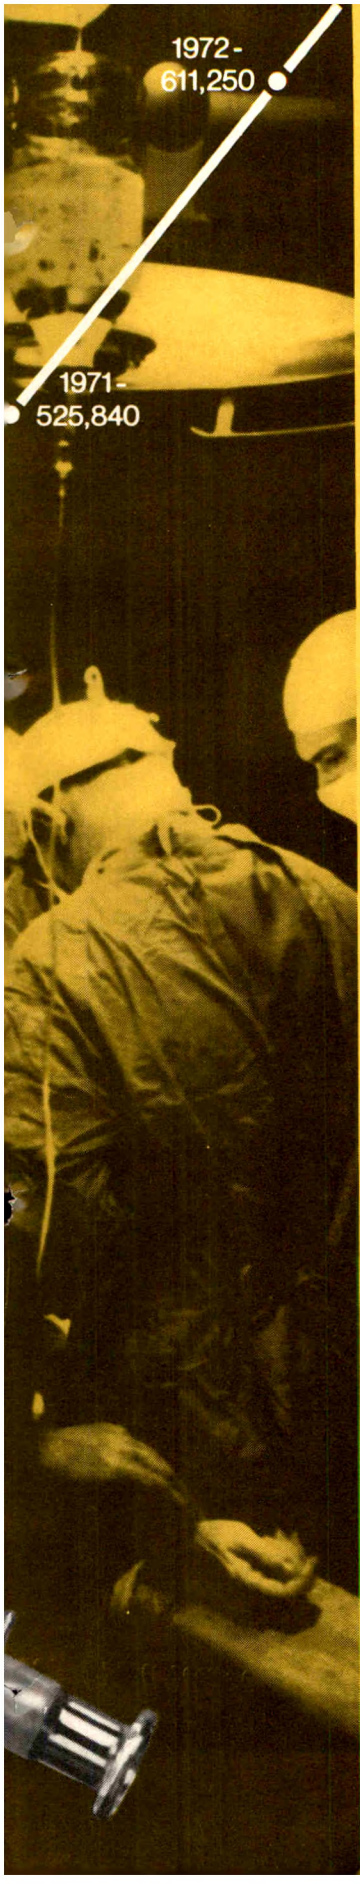
Seven years ago, A. H. Robins introduced Dopram, a unique respiratory stimulant developed in the company's research laboratories. What made this drug so useful to the anesthesiologist was its ability to rapidly restore the respiratory drive in patients with drug-induced post anesthetic depression.

Usage of Dopram has been steadily increasing each year, until today it has become a very important drug in the armamentarium of more than 1,500 hospitals of all types in all 50 states, the District of Columbia, and a number of foreign countries. These hospitals purchased more than 600,000 doses in 1972 alone.

Dopram–an important drug in anesthesiology. Try it for sighs!



As this graph shows, hospital purchases of Dopram have increased steadily from about 285,000 doses in 1968 to over



Indications

1. To stimulate respiration in patients with drug induced post-anesthetic respiratory depression or apnea other than that due to muscle relaxant drugs.
2. To pharmacologically stimulate deep breathing in the so-called "stir-up" regimen in the post-operative patient. Simultaneous administration of oxygen is desirable.
3. To hasten arousal and return of protective pharyngeal and laryngeal reflexes.
4. To aid in the differential diagnosis of post-anesthetic respiratory depression. Failure to adequately stimulate respiration suggests residual muscle relaxant effect.
5. To stimulate respiration, hasten arousal and to encourage the return of laryngopharyngeal reflexes in patients with mild to moderate respiratory and CNS depression due to drug overdosage.

Contraindications—Epilepsy and other convulsive states: incompetence of the ventilatory mechanism due to muscle paresis, flail chest, pneumothorax, airway obstruction, and extreme dyspnea; severe hypertension and cerebrovascular accidents; hypersensitivity.

Doxapram is not recommended for patients 12 years of age or under because studies to evaluate its safety and efficacy have not been performed.

Warnings—Doxapram is an analeptic agent; it is neither an antagonist to muscle relaxant drugs nor a specific narcotic antagonist. Since doxapram has an acid pH, it should not be mixed with alkaline solutions such as thiopental sodium.

Since narcosis may recur after stimulation with doxapram, care should be taken to maintain close observation until the patient has been fully alert for 1/2 to 1 hour. (Duration of drug 5-12 minutes.)

Doxapram is an adjunct to well-accepted supportive measures and resuscitative techniques. It may not stimulate adequate spontaneous breathing or provide sufficient arousal in patients who are severely depressed with CNS depressant drugs.

When doxapram is administered to postoperative patients or to patients in a state of narcosis with chronic pulmonary insufficiency, oxygen should be administered concomitantly. Failure to do so may result in further oxygen debt and more severe dyspnea due to the increased work of breathing.

Doxapram should be administered with great care and only under close supervision to patients with cerebral edema, bronchial asthma, severe tachycardia, cardiac arrhythmia, cardiac disease, hyperthyroidism and pheochromocytoma.

Usage in pregnancy

No adequate clinical studies have been performed to determine the safe use of doxapram in pregnancy. Until further clinical experience has been obtained, the physician must weigh the need against possible risks in using the drug in pregnant patients or in women of child-bearing potential.

Precautions—Recommended dosages of doxapram should be employed and maximum total dosages should not be exceeded. In patients with advanced pulmonary disease with hypoxemia, marked respiratory stimulation increases the work of breathing and may, thus, increase oxygen consumption and carbon dioxide production.

With excessive dosage, hyperventilation induced by doxapram may lead to respiratory alkalosis and hypocapnia with tetany and, theoretically, apnea.

An adequate airway is essential. In order to avoid side effects, it is advisable to use the minimum effective dosage. Monitoring of the blood pressure and deep tendon reflexes is recommended to prevent overdosage.

It is desirable that blood gases (P_{O_2} P_{CO_2} O_2 saturation) be monitored to assess the effectiveness of respiratory stimulation.

Intravenous barbiturates, oxygen and resuscitative equipment should be readily available to manage overdosage manifested by excessive central nervous system stimulation. Slow administration of the drug and careful observation of the patient during administration and for some time subsequently are advisable to insure restoration of the protective reflexes. The possibility of post-stimulation respiratory depression must be kept in mind. In patients who have been lightly curarized, doxapram may temporarily mask the residual effects of muscle relaxant drugs.

Doxapram should be administered cautiously to patients receiving sympathomimetic or monoamine oxidase inhibiting drugs, since a synergistic pressor effect may occur. It should likewise be used with care in post-operative patients with marked dyspnea due to obstructive pulmonary emphysema, acute or chronic asthma, profound metabolic disorders, severe to moderately severe hypertension, increased cerebrospinal fluid pressure, head injury and acute agitation.

Since doxapram may stimulate basal gastric secretion, it should be used with care in patients with peptic ulcer disease and in patients undergoing gastric surgery.

Vascular extravasation or use of a single injection site over an extended period should be avoided since either may lead to thrombophlebitis.

Hypocapnia accompanying forced ventilation is a potent stimulus to cerebral vasoconstriction; it may be postulated that some element of risk may exist from reduced cerebral blood flow following prolonged and intensive hyperventilation.

Since an increase in epinephrine release has been noted with doxapram, it is recommended that initiation of therapy with this respiratory stimulant be delayed for at least 10 minutes following the discontinuance of anesthetics known to sensitize the myocardium to catecholamines, such as halothane and cyclopropane.

As with other intravenous preparations, all precautions should be taken during administration of doxapram to insure that injection is made directly into a suitable vein; extravasation, and inadvertent intra-arterial injection should be avoided.

Adverse reactions—The following adverse reactions have been reported: *Central and Autonomic Nervous Systems.* Hyperactivity, feeling of warmth, sweating, muscle tremor, clonus, increased deep tendon reflexes, dizziness, muscle spasticity, pyrexia, confusion, paresthesia, pupillary dilatation, pilomotor erection, headache, bilateral babinski, fasciculation and carpopedal spasm. A grand mal seizure occurred 95 minutes after drug administration in a known epileptic patient who was on anticonvulsant medication.

Respiratory. Cough, dyspnea, laryngospasm, bronchospasm and hiccough.

Cardiovascular. Hypertension, sinus tachycardia, bradycardia, extrasystoles, lower T-waves, premature ventricular contractions, irregular heart rhythm, tightness in chest. Although a mild to moderate increase in blood pressure is not infrequent, such an increase may occasionally be of concern in hypertensive patients.

Gastrointestinal. Nausea and/or vomiting, salivation, stimulation of lower bowel, sour taste.

Genitourinary. Urinary retention, stimulation of urinary bladder with spontaneous voiding.

Miscellaneous. Pruritus, thrombophlebitis.

Laboratory Determinations. A decrease in hemoglobin, hematocrit, or red blood cell count has been observed in postoperative patients. In the presence of pre-existing leukopenia, a further decrease in WBC was observed following anesthesia and treatment with doxapram hydrochloride. Elevation of BUN and albuminuria have been observed.

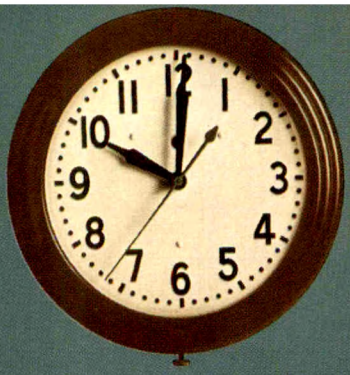
In some of the cases cited above, the patients had received multiple drugs concomitantly, thus preventing an absolute judgment as to the role of doxapram in these reactions.

Dosage—For complete information concerning dosage and administration see package insert.

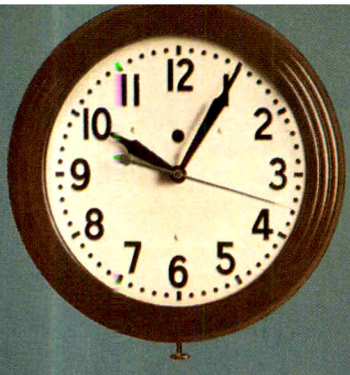
Supply—Dopram (doxapram hydrochloride) is available in 20 cc rubber stoppered vials containing 20 mg/cc, with chlorobutanol 0.5% as the preservative.

A. H. Robins Company
Richmond, Virginia 23220

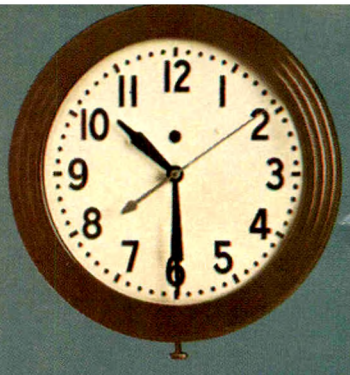
A·H·ROBINS



SUBLIMAZE® (fentanyl) has a uniquely short duration of analgesic action—for more precise control and minimal risk of prolonged narcotic effects.

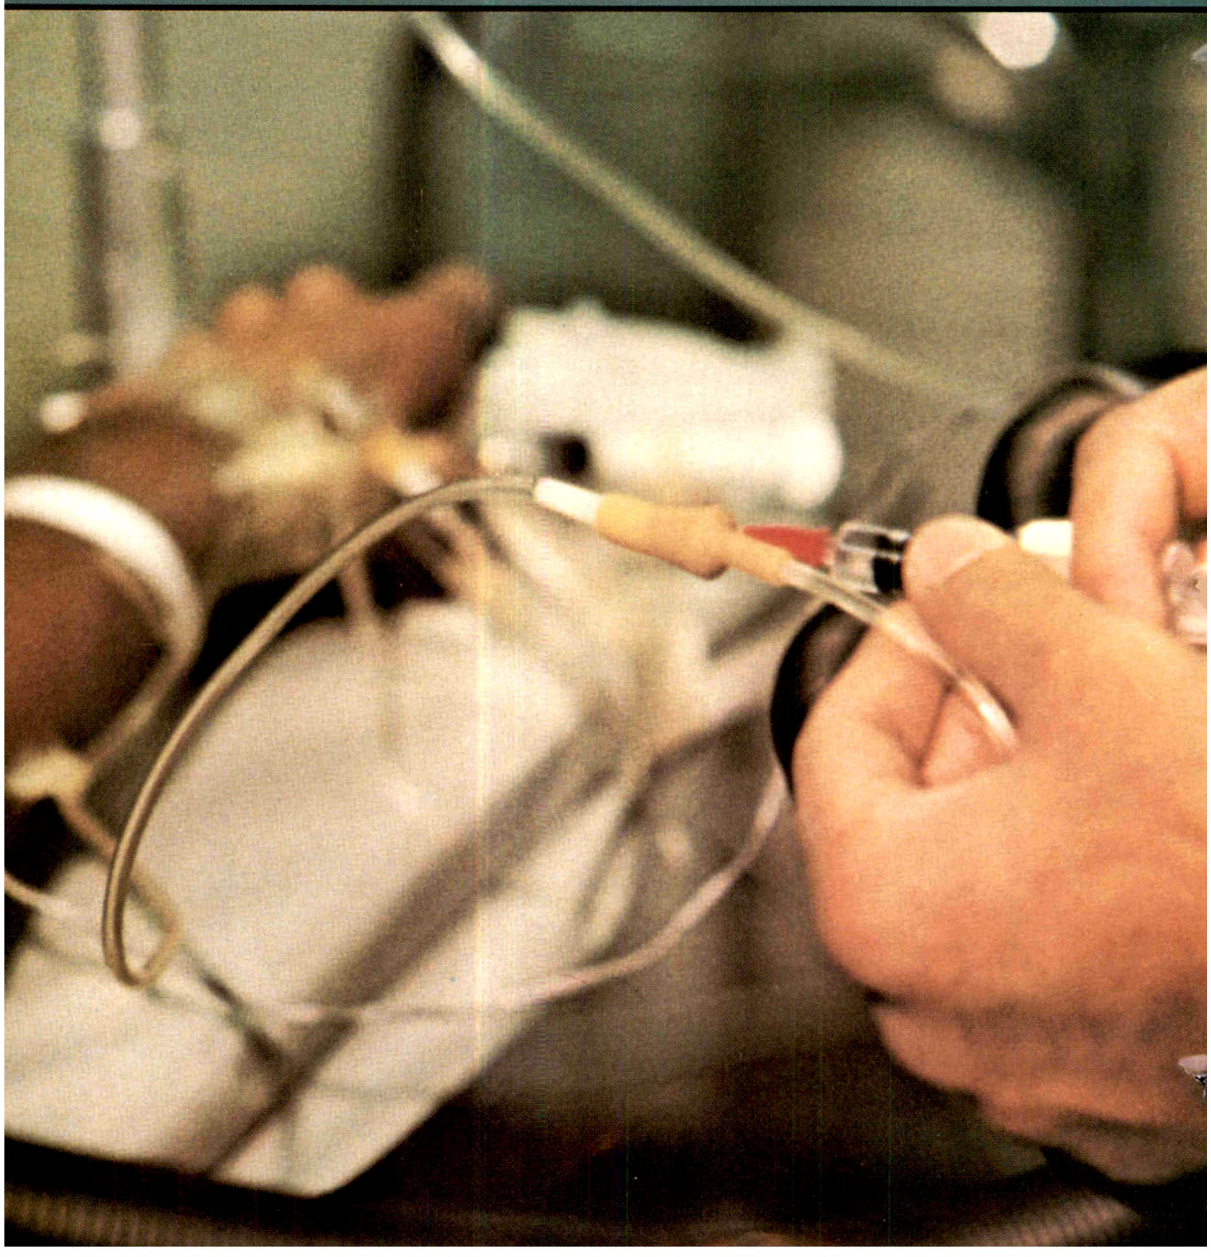


Within 5 minutes I.V., SUBLIMAZE® (fentanyl) reaches its peak analgesic effect.



Within 30 to 60 minutes I.V., the analgesic effect of SUBLIMAZE® (fentanyl) is almost completely dissipated.†

† Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with larger doses, multiple doses or use of postoperative narcotic analgesics.



For potent narcotic analgesic action with rapid onset and short duration:

SUBLIMAZE fentanyl provides profound analgesia without hypnosis and with little or no sedation. With this analgesia as a foundation, it is possible to use light general anesthesia in most cases.

SUBLIMAZE fentanyl is particularly suited for maintenance of analgesia after INNOVAR® injection* has been used for induction. It may also be used preoperatively, during surgery with any common general or regional anesthetic agent, and in the immediate postoperative period whenever the need for potent analgesic action arises.

SUBLIMAZE fentanyl is available both alone and as a component of INNOVAR injection.*

*INNOVAR injection is composed of a 50:1 mixture of droperidol 2.5 mg./cc. and fentanyl 0.05 mg./cc., with lactic acid for adjustment of pH to 3.5 ± 0.3.

SUBLIMAZE® (fentanyl) offers:

☐ Almost immediate analgesia—peak effect within 5 minutes I.V., 8 minutes I.M.

☐ Short duration of analgesic action—30 to 60 minutes with a single I.V. dose of up to 0.1 mg. (Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with larger doses, multiple doses or use of postoperative narcotic analgesics.)

☐ No evidence of liver, heart, or kidney toxicity—expecially valuable in poor-risk patients. However, the drug should be administered cautiously in the presence of liver or kidney dysfunction or cardiac arrhythmias, and the dose should be appropriately reduced in poor-risk patients.

☐ Immediate reversibility by narcotic antagonists.

☐ Little or no histamine release—decreasing the risk of cardiovascular instability.

☐ Minimal emetic effect—has been used successfully to prepare nonfasting patients for awake intubation.

☐ Prevention or reversal of emergence delirium and tachypnea.

SUBLIMAZE® (fentanyl) injection

0.05 mg./cc. as the citrate.
Warning: May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0—7.5

INNOVAR® injection and SUBLIMAZE® (fentanyl) injection are available for use only upon direction of a physician.
For information relating to Contraindications, Warnings, Precautions and Adverse Reactions for SUBLIMAZE fentanyl, please turn page.

© McNeil Laboratories, Inc., 1974

SUBLIMAZE® (fentanyl) injection

Description
Each cc. contains:
Fentanyl as the citrate ..... 0.05 mg.
Warning—May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0–7.5
FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY.

Actions SUBLIMAZE fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. SUBLIMAZE fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. SUBLIMAZE fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays and skin wheal testing in man, as well as *in vivo* testing in dogs, indicate that histamine release rarely occurs with SUBLIMAZE fentanyl.

SUBLIMAZE fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of SUBLIMAZE fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours.

Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics it may be considerably longer than the analgesic effect.

Indications SUBLIMAZE fentanyl is indicated:
—for analgesic action of short duration during the anesthetic periods, premedication, induction, and maintenance, and in the immediate postoperative period (recovery room) as the need arises.
—for use as a narcotic analgesic supplement in general or regional anesthesia.
—for administration with a neuroleptic such as INAPSINE® (droperidol) injection as an anesthetic premedication, for the induction of anesthesia and as an adjunct in the maintenance of general and regional anesthesia.

Contraindications SUBLIMAZE fentanyl is contraindicated in patients who are hypersensitive to the drug.

Warnings PATIENTS WHO HAVE RECEIVED *SUBLIMAZE* FENTANYL SHOULD HAVE APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

If SUBLIMAZE fentanyl is administered with a tranquilizer such as INAPSINE droperidol, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action. In addition, when such a combination is used *fluids and other countermeasures to manage hypotension should be available.*

As with other potent narcotics, the respiratory depressant effect of SUBLIMAZE fentanyl persists longer than the measured analgesic effect. The total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, should be used in reduced doses initially, as low as 1/4 to 1/3 those usually recommended. A neuromuscular blocking agent compatible with the patient's condition may be required to control muscle rigidity which may develop with the use of SUBLIMAZE fentanyl.

Drug Dependence: SUBLIMAZE fentanyl can produce drug dependence of the morphine type and therefore has the potential for being abused.

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl in this regard has not been established, the use of SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: SUBLIMAZE fentanyl should be used with caution in patients who may be particularly susceptible to respiratory depression, such as comatose patients who may have a head injury or brain tumor. In addition, SUBLIMAZE fentanyl may obscure the clinical course of patients with head injury.

Usage in Children: The safety of SUBLIMAZE fentanyl in children younger than two years of age has not been established.

Usage in Pregnancy: The safe use of SUBLIMAZE fentanyl has not been established with respect to possible adverse effects upon fetal development. Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects; therefore, safety for the infant in obstetrics has not been established.

Precautions *The initial dose of SUBLIMAZE fentanyl should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and some peridural anesthetics, can alter respiration by blocking intercostal nerves. Through other mechanisms (see Actions) SUBLIMAZE fentanyl can also alter respiration. When SUBLIMAZE fentanyl is used to supplement these forms of anesthesia, the anesthetist should be familiar with the physiological alterations involved, and be prepared to manage them in the patients selected for these forms of anesthesia. When used with a tranquilizer such as INAPSINE droperidol, blood pressure may be altered and hypotension can occur.

Vital signs should be monitored routinely.

SUBLIMAZE fentanyl should be used with caution in patients with chronic obstructive pulmonary disease, patients with decreased respiratory reserve, and others with potentially compromised respiration. In such patients, narcotics may additionally decrease respiratory drive and increase airway resistance. During anesthesia, this can be managed by assisted or controlled respiration. Postoperatively, respiratory depression caused by narcotic analgesics can be reversed by narcotic antagonists (levallorphan, nalorphine, and naloxone; consult individual prescribing information before using). Should respiration be compromised by muscle rigidity, assisted or controlled respiration and possibly a neuromuscular blocking agent will be required. The occurrence of muscle rigidity is related to the speed of intravenous injection and the incidence can be reduced by slow intravenous injection.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, pulmonary arterial pressure may be decreased. This fact should be considered by those who conduct diagnostic and surgical procedures where interpretation of pulmonary arterial pressure measurements might determine final management of the patient.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, and general anesthetics) will have additive or potentiating effects with SUBLIMAZE fentanyl. When patients have received such drugs, the dose of SUBLIMAZE fentanyl required will be less than usual. Likewise, following administration of SUBLIMAZE fentanyl the dose of other CNS depressant drugs should be reduced.

SUBLIMAZE fentanyl should be administered with caution to patients with liver and kidney dysfunction because of the importance of these organs in the metabolism and excretion of drugs.

SUBLIMAZE fentanyl may produce bradycardia, which may be treated with atropine; however, SUBLIMAZE fentanyl should be used with caution in patients with cardiac bradyarrhythmias.

When SUBLIMAZE fentanyl is used with a tranquilizer such as INAPSINE droperidol, hypotension can occur. If this occurs the possibility of hypovolemia should also be considered and managed with appropriate parenteral fluid therapy. Repositioning the patient to improve venous return to the heart should be considered when operative conditions permit. Care should be exercised in moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus other countermeasures do not correct hypotension, the administration of pressor agents other than epinephrine should be considered. Because of the alpha-adrenergic blocking action of INAPSINE droperidol, epinephrine may paradoxically decrease the blood pressure in patients treated with INAPSINE droperidol.

Adverse Reactions As with other narcotic analgesics, the most common serious adverse reactions reported to occur with SUBLIMAZE fentanyl are respiratory depression, apnea, muscular rigidity, and bradycardia; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Other adverse reactions that have been reported are hypotension, dizziness, blurred vision, nausea, emesis, laryngospasm, and diaphoresis.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, the following adverse reactions can occur: chills and/or shivering, restlessness, and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression); extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have been observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with antiparkinson agents. Postoperative drowsiness is also frequently reported following the use of INAPSINE droperidol.

Overdosage ***Manifestations:*** The manifestations of SUBLIMAZE fentanyl overdosage are an extension of its pharmacologic actions.
Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered and managed with appropriate parenteral fluid therapy. A specific narcotic antagonist such as nalorphine, levallorphan, or naloxone should be available for use as indicated to manage respiratory depression. This does not preclude the use of more immediate countermeasures. Consult the package insert for the individual narcotic antagonists for details about use.

How Supplied SUBLIMAZE® (fentanyl) injection is supplied in 2 cc. (**NDC** 0045-0180-03) and 5 cc. (**NDC** 0045-0180-05) ampuls, in packages of 12.

IMPORTANT: Complete dosage information is available in insert which accompanies each package (or on request). The drug is available only upon direction of a physician.

An opportunity for anesthesiologists and obstetricians/gynecologists to learn or review principles and practices of anesthesia and analgesia for obstetrics and gynecology is being offered in the Department of Anesthesiology at the Valley Medical Center in Fresno, California, under the direction of **John S. McDonald, M.D.**, Chairman of the Department. Four and eight week rotations would include general and regional anesthesia and didactic training in the pharmacology of drugs.

Applicants should be trained in the United States and must possess State or National Board Licensure. In some instances, foreign graduates who have passed the FLEX examination or the equivalent thereof will be considered. More infor-fation may be obtained by writing to **John S. McDonald, M.D.**, P.O. Box 7632, Fresno, California 93727, (209) 251-4833, ext. 2228.

In 16 years of use in the United States, FLUOTHANE (halothane) has been administered over 100 million times in a wide variety of surgical procedures. 100 million . . . extensive usage and evaluation that attests to FLUOTHANE as the most widely used inhalant anesthetic.

Since it was first introduced, over 4,000 papers worldwide have been published, ranging from review articles to in-depth studies. 4,000 papers . . . a bibliographic record of note on the most widely used inhalant anesthetic.

In a continuing program of informational services on anesthesiology, Ayerst provides printed and audiovisual aids reflecting the opinions and experiences of recognized authorities in the field. These include the highly regarded series on *Anesthesia Rounds* and *Clinical Aspects of Anesthesiology*, as well as several films of educational value—all available through your Ayerst Representative.

FLUOTHANE® (HALOTHANE) ...OVER 100 MILLION ADMINISTRATIONS

- nonflammable, nonexplosive
- permits use of high concentrations of oxygen
- allows free use of cautery for more adequate control of bleeding
- minimal odor facilitates smooth, rapid induction, reduces patient distress
- early obtundation of pharyngeal and laryngeal reflexes facilitates intubation
- lessens airway problems
- permits rapid adjustment of depth of anesthesia
- emergence is rapid and tranquil with quick recovery of protective reflexes
- minimal nausea and vomiting, shorter recovery room stay

Ayerst®

See last page of advertisement for prescribing information.

FLUOTHANE®

brand of halothane

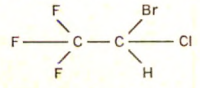
the most widely used inhalant anesthetic

from Ayerst

for precision, experience, quality, and service

(Complete text of package circular.)

Description. FLUOTHANE, brand of halothane, is an inhalation anesthetic. It is 2-bromo-2-chloro-1, 1, 1-trifluoroethane and has the following structural formula:



The specific gravity is 1.872-1.877 at 20° C., and the boiling point (range) is 49° C.-51° C. at 760 mm. Hg. The vapor pressure is 243 mm. Hg at 20° C. The blood/gas coefficient is 2.5 at 37° C., and the olive oil/water coefficient is 220 at 37° C. Vapor concentrations within anesthetic range are nonirritating and have a pleasant odor. FLUOTHANE is nonflammable, and its vapors mixed with oxygen in proportions from 0.5 to 50 per cent (v/v) are not explosive.

FLUOTHANE does not decompose in contact with warm soda lime. When moisture is present, the vapor attacks aluminum, brass, and lead, but not copper. FLUOTHANE is soluble in rubber, some plastics, and similar materials; such materials will deteriorate rapidly in contact with FLUOTHANE vapor or liquid. Stability of FLUOTHANE is maintained by the addition of 0.01 per cent thymol (w/w), and storage is in amber colored bottles.

FLUOTHANE should not be kept indefinitely in vaporizing bottles not specifically designed for its use. It is recommended that vaporizers be emptied at the end of each operating day. Thymol does not volatilize along with FLUOTHANE, and therefore accumulates in the vaporizer, and may, in time, impart a yellow color to the remaining liquid or to wicks in vaporizers. The development of such discoloration may be used as an indicator that the vaporizer should be drained and cleaned, and the discolored FLUOTHANE (halothane) discarded. Accumulation of thymol may be removed by washing with diethyl ether. After cleaning a wick or vaporizer, make certain all the diethyl ether has been removed before reusing the equipment to avoid introducing ether into the system.

Actions. FLUOTHANE is an inhalation anesthetic. Induction and recovery are rapid and depth of anesthesia can be rapidly altered. FLUOTHANE progressively depresses respiration. There may be tachypnea with reduced tidal volume and alveolar ventilation. FLUOTHANE is not an irritant to the respiratory tract, and no increase in salivary or bronchial secretions ordinarily occurs. Pharyngeal and laryngeal reflexes are rapidly obtunded. It causes bronchodilation. Hypoxia, acidosis, or apnea may develop during deep anesthesia.

FLUOTHANE reduces the blood pressure, and frequently decreases the pulse rate. The greater the concentration of the drug, the more evident these changes become. Atropine may reverse the bradycardia. FLUOTHANE does not cause the release of catecholamines from adrenergic stores. FLUOTHANE also causes dilation of the vessels of the skin and skeletal muscles.

Cardiac arrhythmias may occur during FLUOTHANE anesthesia. These include nodal rhythm, AV dissociation, ventricular extrasystoles and asystole. FLUOTHANE sensitizes the myocardial conduction system to the action of epinephrine and norepinephrine, and the combination may cause serious cardiac arrhythmias. FLUOTHANE increases cerebral spinal fluid pressure. FLUOTHANE produces moderate muscular relaxation. Muscle relaxants are used as adjuncts in order to maintain lighter levels of anesthesia. FLUOTHANE augments the action of nondepolarizing relaxants and ganglionic blocking agents. FLUOTHANE is a potent uterine relaxant.

Indications. FLUOTHANE (halothane) is indicated for the induction and maintenance of general anesthesia.

Contraindications. FLUOTHANE should be avoided when a previous exposure was followed by fever and jaundice, or when there was an unexplained postoperative fever.

FLUOTHANE is not recommended for obstetrical anesthesia except when uterine relaxation is required.

Warnings. FLUOTHANE should be used in vaporizers that permit a reasonable approximation of output, and preferably of the calibrated type. The vaporizer should be placed out of circuit in closed circuit rebreathing systems; otherwise overdosage is difficult to avoid. The patient should be closely observed for signs of overdosage, *i.e.*, depression of blood pressure, pulse rate, and ventilation, particularly during assisted or controlled ventilation.

Usage in Pregnancy: Safe use of FLUOTHANE has not been established with respect to possible adverse effects upon fetal development. Therefore, FLUOTHANE should not be used in women where pregnancy is possible and particularly during early pregnancy, unless, in the judgment of the physician, the potential benefits outweigh the unknown hazards to the fetus.

Precautions. The uterine relaxation obtained with FLUOTHANE, unless carefully controlled, may fail to respond to ergot derivatives and oxytocic posterior pituitary extract.

FLUOTHANE increases cerebrospinal fluid pressure. Therefore, in patients with markedly raised intracranial pressure, if FLUOTHANE is indicated, administration should be preceded by measures ordinarily used to reduce cerebrospinal fluid pressure. Ventilation should be carefully assessed, and it may be necessary to assist or control ventilation to insure adequate oxygenation and carbon dioxide removal.

Epinephrine or norepinephrine should be employed cautiously, if at all, during FLUOTHANE (halothane) anesthesia since their simultaneous use may induce ventricular tachycardia or fibrillation.

Nondepolarizing relaxants and ganglionic blocking agents should be administered cautiously, since their actions are augmented by FLUOTHANE.

Adverse Reactions. The following adverse reactions have been reported: hepatic necrosis, cardiac arrest, hypotension, respiratory arrest, cardiac arrhythmias, hyperpyrexia, shivering, nausea, and emesis.

Dosage and Administration. FLUOTHANE may be administered by the nonrebreathing technic, partial rebreathing, or closed technic. The induction dose varies from patient to patient. The maintenance dose varies from 0.5 per cent to 1.5 per cent.

FLUOTHANE may be administered with either oxygen or a mixture of oxygen and nitrous oxide (usually in a 50:50 ratio).

How Supplied. No. 3125—Unit packages of 125 cc. and 250 cc. of halothane stabilized with 0.01% thymol (w/w).

THE MOST POPULAR MONITORS MADE. MADE EVEN BETTER.

For some time now, our monitors have been selected for use in surgery by more medical people than any other battery-powered monitors in the world. Because we give you more of what you want in a monitor than any other monitors in the world.

However, this didn't stop us from improving them.

Our new Datascope 851 and 861 will now give you heart rate not only from ECG, but also from pulse or blood pressure.

And both monitors will give you 2 traces. So you can monitor ECG (or EEG) and pulse simultaneously.

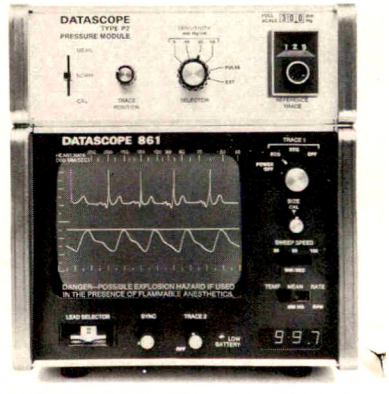
And both give you beat by beat synchronization†. So a single ECG complex shows up with each full sweep.

The 861 does even more. It monitors body temperature. On a digital read-out. And this same digital display will give you heart rate when you want it; or mean blood pressure when you are using the 861 with our Pressure Module.

For all the things our 851 and 861 do, they're surprisingly portable. And they offer longer battery-operating time than any other monitors. In some cases, actually twice as long.

Will they continue to be the most popular monitors made? More so.

For further information about our new 851, 861, or our Pressure Module, write Datascope Corp., 580 Winters Ave., Paramus, NJ 07652.

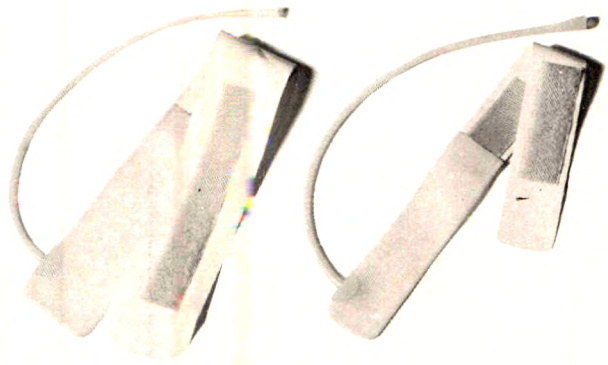


The 861 with Pressure Module.

THE DATASCOPE 851/861

†U.S. PATENT NO. 3457452

The tender touch



These soft, pliable blood pressure cuffs are ideal for use on newborns and infants. Incorporating a Latex bladder, minimizing any chances for skin irritation, and Silicon wrap-around with 12-inch inflating tube. They are secured by the Velcro hook and pile method, with no eyes to hook nor ends to tuck in. They are instantly peeled apart for easy removal.

Cuffs are available in two sizes:
22080 - 1⅜ x 5" (new born)
22081 - 2¼ x 6" (infant)

I.A.R.S. EDUCATIONAL MEMBERSHIP FOR ALL STUDENTS IN ANESTHESIA TRAINING PROGRAMS

Two-year, one-half price membership, including subscription to ANESTHESIA and ANALGESIA . . . Current Researches.

Application forms available from Cleveland business office. Certification by Program Director required.

Nesacaine®
(Chloroprocaine Hydrochloride)

1% and 2% solution in 30-ml. multiple-dose vials

For Infiltration and Regional Anesthesia

Nesacaine®-CE
(Chloroprocaine Hydrochloride)

2% and 3% solution in 30-ml. single-dose vials

For Caudal and Epidural Anesthesia

INDICATIONS

NESACAINE in multiple dose vials and NESACAINE-CE in single dose vials without preservatives are indicated for production of local anesthesia by infiltration injection and nerve block.*

*NESACAINE in multiple dose vials with preservatives is not to be used for caudal or epidural anesthesia. NESACAINE-CE contains no preservatives and the unused portion must be discarded after initial use.

CONTRAINDICATIONS

NESACAINE and NESACAINE-CE are contraindicated in patients hypersensitive to drugs of the PABA ester group. Central nervous system disease is generally considered a contraindication to caudal or epidural nerve block.

WARNINGS

RESUSCITATIVE EQUIPMENT AND DRUGS SHOULD BE IMMEDIATELY AVAILABLE WHEN ANY LOCAL ANESTHETIC IS USED. As NESACAINE-CE contains no preservative, discard unused drug remaining in vial after initial use. Equipment and drugs necessary for the treatment of inadvertent intravascular injection, intrathecal injection, or excessive dosage should be immediately available.

Usage in Pregnancy: Safe use of chloroprocaine hydrochloride has not been established with respect to adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential unless in the judgment of the physician the potential benefits outweigh the unknown hazards. In obstetrics, if vasoconstrictor drugs are used either to correct hypotension or are added to the local anesthetic solution, the obstetrician should be warned that some oxytocic drugs may cause severe persistent hypertension and even rupture of a cerebral blood vessel may occur during the post partum period.

Solutions containing vasoconstrictors, particularly epinephrine and norepinephrine, should be used with extreme caution in patients receiving certain antidepressants such as MAO inhibitors, and tricyclic compounds since a severe prolonged hypertension may occur.

PRECAUTIONS

The lowest dosage that results in effective anesthesia should be used to avoid high plasma levels and serious undesirable systemic side effects. Tolerance varies with the status of the patient. Debilitated patients, elderly patients, acutely ill patients, and children should be given reduced doses commensurate with their age and physical status.

Solutions containing vasoconstrictors should be used cautiously in the presence of disease which may adversely affect the patient's cardiovascular system.

Chloroprocaine hydrochloride should be employed cautiously in persons with known drug allergies or sensitivities.

The decision whether or not to use local anesthesia in the following conditions depends on the physician's appraisal of the advantages as opposed to the risk:

Paracervical block when fetal distress is anticipated or when predisposing factors causative of fetal distress are present (i.e., toxemia, prematurity, diabetes, etc.). Injection of solutions containing epinephrine in areas where the blood supply is limited (i.e., ears, nose, digits, etc.) or when peripheral vascular disease is present.

ADVERSE REACTIONS

Adverse reactions result from high plasma levels due to rapid absorption, inadvertent intravascular injection or excessive dosage. Hypersensitivity, idiosyncrasy, or diminished tolerance are other causes of reactions. Reactions due to overdosage (high plasma levels) are systemic and involve the central nervous system and the cardiovascular system.

Reactions involving the central nervous system are characterized by excitation and/or depression. Nervousness, dizziness, blurred vision or tremors may occur followed by drowsiness, convulsions, unconsciousness and possibly respiratory arrest. Since excitement may be transient or absent, the first manifestations may be drowsiness merging into unconsciousness and respiratory arrest.

Reactions involving the cardiovascular system include depression of the myocardium, hypotension, bradycardia and even cardiac arrest.

Treatment of a patient with toxic manifestations consists of maintaining an airway, and supporting ventilation using oxygen and assisted or controlled respiration as required. Supportive treatment of the cardiovascular system consists of using vasopressors, preferably those that stimulate the myocardium (e.g., ephedrine) and intravenous administration in small increments of an ultrashort acting barbiturate (i.e., thiopental, thiamylal) or a short acting barbiturate if these are not available (secobarbital, pentobarbital) or a short acting muscle relaxant (succinylcholine), together with oxygen. Muscle relaxants and intravenous barbiturates should be used only by those familiar with their use.

Allergic reactions are characterized by cutaneous lesions, urticaria, edema and other manifestations of allergy. The detection of sensitivity by skin testing is of doubtful value.

DOSAGE AND ADMINISTRATION

The maximum single recommended doses of chloroprocaine hydrochloride are: without epinephrine, 800 mg.; with epinephrine (1:200,000), 1000 mg. The recommended dosage is based on requirements for the average adult and should be reduced for elderly or debilitated patients and children.

The recommended doses given below serve only as a guide to the amount of anesthetic required for most routine procedures.

1. INFILTRATION AND NERVE BLOCK (NESACAINE)

Type of Block	Volume	Concentration
Occipital	3-5 ml.	1%-2%
Mandibular	2-3 ml.	2%
Maxillary	2-3 ml.	2%
Infra-orbital	0.5-1 ml.	2%
Cervical	3-4 ml. (for each segment)	1%-2%
Brachial plexus	30-40 ml.	2%
Ulnar nerve	3-5 ml.	2%
Paravertebral	3-5 ml.	2%
Intercostal	3 ml.	1%-2%
Sciatic nerve	10-15 ml.	2%
Stellate ganglion	5-10 ml.	1%-2%
Lumbar sympathetic (1 needle technic)	15-20 ml.	1%-2%
Interdigital	3-4 ml. (without epinephrine)	1%-2%

Fractional doses, up to 300 to 600 mg., may be given at 50 minute intervals.

2. CAUDAL AND EPIDURAL BLOCK (NESACAINE-CE)

For *caudal anesthesia* the initial dose is 15 to 25 ml. of a 2% or 3% solution. Repeated doses may be given at 40 to 60 minute intervals.

For *epidural anesthesia* in the lumbar and sacral regions 2.0 to 2.5 ml. per segment of a 2% or 3% solution can be used. The usual total volume of Nesacaine-CE is from 15 to 25 ml. Repeated doses 2 to 6 ml. less than the original dose may be given at 40 to 50 minute intervals.

HOW SUPPLIED

Nesacaine is supplied as follows:

1% solution (10 mg/ml.) in 30 ml. multiple-dose vials, 12 vials per carton.

2% solution (20 mg/ml.) in 30 ml. multiple-dose vials, 12 vials per carton.

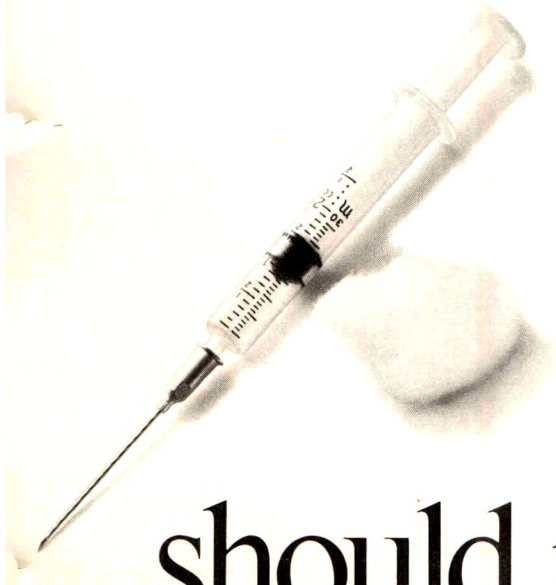
Nesacaine-CE is supplied as follows:

2% solution (20 mg/ml.) in 30 ml. single-dose vials, 12 vials per carton.

3% solution (30 mg/ml.) in 30 ml. single-dose vials, 12 vials per carton.

PENNWALT

Pennwalt Prescription Products
Pharmaceutical Division
Pennwalt Corporation
Rochester, New York 14603



A local anesthetic should meet your needs...

Rapid Onset of Action. Saves doctor, nurse and patient time.

Effective Anesthesia. Nesacaine (Chloroprocaine Hydrochloride) offers 80% to 90% pain-free procedures at recommended doses.

Exceptional Safety. Less potential for postoperative complications. Nesacaine is rapidly hydrolized in plasma, whereas lidocaine and other amide-type local anesthetics are metabolized in the liver. With Nesacaine, therefore, there is minimal potential risk of systemic toxicity, accumulation of metabolites, stimulation of CNS or cardiovascular effects.

Excellent Penetration. Chloroprocaine's lipid solubility and ionization characteristics impart it with excellent penetration.

Minimal Irritation at Injection Site. Few patient complaints about procedural pain, little soreness and inflammation after procedure.

Rapid and Complete Wear-Off. No residual numbness, patient back to normal faster.

See opposite page for brief prescribing information.

Look into

Nesacaine®

(Chloroprocaine Hydrochloride)

It meets your needs.

51ST CONGRESS

MARCH 6-10, 1977

International Anesthesia Research Society

DIPLOMAT RESORT AND COUNTRY CLUBS
HOLLYWOOD, FLORIDA

IMPORTANT INFORMATION ON THE 51st CONGRESS

Scientific Program—August 2, 1976, deadline for submission of titles and abstracts for consideration by program committee. Application forms are available from John T. Martin, M.D., Chairman, Program Committee, Medical College of Ohio at Toledo, Box 6190, Toledo, Ohio 43614.

Scientific Exhibits—Application forms are available from B. B. Sankey, M.D., Executive Secretary, I.A.R.S., 3645 Warrensville Center Rd., Cleveland, Ohio 44122. There is no deadline for applications; however, applications received after November 1, 1976, are subject to exhibit space availability.

Technical (Commercial) Exhibits—Applications available from Charles B. Slack, Inc., Exhibit Manager, 6900 Grove Rd., Thorofare, New Jersey 08086.

C.M.E. Credit—This Continuing Medical Education offering meets the criteria for Category 1 credit (22 hours est.) for the Physician's Recognition Award of the American Medical Association.

On The History of Ideas in Anaesthesia

Tenth Annual Becton, Dickinson and Company Oscar Schwidetzky Memorial Lecture

LEROY D. VANDAM, MD*

Boston, Massachusetts

THIS convocation commemorates the 50 years over which the International Anesthesia Research Society has met annually to perpetuate its unique educational role in Anesthesia. Abiding by custom, a golden jubilee usually connotes a season of general joy and exultation for the good fortune we have had. But inevitably, as the span comprises more than half a lifetime, we are not only compelled to look back but tempted also to peer timorously into the future.

In tracing the history of the National Science Foundation, Detlev Bronk once observed: "The history of an institution is the tale of what people did; its future depends in part on the foundation they created." Thus, in the course of my remarks, some recounting of the people concerned in the development of the Society is justified, as is an affectionate nod in the direction of Oscar Schwidetzky for whom this memorial lectureship is named.

Mr. Schwidetzky's illustrious life in this country coincided with the founding by Francis Hoeffer McMechan and others, of the several regional groups that led ultimately to the formation of the International Society and the subsequent flowering of the specialty of Anesthesia. Earlier in 1900, Mr. Schwidetzky's arrival here from Germany, where he had been an apprentice instrument maker, also signaled the emergence of Anesthesia from the vacuous years following the initial use of nitrous oxide and ether. Probably only a few elders in this audience will recall Mr. Schwidetzky's gracious omnipresence at our anesthesia gatherings, where, as a stalwart of the Becton, Dickinson organization, he stood ready to transform our technical concepts into reality.

Thus, for example, he produced the malleable needle employed in continuous caudal and spinal anesthesia. Subsequently he came up with the prototype of the pediatric scalp vein needle in the form of a fine cannula that could be placed into an umbilical vein. His relations with the International Society were not merely coincidental, for the bond between physician and manufacturer was salubriously close in the early days, resulting in the formation of the National Anesthesia Research Society with both physician anesthetists and manufacturers as members. So did Mr. Schwidetzky function, and in 1956 he was honored for his cooperation by honorary membership in the International Society. At the time of award of an honorary Doctor of Laws degree in 1953 by Fairleigh Dickinson University, the citation read in part: "Probably at every place throughout this country where there are sick and wounded, and suffering persons —some product of his medical skill is relieving pain. . . ."

For this occasion, after considerable reflection, I set myself the goal of ascertaining those ideas that Anesthesia might have given to Medicine. What concepts or ideas have emanated from us? What are our utopian aims? Can we be styled as visionary or are we merely carried along by the tide? For the remainder of this address, I shall retrace the steps by which I arrived at the conclusions that came to mind.

At the outset, I found that I was not exceptionally innovative in my intention. More than a few milestone addresses have been

*Professor of Anaesthesia, Harvard Medical School; Anesthesiologist-in-Chief, Peter Bent Brigham Hospital, Boston, Massachusetts 02115.

Read at the 50th Congress of the International Anesthesia Research Society, March 14-18, 1976, Phoenix, Arizona.

published wherein the speaker elaborates on the contributions to Medicine of his specialty. This proves to be a comparatively easy exercise for Internal Medicine, as revealed by George Thorn's remarks in 1961, wherein he refers among other notable events to Joseph Lind's 1753 *Treatise on Scurvy*, a keystone in the formulation of modern concepts of nutritional and vitamin deficiency: to William Withering's account in 1785 of the medical uses of the foxglove, a classic in pharmacology; to Edward Jenner's *Inquiry into the Causes and Effects of the Variolae Vaccinae*, a fundamental contribution to immunology: successively then to Richard Bright, Thomas Addison, Robert Koch and Paul Ehrlich, and latterly to Sir Archibald Garrod's 1908 monograph on *Inborn Errors of Metabolism*, with notes on alkaptonuria, cystinuria, albinism, and pentosuria. Garrod advanced the concept that certain diseases of lifelong duration arise because an enzyme governing a single metabolic step is reduced in activity or missing altogether.

It is almost as convenient for Pediatrics to lay claim to certain benefits conferred upon mankind, as observed by essayist Harry H. Gordon. We are reminded of von Pirquet's skin test with tuberculin as a path to diagnosis, case finding, and now prophylactic therapy in tuberculosis; of the Schick test as a guide to routines of diphtheria immunization; to the discovery by Dutch pediatricians of gluten sensitivity as a cause for the celiac syndrome in childhood, with extension of their findings by English and other observers to the diagnosis and study of malabsorption syndromes at all ages; and in a more general sphere to the work of Howland, Holt, Marriott, Gamble, et al on the regulation of the intracellular and extracellular metabolism of water and electrolytes. None of the other specialties can lay claim to such extraordinary accomplishments in the specific treatment and prevention of disease, which comprise the essence of ecologic and physiologic medicine.

Perhaps I have already wandered too far from my main theme by referring to the cure and prevention of disease—Medicine's main thrust—for Anesthesia, by the very nature of its mandate, can lay no convincing claims in that direction. But I cannot refrain from going down this pathway for awhile. I have always believed that our highly specialized role in medical care was the chief reason for our nether ranking in the medical hierarchy, an impression confirmed by reading Iago Galdston's oration on the Birth and Death of Medical Specialties. His message has meaning for us all if we will only dwell upon it.

Galdston takes issue with the prevalent concept of modern medicine as a continuous and accelerated detachment of various specialties from the main trunk of medical practice. Rather, he points out that specialism had its origins in antiquity, for it was never more specialized than in Egypt. "Each physician applies himself to one disease only and not more," according to Herodotus. "Some physicians are for the eyes, others for the head, others for the teeth, others for the intestines and others for internal disease."

Are those observations not reminiscent of the current trend toward collateralization away from the main vessel of Anesthesia? Galdston reasons that specialization is not concomitant with nor is it in itself a gauge of the advancement of medicine. "Specialties rise and fall in importance, some disappearing from the scene entirely. Indeed, the long view of the history of science reveals a pattern of periodic diversifications in interest and knowledge, that is—of specialization, followed by periods wherein the synthetic unification of knowledge is achieved. Science is never more innately consonant and rewarding than during its unitary stage." I would like to fancy that some of the ideas generated by Anesthesia fall within the unification process, an argument I shall proceed to.

Anesthesia as a specialty differs from all others in that its origins lie not in the conquest of disease—its causation, prevention, or treatment. Rather it rose upon the scene quite late, beginning (in the 18th century) with the work of biochemists, their recognition of oxygen and carbon dioxide as elements in the life process, and the use by several physicians of gases and vapors in the treatment of disease. Certain keen observers, as typified by Davy and Hickman, reasoned that some of these vapors might be useful in relieving the pain of surgical operations. These were the very first ideas! Elsewhere, your speaker has observed that certain social events and changes in attitude toward man and the relief of pain led to the eventual introduction, in the 1840s, of ether, nitrous oxide, and chloroform. Owsei Temkin notes:

"Sociologists of science have cited in evidence for social causation the multiple appearance of the same discovery—'multiples' in the language of Robert Merton. The independent use of anesthesia by Long, Wells, and Morton is a well known medical example. Though discoveries are not necessarily ideas, both are spoken of as being 'in the air' or ripe for their time."

Now, as we have come a little closer to matters of ideas and discovery, further definition is essential. You may be surprised to learn, as was I, that there is not only a journal devoted to the history of ideas but recently the appearance of a periodical concerned solely with medical hypotheses. In the opening essay of Volume I of the Journal of the History of Ideas, Arthur O. Lovejoy notes: "Whatever other definitions of man be true or false it is generally admitted that he is distinguished among the creatures by the habit of entertaining general ideas. Like Brer Rabbit he has always kept up a heap o' thinking. And ideas are the most migratory things in the world." Furthermore, "One of the safest (and most useful) generalizations resulting from a study of the history of ideas is that every age tends to exaggerate the scope or finality of its own discoveries, or rediscoveries,—to be so dazzled by them that it fails to discern clearly their limitation. . . ." Again it is useful for us to reflect upon this timely observation. Also note that Lovejoy cannot resist using the terms "ideas" and "discovery" interchangeably.

In another analysis, Peter Caws examines the Structure of Discovery. Logical analysis, he avers, is not appropriate to inquiry into the way in which claims to scientific knowledge originate. "Rather, questions about origins are said to belong to the context of discovery, requiring a different kind of logic. The devising of hypotheses is ascribed to genius, intuition, imagination, chance or any number of other extralogical processes. One of the tactics most often used by proponents of the mystique of genius who are always bandying about terms like creativity, insight, ripeness and so on, is the recounting of tales about moments of enlightenment in the lives of great scientists."

While we are too close to the present to discover the genius amongst us, would you not agree that it was something akin to a combination of genius and insight in an aura of ripeness that led the vanguard first to suggest the possibility of relieving the pain of surgical operations—then to demonstrate the means by which it could be done? Among the vanguard we would all cite Humphry Davy, Henry Hill Hickman, Crawford W. Long, Horace Wells, and William T. G. Morton. An analysis of their individual discoveries, as in all matters of this kind, as Caws writes, "shows that in practically every case the individual acted as the catalyst for a complex process in which many other individuals played a role. This need not be taken to mean that no credit is due the individual for having advanced his science in a particular way at a particular time but it does mean that (probably) no individual has been indispensable to the advance of science in general."

So far as perceiving ideas derived from Anesthesia is concerned, one should recall Newton's celebrated remark about "standing on the shoulders of giants." Writes Caws, "It serves to remind us that the development of science is a stepwise process; nobody starts from scratch and nobody gets very far ahead of the rest. At any point in history there is a range of possible discovery; the trailing edge of the range is defined by everything known at the time (I overlook the fact that people are constantly 'discovering' what is known—which blurs the image somewhat) and the leading edge is a function of what is already known, together with variables representing available instrumentation, the capacity of human brains, and so on."

In the context of Caws' analysis, can we say that we have hatched any epochal discoveries or ideas since the first demonstrations? It is not a simple matter to answer this question, for our discoveries, if any, resulting from the research we have done, reside in the realm of clinical rather than physiologic medicine. A. R. Feinstein has raised the question: What kind of basic science for clinical medicine? He explains that the practice of medicine entails two kinds of decisions: the explanatory decisions involving the naming, mechanisms, and causes of disease; and the managerial decisions for therapeutic interventions—to prevent or alter disease. Wouldn't you agree that our thrust has been almost entirely in the managerial sphere?

We cannot claim to have explained much in relation to the foundations of our practice—the mechanisms of narcosis and pain. Progress in these areas is being made nevertheless, as others have begun to collect the

data necessary for establishment of the appropriate hypotheses. Moreover, anesthesiologists are working on the leading edge of discovery in these areas. Managerially, we in Anesthesia cannot accept the praise, if any is due, for synthesizing the many controversial anesthetics that have been introduced to practice. As a rule we receive new compounds from the manufacturers, then discover what they are all about in broad, unsupervised clinical trials. In this respect, perhaps, we have made little progress since the 1840s.

The evolution of technics of balanced anesthesia represents a considerable step forward, inasmuch as the clinical phenomenon designated as anesthesia has been dissected into its components: analgesia, loss of consciousness, and muscle relaxation. But here, too, Claude Bernard first pointed out the benefits to be derived from giving morphine before anesthetization, while George Crile, Senior, combined the attributes of regional and general anesthesia in order to combat the development of surgical shock, according to his anoci-association theory. We were then given the short-acting intravenous barbiturates, and several varieties of neuromuscular blockers to complete the ingredients of modern balanced anesthesia. Several anesthetists deserve credit for hastening the process: J. S. Lundy and R. M. Waters for introduction of the barbiturates and Johnson and Griffith for their daring in giving tubocurarine to man. These people rode on the leading edge of discovery!

It occurs to me that balanced anesthesia, and the detailed study of the drugs used in its format, probably represent the greatest advance in the managerial aspects of anesthesia. Although the mortality resulting from anesthesia probably was enhanced at first, subsequent experience with the use of multiple agents may have led to an apparent decrease in both anesthetic morbidity and mortality. As a result, all of the new potent general anesthetics are used in balanced technics, with a short-acting barbiturate employed for induction and attainment of unconsciousness, nitrous oxide given for its concentration and second gas effects as well as a mainstay for analgesia, and neuromuscular blockers to circumvent the deeper planes of general anesthesia required for good muscle relaxation.

If anesthetic mortality has been reduced thereby, can we not proclaim that we have made a major contribution to preventive or ecologic medicine—the reduction in hazard of a major environmental threat—general anesthesia? The environmental threat to those who work in an atmosphere of anesthesia is also under scrutiny. But in the realm of ideas or discovery we ought not to be praised for making our practice safer, any more than the cardiologist should be cited for the more proficient use of digitalis, for a long time a little-recognized but leading cause of sudden death in patients treated for heart disease.

A few other pharmacologic events come to mind, not that we were the innovators, but we were the practitioners who allowed surgical patients to benefit from these concepts. I recall all that has been learned concerning the uptake, distribution and metabolism of anesthetics, beginning with measurements on ether by H. W. Haggard in the twenties, and the many subsequent studies on other anesthetics, employing quantitative technics. S. S. Kety, working in an atmosphere of anesthetic thought at Pennsylvania, figured out the mathematic equations underlying transport, while it remained for basic scientists in Anesthesia to demonstrate the actuality in man—again along the leading edge of discovery.

Parenthetically, anesthesiologists could lay claim to being among the first to take advantage on a large scale of the human volunteer in experimentation, thereby permitting the action of drugs to be assayed in the absence of disease and surgical stress, apart from considerations of species differences. Conversely, we wouldn't want to bear the onus for the ethical abuses in human experimentation that have led to much-needed regulation and to protection of human subjects, whether volunteer or patient.

A few more general ideas come to mind—all in the pharmacologic arena: the realization that inhalation anesthetics are not after all inert, rather that they are metabolized in varying degree, sometimes to toxic metabolites—either hepatotoxic or nephrotoxic—their sites of metabolism and excretion, and with adverse effects on embryonic tissues. Inadvertently, we have broadened the horizons of pharmacogenetics by the use of xenobiotics such as succinyldicholine, discovering that there are several kinds of genetically transmitted abnormal plasma cholinesterases. A related iatrogenic disease has been rediscovered—malignant hyperthermia. Remember Caws' remark that people are constantly rediscovering what is

already known? Finally, so far as clinical pharmacology may profit from our trials, we have added considerably to the knowledge of drug interactions and in general to the epidemiology of iatrogenic disease.

My remarks thus far have touched upon a few ideas and discoveries in which we have played a role, without necessarily receiving recognition, simply because we work in the managerial rather than the descriptive sphere of medicine. However, transcending all of these accomplishments is one inalienable characteristic of anesthetic practice—that is our ability, willingness, and courage in manipulating man's internal environment, the *milieu intérieur* of Claude Bernard and the homeostatic systems of Walter B. Cannon. I allude to the deliberate control of respiration, circulation, body temperature, and fluid and acid-base balance.

The lessons learned from these excursions or incursions into the physiology of man have had wide-reaching consequences for clinical medicine: the treatment of pulmonary disease, heart disease, neurologic ailments, and allied surgical interventions. With this new power, we had to devise the means to assess quantitatively what we were doing, beneficially or otherwise, to the homeostatic systems of the body. Step by step, in the remaining paragraphs of this discourse, I shall enlarge upon this thesis. As an aside, I call your attention to the recent publication of the proceedings of a conference on Anesthesiology, held in Washington under the auspices of the National Institute of General Medical Sciences, entitled: "Anesthesiology, Its Expanding Role in Medicine." The substance of this report parallels that whereof I speak.

On respiration first! It is interesting to find that in the last half of the 19th century physiologists were using positive-pressure ventilation in the management of the open thorax and they were, of course, aware of the neuromuscular-blocking properties of tubocurarine. Meltzer and Auer in the teens then demonstrated the feasibility of apneic oxygenation in the dog. That anesthetists were slow to adopt these measures is simply a reflection of a contention made before, that Anesthesia had to await the development of Surgery, not only to recruit people unto itself but to take advantage of technics already proven in the laboratory.

Arthur E. Guedel, in the thirties, probably with the encouragement of Ralph M. Waters, was the first to define the means by which respiration could be controlled in man, either by increasing the depth of ether anesthesia, through hyperventilation, or by a combination of both. Pharmacologic control of respiration, he said, led to better operating conditions within the abdomen. Control of respiration became commonplace after the introduction of cyclopropane, and mechanical ventilation of the lungs mandatory following the use of tubocurarine. The proliferation of endotracheal technics arose out of necessity.

But let us reflect on the consequences in terms of general medical utility and treatment of a host of illnesses. A variety of respiratory patterns emerged along with the mechanical equipment to do the job: pressure- or volume-controlled ventilation; intermittent positive-pressure breathing; continuous positive-pressure breathing, positive end-expiratory pressure and intermittent-demand breathing. The box was opened in the effects on ventilation-perfusion ratios, secondary effects on circulation, emergence of iatrogenic phenomena—pneumothorax, tracheal damage, and problems in weaning from controlled ventilation. A vast clinical literature appeared, largely in the managerial sphere, with observations from both basic scientists and clinical investigators in Anesthesia.

New light was cast on the effects of mechanical control of ventilation in respect to small-airway dynamics, the relation between central and peripheral chemoreceptor control of respiration, details of chest and lung compliance, and the consequences of hyper- or hypoventilation in relation to oxygen or carbon dioxide. One could go on and with a myriad of citations while cogitating on the benefits derived in the treatment of disease: pneumonia, pulmonary embolism, coma resulting from poisoning, chest trauma, respiratory-tract burns, aspiration of gastric contents, tetanus, myasthenia gravis, drowning, the postsurgical lung, and the infant and so-called adult respiratory distress syndromes.

A secondary bonus accrued in the management of intracranial disease: anesthesia for intracranial surgery; treatment of stroke, seizures, and head trauma. The pattern and volume of ventilation strongly influence intracranial pressure, the distribution of water between the several compartments, and the course of blood flow. Cerebral blood flow and its partition between normal and diseased tissues is as much influenced by respiratory-induced changes in acid-base balance as by the mean level of blood pressure.

Anesthesiologists have worked on the leading edge of investigation—in the quantitative assessment of the effects of pulmonary ventilation on distribution of cerebral blood flow—an eminent contribution to physiologic medicine. As might have been anticipated, in spite of our facility in altering the respiratory environment, we have rediscovered a basic tenet that maintenance of normal blood levels of oxygen and carbon dioxide is for the better in practically every situation.

As you know, it is hardly possible to separate the physiologic effects of alterations in respiration or circulation, but let us now observe how anesthesiologists have at times taken over control of the circulation. Beginning with the advocacy by Harvey Cushing of the need to measure blood pressure during anesthesia, anesthetists for the first half of this century, in this country at least, devoted much of their clinical effort and research to maintenance of normotension during anesthesia. Then as a byproduct of neurosurgery, W. J. Gardner and D. F. Hale found that lowering of blood pressure by deliberate blood-letting provided better conditions during intracranial operations, at least in the crisis situation.

As a John Clover lecturer in 1950, John Gillies was then impelled to take as his theme, "Anaesthetic Factors in the Causation and Prevention of Excessive Bleeding During Surgical Operation." As the concept was presented, why not control the blood pressure by one of several means, mechanical or pharmacologic, to diminish blood loss and improve operability—via the hypotension resulting from spinal anesthesia, use of ganglionic blocking agents or peripheral vasodilators—and positioning of the part to be operated upon above the level of venous pressure. So was deliberate hypotension conceived, with more than a few complications at first but ultimately with real benefit as soon as the effects on regional circulation in brain, heart, kidneys, and liver were discerned. Blood flow in normal cerebral vessels accommodates to changes in mean blood pressure in a range between 60 and 180 torr. So is it the rule for the coronary artery circulation.

A tertiary benefit emanating from a safe level of hypotension lay in the decreased work of the heart against an afterload, hence less demand for oxygen. Increase in heart rate and enhancement of myocardial contractility also increase the work of the heart. These principles now guide the anesthesiologist in the intraoperative management of patients with coronary arteriosclerosis and myocardial ischemia; a modest blood pressure, slow heart rate, and muted inotropic activity are beneficial. And the impact has not been lost on Cardiology, where dissecting aneurysm, myocardial ischemia and infarction or heart failure may be alleviated by the use of modest degrees of controlled hypotension via an appropriate combination of alpha- and beta-sympathetic agonists and antagonists.

And there is at least one more homeostatic system that we manipulate willingly, sometimes unwittingly, during the course of anesthesia, that is the body temperature. Here we dare not transgress in both directions for we fear the ravages of hyperthermia. In the late 1930s, deliberate cooling of the body was first practiced in an attempt to control the spread of inoperable malignant tumors, abandoned, then resurrected a decade later in conjunction with open-heart surgery. The idea was to lower the oxidative needs of the brain during a brief span of total circulatory occlusion. Much was learned of the physiology of deep hypothermia in the realm of metabolism of tissues, and the dangers thereof. Total body hypothermia became a little too much to handle, but the principle remains in relation to individual organs, where the heart is cooled during bypass surgery, kidney temperature lowered before transplantation, the cerebrum protected by deep hypothermia during complex cerebrovascular operations, and the traumatized brain protected by maintenance of normothermia.

It is high time to conclude this oration. If my analysis can be taken as correct, Anesthesia has conferred a great many benefits on physiologic medicine, not truly in the realm of ideas or discovery but in the managerial sphere. We could not have been held responsible for the introduction of Anesthesia because the discovery preceded our birth, nor have we as scientists explained the mechanism of narcosis or pain. As a result of our investigations, however, and the utilization in combination of new compounds given us, we may have significantly decreased the epidemiologic hazard of surgical anesthesia. In the course of so doing, moreover, our ability, daring, and inventiveness in manipulating respiration, the circulation, and body temperature, which no other physicians had had the opportunity to explore

so thoroughly, have had broad implications for medicine, in the care of the critically ill. This transpires not only in the operating room but in emergency wards, recovery rooms, and the many kinds of intensive care facilities now extant.

We may derive a measure of solace in the knowledge that even though anesthesia may one day become so safe, through the application of better agents and predictive monitoring devices, as to warrant the attention mostly of technically able personnel supervised by physicians—that we shall nevertheless still have a role to play in the intensive care of critically ill patients everywhere. This is a trend resented or denied by some of the older generation of anesthetists, but we are witnessing its rapid evolution in the aspirations of many young people training in Anesthesia today. They are attracted to the field mainly by the prospect of caring for people who are desperately ill. And the reward comes from witnessing recovery and restoration of people to a meaningful existence as contrasted with what at one time might have been the fatal outcome.

Influence of Pancuronium on Potassium Efflux Produced By Succinylcholine

HALAPPA N. KONCHIGERI, MD*
CHENG-HIN TAY, MD†
Chicago, Illinois‡

Serum potassium (K^+) levels were measured after thiopental, succinylcholine, pancuronium, and pretreatment with pancuronium prior to succinylcholine, in 100 patients divided into 4 groups of 25 patients each. Significant increases in serum K^+ were found after succinylcholine (1 mg/kg). Administration of pancuronium in small doses (20 μg/kg) prior to succinylcholine (1 mg/kg) was effective not only in complete prevention of serum K^+ elevation but also produced consistent decrease in serum K^+ concentration below control values. Both thiopental and pancuronium produced moderate fall in serum K^+ levels. Our observations indicate that pretreatment with pancuronium may play a beneficial role in patients at risk from succinylcholine hyperkalemia.

A SMALL but significant increase in plasma potassium (K^+) level (0.25 to 0.8 mEq/L) following succinylcholine administration has been observed in normal anesthetized patients. But extraordinary increase of K^+ (massive hyperkalemia) has been witnessed in patients with extensive burns,[1] massive trauma,[2] neuromuscular disorders,[3-5] and tetanus,[6] leading to serious, even fatal cardiac arrhythmias and cardiac arrest. These reports have induced great interest in searching for preventive measures against succinylcholine hyperkalemia. Some investigators[5,7-10] have studied the influence of pretreatment with d-tubocurarine and gallamine before succinylcholine administration and found beneficial effects in attenuation of K^+ efflux after succinylcholine. These studies prompted us to pursue the course further in this area and study the effect of pretreatment with pancuronium on serum K^+ changes produced by succinylcholine.

MATERIALS AND METHODS

Serum K^+ levels were measured during induction of anesthesia in 100 patients undergoing various elective surgical procedures. Patients were of both sexes, ranged in age from 17 to 87 years (average 44.7), and were of ASA physical status I or II. All were free from neuromuscular, cardiovascular, acid-base, and electrolyte disorders.

Preoperative laboratory work-up included hemogram, urinalysis, electrolyte measurements, chest x-rays, and ECG.

Premedication.—Patients received atropine (0.4 to 0.6 mg) with or without the combination of morphine (0.1 mg/kg) or meperidine (1 mg/kg) IM approximately 1 hour before anesthetic induction.

Anesthetic Management.—The 100 patients were divided into 4 groups of 25, according to technic of induction. All patients received sodium thiopental (3 to 5

mg/kg), but patients in group I received no muscle relaxants during the study period, group II was given succinylcholine (1 mg/kg) prior to endotracheal intubation, group III received pancuronium (0.1 mg/kg), and group IV received pancuronium (20 μg/kg) 3 minutes before administration of succinylcholine (1 mg/kg). The trachea was sprayed with 4% (4 ml) lidocaine by LTA Kit® before placement of the endotracheal tube in all but group I patients. Anesthesia was maintained with 70 percent N_2O and O_2, supplemented with either divided doses of thiopental sodium or fentanyl during the observation period. Respiration was either assisted or controlled to maintain the adequacy of ventilation. Monitoring included pulse rate, blood pressure, respiratory rate, temperature, and ECG.

Measurements.—Blood samples (venous) for K^+ estimation were obtained through a large-bore cannula placed in a vein from the forearm opposite the one in which induction agents were administered. Blood samples were drawn into heparinized syringes immediately before induction of anesthesia, and 1, 2, 3, 4, 5, 6, 7, 10, and 15 minutes after, the administration of succinylcholine (groups II and IV), pancuronium (group III), and sodium thiopental (group I). During the sampling period, fluid administration was limited to minimal amount (less than 50 ml) of either 5% dextrose or normal saline solution. Surgical incision was delayed until the completion of the sampling period. Blood gases were analyzed in 8 patients of each group, selected at random, to monitor the adequacy of ventilation and oxygenation.

Serum K^+ was measured by an Instrumentation Laboratories Flame Photometer Model 343. Blood gases (Pao_2 and $Paco_2$) and pH were determined by a Radiometer Digital Acid-base Analyzer.

Statistical comparisons of the serum K^+ changes were made using Student's *t*-test for paired data. A probability of 0.5 percent or less ($p<0.05$) was considered significant.

RESULTS

Thiopental administration (group I) produced a sustained fall in serum K^+ levels during the entire observation period. However, the changes reached significant level ($p<0.05$) only at 1 and 4 minutes of the postinduction period. Mean maximum change was −6.5% of the control value (table).

TABLE
Serum Potassium (mEq/L ± SD) Before and After Induction Agents

Group and agents	Preinduction (control)	Minutes after induction								Maximum change	
		1	2	3	4	5	7	10	15	Absolute	Percent
Group I Thiopental	3.53 ±0.31	3.30 ±0.36	3.34 ±0.39	3.38 ±0.32	3.31 ±0.29	3.34 ±0.29	3.34 ±0.29	3.32 ±0.33	3.39 ±0.32	−0.23	−6.5
		<0.05	>0.05	>0.05	<0.05	>0.05	>0.05	<0.05	>0.05		
Group II Thiopental + succinylcholine	3.56 ±0.30	3.52 ±0.40	3.99 ±0.90	3.81 ±0.30	3.82 ±0.49	3.80 ±0.49	3.76 ±0.45	3.66 ±0.45	3.64 ±0.47	0.43	12.0
		>0.05	<0.05	<0.05	<0.05	<0.05	>0.05	>0.05	>0.05

		<0.01	<0.01	>0.05	>0.05	<0.05	>0.05	<0.05	<0.05		
Group IV Thiopental + pancuronium + succinylcholine	3.81 ±0.49	3.49 ±0.45	3.58 ±0.42	3.66 ±0.43	3.66 ±0.46	3.68 ±0.58	3.69 ±0.42	3.69 ±0.46	3.70 ±0.43	−0.31	−8.1
		<0.05	>0.05	>0.05	>0.05	>0.05	>0.05	>0.05	>0.05		

After succinylcholine administration (group II), there was a prompt rise in serum K^+ in 2 minutes, which remained significantly ($p<0.05$) elevated between 2 and 5 minute intervals. Mean changes in K^+ values in group II were significantly higher than those in group I. Peak rise in K^+ level was 12 percent (table).

Pancuronium (group III) produced variable decrease in serum K^+ concentration, and changes were significantly lower than the control values during 1, 2, 5, 10, and 15-minute sampling periods. No significant difference between groups III and II was found. Mean maximum drop in serum K^+ was 10.7% (table).

Pretreatment with pancuronium before administraton of succinylcholine (group IV) resulted not only in complete prevention of rise in serum K^+ concentration but also in a milder degree of drop in serum K^+ levels. The results were not significantly different from control values but were highly significant ($p<0.001$) in comparison with group II (table).

Fasciculations developed in all 25 patients who received succinylcholine (group II). Fasciculations were completely prevented in 23 patients by pancuronium pretreatment (group IV). Mean changes in heart rate of −15 to +20 per minute, and systolic blood pressure of −15 to +30, were recorded during the study period. Mean values of blood-gas results were: Pao_2, 153 torr; $Paco_2$, 38 torr; pH, 7.41.

DISCUSSION

In 1956, Paton[11] demonstrated that the release of potassium from the isolated perfused gastrocnemius cat muscle after succinylcholine was about 1% of the potassium content of the muscle. He also confirmed that the muscle was the source of this potassium in his experiments. In intact animals, there was a substantial (as much as 30%) increase in serum K^+ after succinylcholine and decamethonium administration.[8,9]

Succinylcholine, acting at the motor endplate receptor site, decreases the transmembrane potential and increases the ionic permeability of Na^+ and K^+ in the process of depolarization. Rapid influx of Na^+ is followed by efflux of intracellular K^+, producing elevated serum K^+ levels with an average increase of 0.5 mEq/L in subjects with normal muscle.[12-14]

Hyperkalemia following administration of succinylcholine in patients with extensive burns, massive trauma, and neuromuscular disorders involving loss of motor function with resultant atrophy is believed to be the result of release of unusual amounts of K^+ from abnormal skeletal muscle. Gronert and colleagues[15] reported a twentyfold increase in efflux of K^+ from the denervated muscle, while the efflux from normal muscle remained unchanged after succinylcholine. These observations are indicative of a change in receptor properties of the denervated muscle. The receptor area of denervated muscle progressively enlarges, until the entire surface membrane of muscle fiber develops greater sensitivity to a chemical depolarizer. Succinylcholine depolarization of this entire supersensitive membrane will lead to massive release of intracellular K^+ into the circulation, producing abnormally high levels of serum $K.^{+13-15}$

In contrast to depolarizing muscle relaxants, nondepolarizing muscle relaxants (d-tubocurarine and gallamine) are found to produce either no change or a decrease[7,9,16] in serum K^+ levels, both in man and animal studies. Bali and associates[16] observed that decrease in serum K^+ concentration was more marked after pancuronium than after the other 2 nondepolarizing relaxants. Gallamine and d-tubocurarine, when administered in small doses before succinylcholine, have been shown to effect beneficial attenuation of serum K^+-level rise.[5,7-9,14,15] Although the exact mechanism for these effects is not well established, it is quite possible that nondepolarizing relaxant drugs provide stabilization of muscle-cell membrane, decrease the number of depolarizations at the motor end-plate, and help in intracellular influx of serum K^+.[16]

The present investigation indicates that barbiturates produce a sustained fall in serum K^+ levels. This finding is consistent with observations of other investigators.[17,18] There was an immediate rise in serum K^+ concentration after succinylcholine, which peaked at the 2-minute interval and remained higher than the preinduction value during the entire sampling period. However, elevation in serum K^+ levels were significant only between 2 and 5 minutes of the postrelaxant period. Studies[17] on the relationship between the induction agents and K^+ efflux due to succinylcholine have revealed that there was a greater elevation of serum K^+ levels with halothane than with thiopental when these agents were used for induction. At present, no explanation is

available for the changes related to induction agents.

Pancuronium kept the serum K^+ levels consistently lower than the control values; similar findings have been witnessed by other investigators.[16] An interesting observation was that pretreatment with pancuronium prior to succinylcholine (group IV) was successful, not only in complete prevention of the rise in serum K^+ levels, but also in maintaining the K^+ concentrations in serum below the control values during the study period.

Acidosis or alkalosis can significantly affect serum K^+ measurements.[19,20] In the present study, arterial blood gas and pH measurements were within normal limits and had no effect on serum K^+ determinations.

We conclude that pancuronium pretreatment before succinylcholine administration results in complete attenuation of the rise in serum K^+ concentration. Similar measures may play a beneficial role in patients at risk from succinylcholine hyperkalemia. However, further studies are needed to confirm our viewpoint.

ACKNOWLEDGMENT

We wish to express our thanks to Drs. K. Patel, S. Akkineni, and M. T. Shin for their valuable help in this study.

Physostigmine Reversal of Sedation in Parturients

DOUGLAS B. SMITH, MD*
RICHARD B. CLARK, MD†
STACY R. STEPHENS, MD
ROBERT L. SHERMAN, MD‡
MARSHALL L. HYDE, MD§

Parturients in whom meperidine HCl, propiomazine HCl, and scopolamine were used for analgesia and amnesia in labor and delivery were studied to determine the efficacy and safety of physostigmine reversal after delivery. Of a total of 120 patients, 108 received physostigmine salicylate at the completion of episiotomy closure, awakening in an average of 7.5 minutes compared with 137.8 in 12 controls. Physostigmine appears to be a safe, rapidly effective agent for reversing the prolonged somnolence of this sedation regimen.

SMALL doses of scopolamine combined with various analgesics and tranquilizers have been found useful for pain relief during labor.[1]** Small doses of the phenothiazine, propiomazine, added as a narcotic adjuvant to minimal doses of meperidine, produce a sedated, amnesic, and comfortable patient. While our patients have been generally satisfied with this regimen, their one complaint is that it is several hours before they are reactive enough to talk to their families and see their babies.

Encouraged by reports of the safety and effectiveness of physostigmine,[2-11] an anticholinesterase capable of reversing the central effects of scopolamine and a variety of other drugs that may have anticholinergic activity, we have found Antilirium®, the salicylate of physostigmine, useful in providing more rapid awakening of the sedated parturient.

MATERIALS AND METHODS

For clinical and statistical comparisons, physostigmine was given IV at the completion of episiotomy closure to a series of 108 normal parturients (mean age 24.2 years, mean weight 66 kg, 1st postpartum day) given fractional doses of meperidine HCl, propiomazine HCl, and scopolamine for analgesia and amnesia. When active labor began, the 1st dose, comprising meperidine (50 mg), propiomazine (20 mg), and scopolamine (0.6 mg), was given IV. Additional increments, usually one-half the original dose, were given IV as needed during labor. The total dosage and the last dose of each drug given were recorded (table).

Half of each group were primigravidas. Either pudendal block or local infiltration

TABLE

Drug Dosage and Awakening Time in Control and Study Patients

(Figures represent mean ± 1 SD)

Patients	Control group (N = 12)	Study group (N = 108)
Total dose meperidine, mg	100 ± 33.7	101.3 ± 38.9
Last dose meperidine, mg	29.2 ± 9.7	30.2 ± 10.4
Total dose propiomazine, mg	40 ± 13.5	40.2 ± 15.35
Last dose propiomazine, mg	11.7 ± 3.9	12.3 ± 4.2
Total dose scopolamine, mg	1.1 ± 0.4	1.0 ± 0.3
Last dose, scopolamine, mg	0.35 ± 0.1	0.4 ± 0.1
Physostigmine, mg	—	2.0 ± 0.6
Time from episiotomy closure to awakening, minutes	137.8 ± 49.6	7.5 ± 12.8

anesthesia was used for delivery. Physostigmine was given immediately after closure of the episiotomy in a dose double the amount of scopolamine used during labor, as recommended by others.[5,7,11] The time from episiotomy closure until the patient was coherent enough to give her home phone number was recorded as the awakening time, and the results were compared with those of 12 controls (mean age 22.6 years, mean weight 66.7 kg), not given physostigmine.

Arterial blood pressures and peripheral pulse rates were recorded immediately after episiotomy closure, before physostigmine administration and recorded at 2, 4, 6 minutes and 1, 2, and 24 hours after injection. In addition, such physostigmine side effects as nausea, vomiting, irregular pulse, salivation, and the complaint of being cold were noted (although temperatures were not recorded as part of the study).

RESULTS

Mean total doses of meperidine, propiomazine, and scopolamine were similar in the 2 groups (table). This dosage schedule gave satisfactory analgesia and amnesia in all patients. Mean awakening time following episiotomy closure in the physostigmine group was 7.5 ± 12.8 minutes, compared with 137.8 ± 49.6 minutes in the control group, a highly significant difference ($p<0.001$, Student's t-test).

Mean blood pressure was similar in both groups except at 60 and 120 minutes, when it was slightly lower in the physostigmine group; however, this slight drop was not believed clinically significant. While the mean pulse rate fell after episiotomy closure in each group, the drop was significantly greater in the study group at each time interval, falling from a mean of 91.8 ± 14.7 torr before physostigmine to a low of 75.6 ± 10.9 after 60 minutes. After 24 hours, blood pressures and pulse rates were similar in both groups.

In the study group, the mean 1-minute Apgar score was 8, with a range of 3 to 10, and 10.2% with a score below 7. In the control group, the mean was 8.2 with a range of 6 to 10, and 8.3% with a score below 7.

Few side effects were observed. Seven patients in the study series (6.5%) and one in the control group (8.3%) developed a transient irregular pulse. One patient in the study group developed bradycardia (56 bpm at 60 min). Seven patients in the study group complained of being cold upon awakening; one developed nausea; another cried; none experienced excessive salivation.

DISCUSSION

Scopolamine, classified as an anticholinergic agent, competes with acetylcholine at the motor endplate and in postganglionic neural synapses. Anticholinesterases such as physostigmine inhibit the hydrolysis of acetylcholine by cholinesterase, permitting prolonged action and buildup of acetylcholine at these synapses.

Bernards[2] has shown that physostigmine will arouse patients sedated with certain phenothiazines such as chlorpromazine and thioridazine, although the mechanism of action is not clear. Thus, it is possible that the physostigmine not only reversed the scopolamine but also the propiomazine in our patients.

Physostigmine is totally eliminated from the body within 2 hours.[9,12] Unlike its analogue, neostigmine, it passes the blood-brain

barrier and readily affects central nervous tissue synapses.[13] Hence, the patient, who has been completely unconscious during her labor and delivery, suddenly awakens when given this drug, looks around, and converses.

Although our total meperidine and scopolamine dosage was not as high as reported by some authors,[14,15] we have found it adequate for satisfactory analgesia and amnesia. Only occasionally have we seen untoward side effects. The mean dose of 2 mg of physostigmine was similar to that given in other studies. Our largest dose was 3.6 mg. Smiler's group[9] gave 4 mg IV, while Goldner[16] gave 10 mg IM without untoward results.

Anticholinesterases can cause bradycardia through muscarinic effects.[13] Only 1 patient experienced this effect in our series. In previous studies of physostigmine reversal of anticholinergic agents, only 1 other case of bradycardia has been reported.[11] Atropine, which in a dose of one-half that of the administered physostigmine will reverse any side effect of physostigmine,[10] was available if significant decrease in maternal pulse occurred but was never needed.

Greene[7] reported transient ectopic heartbeats secondary to physostigmine administration in 1/31 patients. The irregular pulse in 7 of our patients was also transient and was not dose related. These phenomena possibly reflect the fact that anticholinesterase drugs can increase the conduction time in the heart. They can also cause a prolonged P-R interval, inversion of P waves, increased amplitude of the QRS complex, and increased height of T waves.[13] We did not consider the cardiovascular changes in our study to be clinically significant.

That 7 patients in the study series complained of being cold upon awakening was of interest. Forrer and Miller[4] noted a drop in temperature in some of their patients given physostigmine. It is known that scopolamine will cause a rise in body temperature, especially after high doses.[13] Goldner[16] demonstrated an apparent reversal of high-dose scopolamine hyperthermia with physostigmine. Although excessive salivation was reported in one-half of Holzgrafe's series,[11] none of our patients experienced this problem.

ACKNOWLEDGMENT

The authors express their appreciation to the Division of Biometry, University of Arkansas for Medical Sciences, for statistical evaluations, Mrs. Renee Robbins, BS, for her help in organizing the data, and to Mrs. Carol Bridges, RN, and her nursing staff for their help in collecting the data.

Respiratory Distress With Left Aortic Arch, Right Descending Aorta, And Right Ligamentum Arteriosum: A Case Report

S. S. MOORTHY, MB, BS, MD*
EDMUND A. FRANKEN, MD†
ALVIN M. LoSASSO, MD‡
HAROLD KING, MD§
Indianapolis, Indiana‖

A 7-year-old girl manifested the rare anomaly of a ventricular septal defect (VSD) with left aortic arch, right descending aorta, and right ligamentum arteriosum. After open-heart surgery to correct the VSD, symptoms of tracheal obstruction on spontaneous breathing developed, due to tracheal compression by the right ligamentum arteriosum. The compressed segment of the trachea was found to be thin and unstable following division of the ligamentum. Positive-pressure breathing and continuous positive airway pressure breathing effectively splinted the patient's airway during the postoperative period, with recovery of the patient.

VASCULAR rings associated with anomalies of the great vessels in the superior mediastinum are common and may assume many forms.[1-3] In view of their close proximity to the trachea and esophagus, vascular rings can produce symptoms by compression of these vital passages. The presence of a left-sided aortic arch with a right-sided descending aorta and a right ligamentum arteriosum is uncommon. Murthy's group[4] reported a case and reviewed 13 previously recorded cases.

The present report describes a case of a 7-year-old girl who had a ventricular septal defect (VSD), left aortic arch, right descending aorta, and right ligamentum arteriosum. The ligamentum produced respiratory distress by compression of the trachea and tracheomalacia.

CASE REPORT

The patient, admitted for repair of a large VSD, had undergone pulmonary artery banding with good results at 3 months of age. She had repeated respiratory tract infections with occasional croup, considered of infectious origin, and had been treated with digoxin for recurrent congestive heart failure. There was no history of dysphagia or chronic respiratory distress.

The patient was underdeveloped, with normal vital signs. While the cardiovascular system revealed signs of VSD, other systems showed no abnormalities.

The PA chest roentgenogram showed cardiomegaly and increased pulmonary vasculature. The aortic knob was not visualized

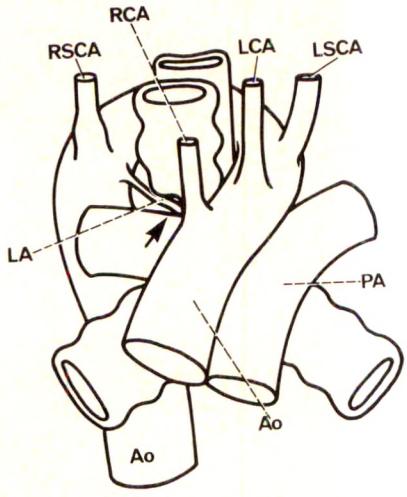

FIG 1. Diagram of the vascular anomaly. Arrow indicates ligamentum arteriosum with compression of trachea. AO = aorta; PA = pulmonary artery; LSCA = left subclavian artery; LCA = left common carotid artery; RCA = right common carotid artery; RSCA = right subclavian artery; LA = ligamentum arteriosum.

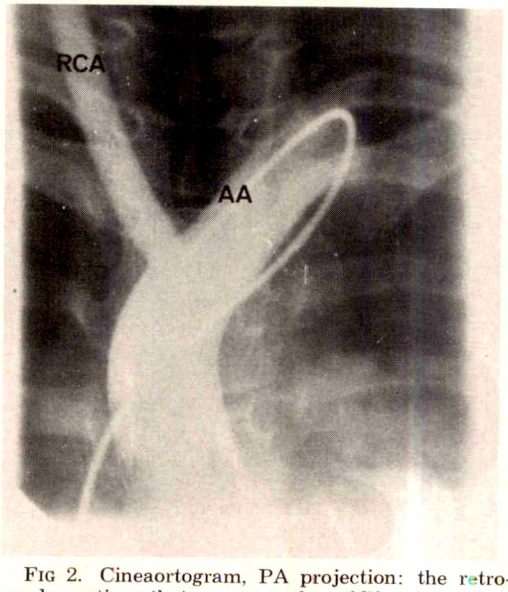

FIG 2. Cineaortogram, PA projection: the retrograde aortic catheter crosses the midline from right to left at the level of the 5th dorsal vertebra and enters the ascending aorta from the left. This initial cine frame after supravalvar injection of contrast material opacifies the ascending aorta (AA). The first brachiocephalic vessel is the right common carotid artery (RCA).

but a right descending aorta could be identified. On the lateral roentgenogram, posterior indentation of the trachea superior to the carina was noted.

Aortography in PA and lateral projections demonstrated a left aortic arch with right descending aorta (figs 1-4). The operative

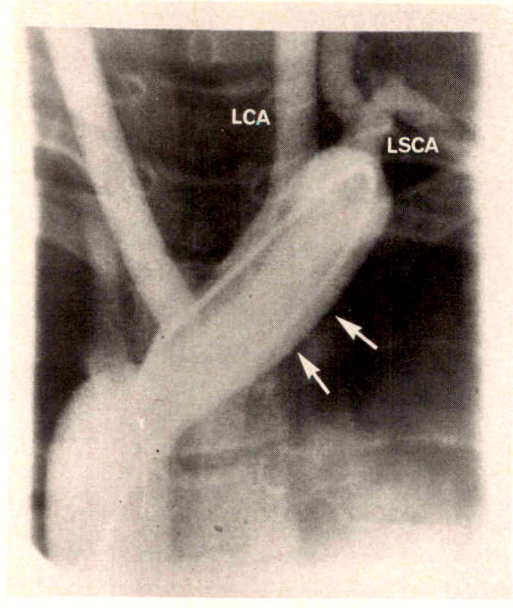

FIG 3. A later frame from the same injection as figure 2, showing the left common carotid (LCA) and left subclavian (LSCA) arteries originating from the aortic arch. The aortic arch is above the clavicle, and the distal left arch (arrows) extends inferiorly, to the right, and posteriorly (noted on the lateral cine, not illustrated), and joins the right descending aorta at the origin of the right subclavian artery.

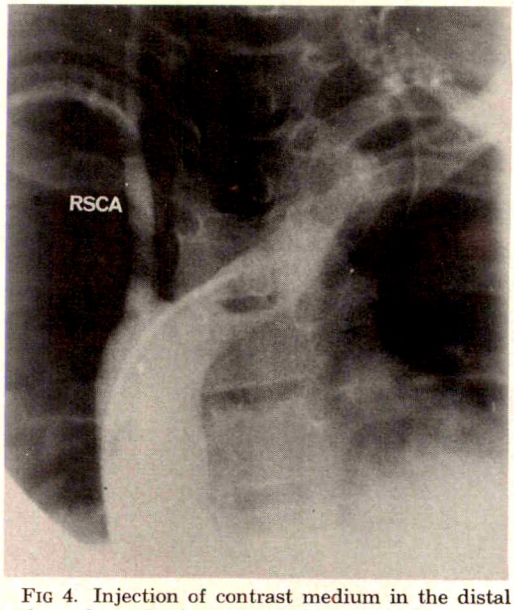

FIG 4. Injection of contrast medium in the distal arch confirms the junction of the arch and descending aorta on the right at the origin of the right subclavian artery (RSCA).

and anesthetic procedures involved meperidine, dimethyltubocurarine, N_2O-O_2, and cardiopulmonary bypass. The pulmonary

artery banding and the VSD were repaired. The origin of the aorta and pulmonary trunk were noted to be normal but the descending aorta was found to be on the right side.

Postoperatively, the patient was placed on an Engström volume ventilator with controlled ventilation. With the administration of 35% O_2, blood gases were Pao_2 118 torr, $Paco_2$ 35.7 torr, pH 7.395, and base excess −1. On the morning of the 2nd postoperative day, the patient was tried off the ventilator, breathing 40% O_2 via T-tube. Within 2 minutes, she became restless, cyanotic, and showed signs of upper-airway obstruction. The endotracheal tube was patent and the patient was returned to the ventilator.

She was again tried off the ventilator several times in the next 24 hours without success, each time showing symptoms of upper-airway obstruction. Endoscopy under general anesthesia, using halothane-O_2 and a ventilating bronchoscope, revealed a 1-cm extrinsic, nonpulsatile compression of the trachea of the right and posterior side just above the carina, indicating compression by a vascular ring.

On the 4th postoperative day, operation was performed through a right thoracotomy using fluroxene-N_2O-O_2. A ligamentum arteriosum, 0.5 cm in diameter, was found to the right of the trachea, extending from the right pulmonary artery to the arch of the aorta, with the right recurrent laryngeal nerve around it. After division of the ligament, the trachea was found to be thin and easily collapsible at the site of compression (tracheomalacia) (fig 1).

After operation, repeated attempts to wean the patient from the ventilator failed, the patient again manifesting signs and symptoms of upper-respiratory obstruction. An elective tracheostomy was done on the 8th postoperative day. On the 10th postoperative day, she could be maintained for a few minutes off the ventilator with the use of continuous positive airway pressure (CPAP). Progressively, the periods on CPAP were increased, with final weaning from the ventilator. The patient could then be gradually weaned off the CPAP by the 15th postoperative day. Throughout the postoperative course, the O_2 exchange was satisfactory.

DISCUSSION

The association of a left aortic arch with a right descending aorta is an uncommon anomaly, 2 cases associated with tetralogy of Fallot and 1 case not associated with cardiac abnormality[6] having been reported in 1948. Klinkhamer[7] reviewed 8 cases in 1969, and in addition reported 1 case of his own, noting symptoms of tracheoesophageal compression in 3 of the 8 cases. While the course of the transverse segment of the arch of the aorta may be retroesophageal or pretracheal, the former is more common.[7]

The vascular ring is formed on the left by the aortic arch, posteriorly by the transverse portion of the aortic arch, to the right by the ligamentum arteriosum or patent ductus, and anteriorly by the pulmonary arteries.[6] Symptoms due to vascular ring are usually manifest in the newborn or the elderly.[6]

In this anomaly, the ascending aorta is elongated with the aortic knob usually in the neck. The first branch is a right common carotid artery, followed by a left common carotid artery and left subclavian artery. Beyond the aortic knob, the aorta swings posteriorly and to the right behind the esophagus to join a right descending aorta. At this junction a right subclavian artery usually arises with a bulbous origin.

Even though our patient showed radiologic evidence of tracheal compression preoperatively, there were no symptoms indicative of obstruction. She became symptomatic following operation.

Ductus arteriosus or ligamentum arteriosum commonly lies on the same side of the body as the upper portion of the descending aorta.[6] In the present case, bronchoscopy aided in the localization of the site of compression. Surgical correction of the compressing lesion has been helpful to alleviate the symptoms and has been recommended by Gross[1] and by Neuhauser.[3] Tracheomalacia in a patient suffering from infectious polyneuritis with inspiratory obstruction, whose symptoms improved with temporary reinsertion of an uncuffed cannula, has been reported.[8] Our patient demonstrated tracheal weakness just above the carina, and introduction of an endotracheal tube was prevented by the likelihood of carinal stimulation and endobronchial intubation.

Preoperative evaluation of the trachea and esophagus by radiology is important in all cases with vascular anomalies in the mediastinum. Ligaments, vessels, and fibrous bands or sheaths accompanying the

vessels and ligaments produce an obstruction of the trachea and esophagus. Positive-pressure breathing and CPAP appear beneficial for treating the respiratory distress associated with airway obstruction or tracheomalacia in these cases.

ACKNOWLEDGMENT

We thank Dr. Donald A. Girod, Professor and Director of Pediatric Cardiology, Indiana University Medical Center, for his cooperation, and Miss Linda Hicks for her secretarial assistance.

Influence of Pancuronium or d-Tubocurarine on Circulatory Responses During Thiamylal-N_2O-Halothane Anesthesia

ROBERT K. STOELTING, MD*

Circulatory responses after thiamylal (4 mg/kg) and pancuronium (0.08 mg/kg, 20 patients) or d-tubocurarine (dTc, 0.5 mg/kg, 20 patients) followed by tracheal intubation and nitrous oxide-halothane administration were measured. Three minutes after thiamylal, the mean arterial pressure (MAP) and cardiac index (CI) decreased significantly only in patients receiving dTc. Heart rate (HR) was increased 12 bpm in both groups. The magnitude of reduction in MAP and CI was similar and the HR was not greatly different between groups after 5 minutes of N_2O-halothane administration.

MAP and CI were better maintained following thiamylal in patients receiving pancuronium as compared with dTc. However, circulatory responses during early anesthetic maintenance were not influenced by the choice of neuromuscular blocker.

CIRCULATORY changes may result from drugs used for anesthetic induction and maintenance and from the stimulation of tracheal intubation. In addition, competitive neuromuscular blocking agents may produce hemodynamic alterations. For example, in one report,[1] pancuronium (0.08 mg/kg) increased mean arterial pressure (MAP), heart rate (HR), and cardiac output following rapid IV administration during N_2O-halothane anesthesia, while 0.4 mg/kg of d-tubocurarine (dTc) slightly increased HR and decreased blood pressure (BP), cardiac output, and systemic vascular resistance (SVR). In view of the different circulatory responses produced by these two drugs, we speculated that the direction and/or magnitude of circulatory changes occurring during anesthetic induction, tracheal intubation, and anesthetic maintenance might be influenced by the choice of neuromuscular blocker.

This study compares circulatory responses after thiamylal anesthetic induction, tracheal intubation, and subsequent anesthetic maintenance with N_2O-halothane in the presence of either pancuronium or dTc paralysis.

METHODS

Forty adult patients without known heart disease and requiring elective operations were studied. All had received morphine (8 to 12 mg) and atropine (0.4 mg) IM as preanesthetic medication 60 to 90 minutes before operation. On their arrival in the operating room, a radial artery catheter was inserted percutaneously and attached to a strain gauge and recorder for continuous recording of MAP. Lead 2 of the ECG was recorded continuously. After breathing O_2 by mask for 3 minutes, awake MAP and cardiac output (dye-dilution method with indocyanine green dye) were measured. Cardiac index (CI), stroke volume index (SVI), and SVR were calculated, while HR was measured from a 15-second portion of the ECG.

Twenty patients received pancuronium (0.1 mg/kg) as a bolus IV and the other 20 patients dTc (0.5 mg/kg). Thirty seconds after neuromuscular blocker injection, anesthetic induction was accomplished in

*Professor of Anesthesiology/Pharmacology, Indiana University School of Medicine, Indianapolis, Indiana 46202.

Paper received: 11/6/75
Accepted for publication: 11/19/75

all patients by the rapid IV administration of thiamylal (4 mg/kg). Ventilation was manually controlled by mask with O_2 within 15 seconds of thiamylal injection.

Cardiac output was again measured 1 and 3 minutes after thiamylal administration. After the 3-minute measurement, the response to 3 seconds of continuous ulnar nerve stimulation (tetanus) was visually noted utilizing a peripheral nerve stimulator (Block-Aid® Monitor, 50 Hz). Direct laryngoscopy and orotracheal intubation was then accomplished. Laryngotracheal lidocaine (2 mg/kg) was administered just before placement of the tube in the trachea. Immediately following endotracheal intubation, ventilation was mechanically controlled with 60% N_2O-O_2 (3:2) and about 1% delivered halothane. All measurements were repeated after 5 minutes of anesthetic maintenance with these drugs. Arterial blood for blood-gas analysis and blood-halothane levels were also obtained at this time.

Data within and between the 2 groups were compared by Student's *t*-test, with $p<0.05$ considered statistically significant. This study was approved by the Indiana University School of Medicine Clinical Research Committee.

RESULTS

Patient data and drug dosages are summarized in table 1 and all other measurements are detailed in table 2. Awake MAP was not changed from control measurements

*$p<0.05$ compared with awake measurement.

†$p<0.05$ dTc compared with pancuronium measurement at same time.

30 seconds after either pancuronium or dTc, but HR was increased after pancuronium ($p<0.05$). MAP was decreased an average of 24 torr ($p<0.05$) and 18 torr ($p<0.05$) 1 and 3 minutes, respectively, after thiamylal administration to patients receiving dTc. In contrast, MAP was not significantly decreased at these times following thiamylal administration to patients given pancuronium. Three minutes following thiamylal administration, CI and SVI were decreased ($p<0.05$) in patients receiving dTc but not in those given pancuronium.

Tracheal intubation between 3 and 4 minutes following thiamylal administration was accomplished in all patients but intubating conditions were considered better in patients receiving pancuronium. Of 20 patients receiving dTc, 17 coughed with placement of the tracheal tube, while only 2/20 coughed with pancuronium. The tetanus response to ulnar nerve stimulation was visually judged to be depressed at least 75% in 5/20 patients receiving dTc and 14/20 receiving pancuronium. Despite similar durations of direct laryngoscopy, the MAP achieved in response to this stimulation was greater in patients receiving pancuronium than in those given dTc (140 versus 115 torr, $p<0.05$).

Compared with awake measurements, MAP, CI, and SVI were decreased ($p<0.05$) in both groups after 5 minutes of controlled ventilation with 60% N_2O and 1% halothane. Furthermore, MAP, HR, CI, SVI, and SVR at this time were not significantly different between groups. The arterial halothane concentrations and blood gases were similar in both groups. The halothane concentrations were equivalent to 0.3 to 0.4 vol/100 ml, assuming a blood/gas partition coefficient equal to 2.4.

DISCUSSION

Pancuronium (0.08 mg/kg) has been demonstrated to increase MAP, HR and cardiac output following rapid intravenous administration during nitrous oxide-halothane anesthesia while dTc (0.4 mg/kg) slightly increased HR and reduced blood pressure, cardiac output and SVR.[1] Conceivably, large doses of dTc combined with thiamylal for anesthetic induction could have an additive effect with barbiturate-produced circulatory effects, resulting in undesirable degrees of hypotension. In contrast, the circulatory effects of pancuronium might attenuate the circulatory response to barbiturate anesthetic induction. Indeed, this study demonstrated that MAP and cardiac output did not change significantly in the first 3 minutes after thiamylal administration to patients receiving pancuronium, as contrasted with significant reductions in these parameters in patients given dTc. HR increased by similar amounts regardless of the neuromuscular blocker chosen, although the increase occurred sooner and was statistically significant only in patients receiving pancuronium.

Intubating conditions at the dose and time interval chosen in our study were better with pancuronium than with dTc. Other workers[2,3] have also reported more acceptable intubating conditions with pancuronium than with dTc. Perhaps a larger dose of dTc would have provided more acceptable conditions with this drug, although Bennett and associates,[4] using 0.12 mg/kg pancuronium or 0.6 mg/kg dTc, found no significant difference between the drugs for tracheal intubation.

Despite similar durations of direct laryngoscopy the maximal MAP attained in response to this stimulation was significantly greater in patients receiving pancuronium. Considering the MAP at the start of laryngoscopy the absolute increase in blood pressure was 33 torr in patients receiving dTc and 47 torr in patients given pancuronium. This decreased pressor response to laryngoscopy and tracheal intubation might reflect dTc-produced autonomic ganglion blockade which would be less with pancuronium.[5]

Controlled ventilation with N_2O-halothane may be associated with circulatory depression. We speculated that circulatory changes resulting from pancuronium might attenuate subsequent responses during anesthetic maintenance, while dTc might produce an additive depressant effect, especially on blood pressure. However, MAP, CI, and SVI were significantly reduced from awake measurements after 5 minutes of similar anesthetic maintenance in both groups. Furthermore, the MAP, HR, CI, SVI, and SVR were not significantly different between groups, although CI was nearer awake measurements in patients receiving pancuronium.

We conclude that MAP and CI are better maintained following thiamylal anesthetic induction in patients receiving prior pancuronium as compared with dTc. Intubating conditions at the drug dosages and time intervals chosen in this study were better

with pancuronium than dTc. Blood pressure increased more in response to laryngoscopy and tracheal intubation in patients receiving pancuronium. Circulatory changes after controlled ventilation for 5 minutes with N_2O-halothane did not seem to be altered by the presence of pancuronium or dTc paralysis.

PROPRANOLOL WITHDRAWAL. The authors measured the persistence of propranolol in plasma and atrial tissue following drug withdrawal, tested for residual beta-adrenergic blockade with isoproterenol and determined the plasma disappearance rate following a single intravenous dose to treat intraoperative dysrhythmias. In 34 patients withdrawn from chronic propranolol therapy 18-48 hours preoperatively, propranolol was detected in the plasma of 9 and in atrial tissue of 5. Following bolus, intravenous isoproterenol, 3 μg, heart rate increased greater than 20 beats/min in all patients withdrawn from propranolol at least 18 hours preoperatively as well as patients never having received propranolol. The highest plasma propranolol was 23 ng/ml in a patient taking 300 mg/day orally. These data suggest that concern about persisting beta blockade after oral propranolol withdrawal need arise only in patients taking doses greater than 300 mg. Furthermore, any questions concerning persisting blockade could be resolved by administering 3 μg isoproterenol and observing the heart rate response. Propranolol was not detectable in the plasma or atrial tissue 5 minutes after a single intravenous 0.5 mg injection. The authors conclude that early preoperative withdrawal (greater than 24 hours) of propranolol in patients with coronary artery disease may be more hazardous than beneficial. *(Romagnoli A, Keats AS: Plasma and atrial propranolol after preoperative withdrawal. Cir 52:1123-1127, 1975)*

Spinal Anesthesia: Bupivacaine Versus Tetracaine

A. EUGENE PFLUG, MD*
GEORDIS M. AASHEIM, MD†
HAROLD A. BECK, BS‡
Seattle, Washington§

The clinical effects of equal hyperbaric doses of bupivacaine HCl and tetracaine HCl were studied and compared in 99 adult men undergoing spinal anesthesia for similar surgical procedures. The spinal anesthetic agents were used in random order in various dosages. Comparisons were made of (1) amount of anesthetic agent used, (2) elapsed time for onset of analgesia, (3) elapsed time for obtaining maximum anesthesia, (4) cephalad dermatome level of anesthesia, (5) incidence of motor blockade, and (6) duration of anesthesia. Results with the 2 drugs in equal dose, volume, and specific gravity were almost identical. However, tetracaine provided a motor block in a significantly greater number of patients than did bupivacaine (100 versus 42%, $p<0.001$) when both drugs were used at the 9.75-mg dose level.

ONE OF the objectives of research involving local anesthetics for regional anesthesia is the prolongation of the duration of sensory anesthesia without an increase in adverse effects or toxicity. Bupivacaine (Marcaine®) extends the duration of sensory anesthesia without increasing toxicity when used for peridural or peripheral nerve blocks.[1] Spinal anesthesia with bupivacaine is reportedly efficacious and safe,[2-4] and may be of longer duration than subarachnoid block with tetracaine (Pontocaine®).

The objective of our study was to compare the observed clinical properties of bupivacaine spinal anesthesia with those of a conventional tetracaine spinal, using equal hyperbaric doses for similar surgical conditions.

METHODS

Ninety-nine adult men were studied for 24 hours after spinal anesthesia for elective surgery. Prior informed consent was obtained from each. Patients were accepted for study if they were without infection of tissues in the lumbar area, evidence of hypovolemia, uncontrolled systemic disease, or history of cerebrospinal-system disease.

Ninety-nine numbered vials‖ were arranged in random order, each containing 15 mg of either bupivacaine or tetracaine in 5 percent glucose solution within a total volume of 2 ml. The resultant solutions contained 7.5 mg/ml of local anesthetic agent of the same volume and specific gravity, which allowed direct comparison of the drugs. Dosage was based on age, weight, height, physical condition, and anesthetic and surgical procedures, these factors being standardized in grouping, so far as possible.

The more anxious patients (11 receiving

tetracaine, 7 receiving bupivacaine) received preoperative medication consisting of 5 or 10 mg of IM diazepam, depending on size and age. All patients had an IV infusion started with an 18 or 16-gauge plastic catheter, blood pressure cuff applied to an arm, and leads connected to a cardioscope monitor. Standard lumbar paramedian spinal anesthesia was administered with a 22-gauge needle while the patient was in the left lateral recumbent position. Mephentermine 1 ml (30 mg) was injected through the skin wheal used for insertion of the spinal needle into the perispinal muscles immediately following injection of the local anesthetic agent into the subarachnoid space. An IV infusion of 500 to 700 ml of lactated Ringer's solution was completed prior to injection of the spinal anesthetic agent. The mephentermine and IV fluids were used to help prevent the vascular hypotension which can be associated with spinal anesthesia. The operating table was flexed (patient's legs elevated, back horizontal) to help prevent backache, which often follows the prolonged supine position, and to promote venous return from the legs. The entire table was further manipulated to obtain the desired dermatome level of analgesia.

Spinal anesthesia was supplemented by intermittent IV diazepam (5 to 10 mg) or thiamylal (50 to 75 mg) for sedation after maximal regional anesthesia had been obtained (10 patients in the bupivacaine group, 16 patients in the tetracaine group). Nasal O_2 was administered during the operative procedure when indicated by age or chronic disease. Measured blood loss was replaced intraoperatively in addition to maintenance fluids to help prevent vascular hypovolemia.

The following observations were made: (1) amount of anesthetic agent used, (2) time anesthetic agent was injected, (3) time of onset of analgesia, (4) time maximum surgical anesthesia was obtained, (5) presence or lack of motor function blockade of the legs, (6) highest dermatome level of maximum anesthesia, (7) time of onset anesthesia regression, and (8) time anesthesia regression was complete (table). Blood pressure, pulse, and respiration were monitored at the following times: preoperatively on the ward, preoperatively in the operating room, intraoperatively at 5-minute intervals, and postoperatively at 10-minute intervals until sensory sensation had fully returned. Drugs and amounts used to supplement spinal anesthesia were recorded intraoperatively and quality of surgical anesthesia assessed postoperatively.

Onset of analgesia was defined as loss of sensory sensation to pinprick in the suprapubic area, and surgical anesthesia as loss of sensory sensation to skin-fold clamping with an Allis forceps to the first rachet. Motor blockade was arbitrarily defined as the inability to straight-leg raise the heels off the operating table. Maximum surgical anesthesia (Allis forceps) was equated with the time cephalad dermatome progression of anesthesia ceased, onset of regression as the time the dermatome level of anesthesia started moving in a caudad direction, and complete regression as the time sensation returned in the suprapubic area (Allis forceps). Anesthesia was rated as satisfactory when the patient did not complain of pain during the operation or the surgeon comment negatively about anesthetic conditions.

The key to the identity of all numbered vials was opened at the completion of the study for analysis of results. Statistical significance was determined by Student's *t*-test for paired data.

RESULTS (table)

No significant difference was noted between mean values for the tetracaine and bupivacaine groups for age and height. However, the mean kilogram weight of the patients receiving the 15 mg tetracaine anesthesia was significantly greater than the corresponding value for the bupivacaine group (84.5 versus 71.5 kg, $p<0.01$), and the mean mg/kg local anesthetic dose received by the patients in the 15 mg bupivacaine group was significantly greater than the corresponding amount for the tetracaine group (2.2 versus 1.8 mg/kg, $p<0.01$).

These differences did not, however, significantly prolong the duration of the 15 mg bupivacaine spinal anesthesia compared with 15 mg of tetracaine, results obtained with the 2 drugs in equal dose, volume, and specific gravity being almost identical. No significant difference was found between the mean values for time of onset, time of maximal anesthesia, dermatome level of anesthesia, or duration of spinal anesthesia produced by equal amounts of bupivacaine and tetracaine.

The only difference noted in comparing the 2 drugs was in the incidence of motor function blockade. Tetracaine provided a motor block in a significantly greater number of patients than did bupivacaine (100 versus 42%, $p<0.001$) when both drugs were used at the 9.75 mg dose level. Both

*$p<0.01$.

†Onset = time of onset suprapubic analgesia.

‡Max = time cephalad dermatome progression of anesthesia ceased.

§Level = highest dermatome level of anesthesia.

‖Percent motor = percent of patients with leg paralysis.

**$p<0.001$.

††Regression start = elapsed time from injection of anesthetic agent to time the dermatome level of anesthesia started moving in a caudad direction.

‡‡Regression complete = elapsed time from injection of anesthetic agent to time sensation returned to suprapubic area.

bupivacaine and tetracaine provided satisfactory spinal anesthesia for all the surgical procedures studied. Tetracaine was used for spinal anesthesia for the following operations: urology (other than intraperitoneal) 39, perineum 4, orthopedic (hips and legs) 4, inguinal hernia 3. Spinal anesthesia with bupivacaine was used for urology 37, perineum 2, orthopedic 8, and inguinal hernia 2. Hypotension (20% decrease in systolic blood pressure from preoperative level) was noted in 3/99 anesthetic procedures, all in the bupivacaine group. These episodes of hypotension were easily reversed by the use of increased IV fluids and IV ephedrine. One patient developed a headache after tetracaine, which resolved with conservative treatment.

DISCUSSION

Reported results of bupivacaine peridural anesthesia indicate a longer duration of block than a similar block with tetracaine.[1] Bupivacaine might be expected to also prolong duration of spinal anesthesia, but such prolongation was not revealed by our study (table) when the 2 drugs were compared on

a milligram-to-milligram basis. However, the duration of spinal anesthesia was increased 33 and 63% by doubling dosage of both agents (7.5 versus 15 mg), without changing the time of onset, time of maximum anesthesia, or thoracic dermatome level of anesthesia (table).

In 321 cases of orthopedic and trauma surgery, Ramaioli and Pagani[3] found that 10 mg of 1% bupivacaine without adrenalin provided 135 minutes of spinal anesthesia for hip and femur operations, which compares favorably with our duration of 143 minutes for a similar dose. Comparison of the duration of spinal anesthesia between various studies is difficult due to lack of standardization of the manner and site of testing for termination of anesthesia. Our arbitrary choice of Allis forceps clamping in the suprapubic area as the endpoint of anesthesia cannot be compared with tests for duration of anesthesia in ankle or foot surgery.

Ramaioli and Pagani also found that duration of spinal anesthesia was a function of milligram dose of local anesthetic agent, reporting that bupivacaine anesthesia of 135 minutes with 10 mg increased to 350 minutes with 40 mg. Their maximum duration was 480 minutes (8 hours of spinal anesthesia) produced by 40 mg of bupivacaine and 0.5 mg adrenalin for leg and foot operations (16 cases) without apparent increase in adverse or toxic effects.

Lack of complete muscle paralysis in the area of spinal anesthesia may be desirable for obstetric or urologic anesthesia when abdominal muscle contraction by the patient is helpful, as in obstetric delivery or spontaneous-voiding x-ray. However, bupivacaine spinal anesthesia, regardless of dose, did not always provide a reduced motor blockade, but did provide in all cases satisfactory muscle relaxation for inguinal hernia repair.

We conclude that the results obtained with bupivacaine and tetracaine spinal anesthesia are clinically the same (except for an occasional decreased motor block with bupivacaine) when equal hyperbaric doses are used for similar surgical conditions.

Anaphylaxis: Etiology and Guidelines for Management

DEAN H. MORROW, MD*
ROBERT R. LUTHER, MD†

The successful management of anaphylaxis requires a thorough understanding of this syndrome and the application of various therapeutic agents. Although the mechanisms responsible for human anaphylaxis are not fully known, sufficient data and clinical experience are available to guide the anesthesiologist faced with this medical emergency.

THE term "anaphylaxis" was introduced by Poitier and Richet in 1902 to describe the syndrome of shock and subsequent death which occurred in dogs following reinjection of the poison of the sea anemone.[1] Since that time, use of the term has broadened to include unusual or exaggerated hypersensitivity reactions to a variety of drugs and other substances.[2] Of particular importance to the anesthesiologist is the fact that anesthetic agents,[3-8] anesthesia adjuncts,[9,10] and other materials to which the patient may be exposed during operation[11-15] are now known to be capable of producing anaphylaxis.

Although the precise mechanisms underlying human anaphylaxis are not fully known, sufficient data are available to support a clinically useful explanation and basis for therapy. These considerations constitute the basis for this review, which is presented to aid the anesthetist dealing with anaphylaxis in his practice or as a member of the team responding to this medical emergency.

I. The Theoretic Basis for Anaphylaxis.

Systemic anaphylaxis is the most dramatic and dangerous hypersensitivity reaction and may cause death within minutes. This syndrome consists of a highly variable symptom complex including at least some of the following: conjunctivitis, vasomotor rhinitis, pilomotor erection, pruritic urticaria, angioedema, various gastrointestinal disturbances, laryngeal edema, bronchospasm, hypotension, arrhythmias, cardiac arrest, coma, and death. In fatal anaphylaxis, physiologic disturbances of the cardiovascular and respiratory systems predominate and frequently occur early.

The clinical signs, severity, progression, and duration of an anaphylactic reaction are highly unpredictable. The initial signs and symptoms do not necessarily reflect the severity, duration, or ultimate progression of the reaction. Anaphylaxis may be limited to a single symptom or may progress to cardiovascular and respiratory collapse within minutes. Fatal anaphylaxis may occur without milder premonitory symptoms and may be manifest only by rapidly progressive laryngeal edema and profound cardiovascular collapse, refractory to all treatment.

The duration of a reaction and any of its components varies from minutes to a day or longer. Appropriate immediate therapy may terminate the entire symptom complex quickly; however, laryngeal edema and hypotension may persist for hours or days despite appropriate therapeutic measures. Death may intervene at any time. Because the clinical spectrum of anaphylaxis is as wide as patient responses are variable, any systemic manifestation must be considered the forerunner of a potentially lethal process and be treated vigorously.

Anaphylactic reactions may occur following the administration of an exogenous antigenic stimulus. The time from antigenic challenge to the onset of a reaction is variable but typically occurs within 30 minutes. On the other hand, delays of an hour or more are possible, depending upon various factors, including the rate at which the antigen reaches the circulation.

The physiologic alterations of systemic anaphylaxis are mediated by various endogenous, pharmacologically active agents, the release of which is the result of complex antigen-antibody interactions at the cellular level. Anaphylaxis may occur in any subject appropriately sensitized to a particular antigen. Importantly, negative skin testing, negative history, and uneventful previous exposures to the antigen do not preclude the possibility of an anaphylactic type of reaction.[16]

When a susceptible individual is first exposed to a *specific* antigen, antigen-specific immunoglobulin E (IgE; reagin) antibodies are formed which will interact only with that particular antigen. These IgE antibodies are cytophilic and selectively attach to the cell membranes of circulating basophils and tissue mast cells. Subsequent exposure to the specific antigen results in an antigen-antibody interaction believed to be initiated by the bridging of 2 adjacent IgE molecules on the membranes of those cells. This bridging induces a complex series of intramembrane and intracellular events, which culminate in the release of histamine and the slow-reacting substance of anaphylaxis (SRS-A) from the cell. These mediators in turn may directly elicit local and systemic pharmacologic effects, cause the release of other mediators, or activate reflexes that ultimately produce the clinical picture of anaphylaxis.

The Role of Histamine.—Histamine is found in several mammalian tissues. In man, the presence of histamine in mast cells and basophils is most important. Histamine can cause bronchial constriction, increased capillary permeability, and vasodilation. Experimentally administered histamine produces rhinitis and bronchoconstriction, as well as headache, pruritus, blushing, and hypotension. By virtue of its presence in the metachromatic granules (as a protein-heparin-histamine complex) of mast cells and basophils, and the physiologic responses it elicits, histamine is believed to be a major mediator of anaphylaxis. The end-organ responses to histamine can be moderated or blocked by pharmacologic doses of antihistamine given before the histamine is released.

Slow-Reacting Substance.—SRS-A, a lipid synthesized and released in response to the antigen-antibody interaction, causes constriction of bronchial smooth muscle *in vitro* and has been shown to increase capillary permeability (wheal formation) after intracutaneous injection. Experimentally, SRS-A is released from human lung (rich in mast cells) which has been pretreated with IgE and then challenged either with anti-IgE or specific antigen. Since SRS-A can be released from immunologically challenged human lung, and because of its pharmacologic action on bronchial smooth muscle, it is believed to play an important role in human allergic asthma and perhaps anaphylaxis.

The origin of SRS-A released following an immunologic challenge is not known with certainty but is presumed to be mast cells and basophils. SRS-A release is enhanced by cholinergic agonists and can be moderated or blocked experimentally by anticholinergic agents.[17] Whether anticholinergic-related alterations in the release of SRS-A have a place in the treatment of human anaphylaxis has yet to be clarified.

This release of chemical mediators is an energy-dependent process related to alterations in the levels of intracellular cyclic adenosine-3′5′-monophosphate (cAMP). Beta-adrenergic agonists, for example epinephrine, isoproterenol, and other agents which activate the cell membrane-bound adenyl cyclase system, cause an increase in intracellular cAMP and inhibit the release of histamine and SRS-A. Similarly, mediator release is inhibited by the methylxanthines, which reduce the degradation of cAMP by phosphodiesterase and thereby increase intracellular cAMP levels. Conversely, interventions capable of decreasing intracellular cAMP enhance the release of histamine and SRS-A. The specific intramembrane and intracellular biochemical processes underlying these inverse correlations, however, have not been defined.

II. Treatment of the Anaphylactic Syndrome.

Anaphylaxis must be promptly and vigorously treated. While the anesthesiologist may be familiar with the drugs used to treat

TABLE 1

Drugs Useful in Treating Anaphylaxis

Drug class/agents	Physiologic action	Indication
1. Adrenergic agonists		
Epinephrine	Alpha and beta agonist	IMMEDIATE AND INITIAL TREATMENT OF ALL ANAPHYLACTIC REACTIONS
Isoproterenol	Beta agonist	Bronchospasm and hypotention with low cardiac output
Methoxamine	Alpha agonist	Hypotension with decreased peripheral vascular resistance
Ephedrine	Alpha and beta agonist	Hypotension and laryngeal edema
Metaraminol	Alpha and beta agonist	Hypotension
2. Methylxanthines		
Aminophylline	Bronchiolar dilation	Bronchospasm not reversed by epinephrine
3. Anticholinergics		
Atropine	? inhibit release of mediators	As preoperative prophylaxis
Scopolamine	? inhibit release of mediators	As preoperative prophylaxis
4. Antihistamines		
Diphenhydramine	Histamine blockade	ALL ANAPHYLACTIC REACTIONS FOLLOWING EPINEPHRINE ADMINISTRATION.
		? as preoperative prophylaxis
5. Corticosteroids		
Hydrocortisone	Unknown	Anaphylactic reactions refractory to above therapies, especially persistent bronchospasm or hypotension.
		? as preoperative prophylaxis

anaphylaxis, he may not be thoroughly familiar with their application in this potential catastrophe.

A. General Pharmacologic Principles.

The therapy of anaphylaxis is based on empiric clinical effectiveness and, more recently, some understanding of the fundamental actions of 5 general classes of drugs: (1) adrenergic agonists, (2) methylxanthines, (3) anticholinergics, (4) antihistamines, and (5) corticosteroids (table 1).

1. Adrenergic agonists.—These are agents which evoke physiologic responses similar to those produced by efferent sympathetic (adrenergic) nerve activity. They are further categorized on the basis of their physiologic effects. Adrenergic agents producing primary effects on the heart and lungs are classified as *beta agonists;* those producing primary effects on the peripheral vasculature are classified as *alpha agonists.* Some agents produce both effects and are said to have a mixed action.

With reference to anaphylaxis, useful beta-agonistic responses include bronchodilation, increased myocardial contractility, increased heart rate, and constriction of the muscular arterioles with redistribution of blood to the central circulation. Beneficial alpha-agonistic responses include cutaneous, mucosal, and splanchnic vasoconstriction with increased total systemic vascular resistance. The increased myocardial contractility and heart rate increase cardiac output, which in combination with the increased total systemic vascular resistance elevates blood pressure and improves perfusion.

A spectrum of adrenergic agonistic drugs is available for treatment of anaphylaxis. These range from isoproterenol, a pure beta agonist, to methoxamine, a drug producing pure alpha stimulation. However, epinephrine, a drug with mixed action, is the agent of choice for the early treatment of anaphylaxis. The precise mechanisms responsible for the efficacy of epinephrine in reversing rhinitis, urticaria, bronchoconstriction, and hypotension during anaphylaxis are not known. However, these beneficial therapeutic effects are attributed to concomitant beta- and alpha-agonistic effects on the heart, lungs, and peripheral vasculature, in addition to a beta-effector-mediated increase

in the intracellular cAMP of mast cells and basophils.

As developed above, increased intracellular cAMP is correlated with a reduction in the release of histamine and SRS-A. The importance of the cellular effect of epinephrine in treating anaphylaxis probably depends on the stage of anaphylaxis at which the drug is administered. Early in the clinical syndrome, epinephrine should effectively decrease mediator release. After maximal mediator release has occurred, however, epinephrine would be less beneficial.

Other adrenergic-agonistic drugs that may have a place in treating anaphylaxis, particularly in patients in whom the use of epinephrine is contraindicated because of a concurrent medical problem, are listed in table 2. For example, in an elderly patient with advanced coronary atherosclerosis and myocardial ischemia, the selective alpha-effector response of methoxamine *might* be considered therapeutically preferable to epinephrine to treat hypotension secondary to anaphylaxis. However, in deciding to use this agent to avoid the cardiac stimulation of epinephrine, one would have to accept loss of beta-mediated effects on the bronchial smooth muscle, as well as the effects of epinephrine in decreasing histamine and SRS-A release.

Similarly, profound bronchospasm *without hypotension* might best be treated by the pulmonary beta-effector action of isoproterenol causing bronchiolar dilation. In this instance, however, diligent ECG monitoring would be obligatory to detect cardiac arrhythmias that may result from isoproterenol administration.

Patients under therapy for intercurrent medical problems which might preclude or alter the anticipated responses to epinephrine and other adrenergic-agonist agents should also be considered carefully. For example, hypertensive patients under treatment with the adrenergic neuronal blocking agents reserpine or guanethidine might exhibit accentuated beta- and alpha-adrenergic physiologic responses to usual doses of epinephrine. Similarly, patients in whom beta blockade had been established by the administration of propranolol might require unusually large doses of epinephrine to obtain relief of bronchospasm and/or enhanced cardiac activity during the treatment of anaphylaxis. As with any form of treatment, the selection of subjects is dependent upon medical judgment.

2. Methylxanthines.—Intravenous methylxanthines, in particular aminophylline, have been found useful in the treatment of anaphylaxis. This use is based on the ability of these drugs to relax bronchiolar smooth muscle and to increase cardiac output. Thus, these actions of the methylxanthines mimic the beta actions of the adrenergic agonists. The xanthines are more effective in decreasing pathogenic bronchospasm, such as that induced by histamine, serotonin, or acetylcholine, although the mechanism for this action is not known.[18]

These agents increase cardiac output through a direct action on myocardial contractility. At the peripheral vascular level, the xanthines produce vasodilation. In any given patient, the systemic arterial blood pressure response is determined by the degree to which augmented cardiac output compensates for the xanthine-induced decrease in peripheral resistance. This hemodynamic interaction is of particular importance in deciding whether to use xanthines in anaphylactic situations, including both bronchospasm and hypotension.

At the cellular level, the methylxanthines are known to inhibit phosphodiesterase, the enzyme responsible for the degradation of cAMP. By virtue of this action, xanthine administration is followed by increased intracellular cAMP. In anaphylaxis, treatment with methylxanthines theoretically would reduce the release of histamine and SRS-A following an antigenic challenge.

3. Anticholinergics.—Drugs which act at the receptors of tissues and organs by competitively blocking the action of acetylcholine released from cholinergic postganglionic autonomic nerves, are referred to as cholinergic blocking agents or anticholinergics. This group includes atropine and scopolamine, two drugs familiar to the anesthesiologist.

Bronchiolar smooth muscle is slightly relaxed by both atropine and scopolamine. In man, the duration of this action is longer after scopolamine. Additionally, the anticholinergic drugs reduce the mucus flow and ciliary movement in the trachea. These actions of the anticholinergics on the pulmonary tree are ascribed to inhibition of locally released acetylcholine secondary to efferent vagus nerve activity.

Although the bronchiolar dilatory action of the anticholinergics has not been widely used in the treatment of bronchial asthma, it is known that these drugs will directly

TABLE 2

Suggested Therapy for Anaphylaxis

Manifestation	Immediate treatment (use in order enumerated)	Supportive measures: Drug therapy	Supportive measures: Clinical monitoring
Minor			
Conjunctivitis Erythema Pruritus Rhinitis Urticaria	1. Epinephrine HCl, 0.3 ml of 1:1000 IM 2. Diphenhydramine HCl, 50 mg IV	Diphenhydramine HCl, 50 mg q 6 hr	Observe for response to therapy
Major			
Arrhythmias		Oxygen; vasopressors as needed; antiarrhythmic agents as needed	ECG monitoring
Bronchospasm	1. Epinephrine HCl, 0.3 ml of 1:1000 IM or IV 2. Diphenhydramine HCl, 50 mg IV (1 dose only) 3. Oxygen	Epinephrine HCl, 0.3 ml of 1:1000 IM; aminophylline, 250 mg IV over 10 min and 500 mg IV q 6 hr; IV solutions; hydrocortisone; oxygen	Observe for respiratory failure and monitor blood gases
Hypotension	1. Epinephrine HCl, 0.3 ml of 1:1000 IM or IV 2. Diphenhydramine HCl, 50 mg IV	Metaraminol bitartrate, 100 mg/1000 ml of 5% D/W; IV solutions; oxygen; isoproterenol (to improve low cardiac output hypotension)	Monitor blood pressure and blood volume; observe for cardiac insufficiency or arrhythmias; observe for renal failure
Laryngeal edema	1. Epinephrine HCl, 0.3 ml of 1:1000 IM or IV 2. Diphenhydramine HCl, 50 mg IV	Diphenhydramine HCl, 50 mg q 6 hr; ephedrine sulfate, 25 mg q 6 hr; hydrocortisone; oxygen	Observe for hypoventilation and monitor blood gases; endotracheal intubation or tracheostomy if necessary

Adapted from Kelly and Patterson.[16]

antagonize the bronchiolar muscle spasm produced experimentally by a number of substances, including histamine.[19] Further, recent evidence has indicated that atropine blocks the ability of cholinergic stimuli to enhance the cellular release of histamine and SRS-A.[17] This action of anticholinergics in inhibiting anaphylactic mediator release is attributed to blockade of cholinergic-mediated increases in cellular cyclic 3′,5′-guanosine monophosphate (cGMP).[20]

4. Antihistamines.—Pharmacologically, the antihistamines represent a broad group of drugs which block most of the actions of histamine through competitive affinity to specific receptors for which histamine is the agonist. There is no evidence that the antihistaminic drugs in any way inactivate or interfere with the synthesis of histamine. The efficacy of antihistamines in competitively blocking the effects of histamine is greatest in situations associated with a high level of circulating histamine. Clinical experience indicates that these drugs are less effective in situations where histamine is released in close proximity to specific receptor sites.

Although still in part theoretic, these data provide an explanation for the therapeutic efficacy of antihistamines in abolishing urticaria associated with circulating histamine and the relative ineffectiveness of these drugs in bronchospasm accompanying human anaphylaxis where histamine is locally released, not systemically circulating. Alternatively, the limited effectiveness of antihistamines in relieving human bronchospasm may be attributed to the concomitant release of other chemical-mediator substances.[19]

5. Corticosteroids.—Although the corticosteroids have been recommended for use in anaphylaxis, the evidence justifying their use is equivocal. Steroids modify various clinical immune reactions such as homologous organ rejection and both immediate and delayed hypersensitivity. Further, steroids have been used successfully in treating and in preventing bronchial asthma and in moderating the ongoing hypotension and bronchospasm of anaphylaxis.[16] Although pretreatment with steroids has not yet been shown to alter the human anaphylactic response, experimentally induced systemic anaphylaxis is *decreased* by glucocorticoids.

Further, while the release of histamine in response to an allergic stimulus is unaffected or increased by glucocorticoids, the subsequent regeneration of histamine may be inhibited, presumably by a steroid-related action. Interestingly, the glucocorticoids do not modify the effects of histamine on smooth muscle or other cells.[21] Thus, despite the lack of a clear-cut basis for using steroids in the prevention or immediate treatment of anaphylaxis, presumptive evidence suggests potential benefits.

Again, it must be emphasized that epinephrine is the definitive therapeutic agent in the immediate treatment of anaphylaxis and that the substitution of other agents such as the steroids should be reserved for cases where epinephrine is relatively contraindicated.

B. Specific Therapy.

Table 2 categorizes the order, doses, and routes of administration for each of the 5 classes of drugs used to treat anaphylaxis.

COMMENT

The successful management of anaphylaxis is dependent on a thorough understanding of the syndrome and its prompt treatment. While there is a common misconception that anesthesia alters the classic signs of anaphylaxis and/or offers some protection against this syndrome, it has been recently pointed out by Bruce and Wingard[22] that available information and, in particular, data about the influence of newer general anesthetic agents on immune responses are insufficient to permit clinically useful conclusions. Indeed, between 1970 and the present, there have been more than 10 reports describing anaphylactic reactions during the perioperative period.[3-8,10,12-15] Were it possible to predict which patients would develop and what circumstances would lead to anaphylaxis, recent evidence about the cellular actions of anticholinergics and antihistamines might be used to greater advantage. Unfortunately, except for selected circumstances, the predictability of anaphylaxis remains obscure. Whether or not the incidence of anaphylactic reactions in anesthetized patients is increasing as has been suggested,[23] it would appear prudent for the anesthesiologist to help establish a program for the immediate treatment of anaphylaxis, including appropriate consultation and defined responsibilities. The success of such a program and its benefits to the patient can only be optimized by careful prior planning.

Neuromuscular Blocking Effects of Aminoglycoside Antibiotics on Fast- and Slow-Contracting Muscles of the Cat

H. R. ADAMS, DVM, PhD*

H. D. MERCER, DVM§

The neuromuscular-blocking effects of neomycin, streptomycin, and gentamicin were examined in fast- and slow-twitch muscles of pentobarbital-anesthetized cats. These antibiotics were more effective in reducing indirectly stimulated contractions of the gastrocnemius muscle than of the ipsilateral soleus muscle in adult cats. Respiratory-depressant effects of these antibiotics were more closely associated temporally with effects on soleus than on gastrocnemius twitch. Neomycin was a more potent neuromuscular blocking agent in kittens >7 weeks old than in kittens <6 weeks old. Calcium ions were more effective in antagonizing the effects of neomycin on gastrocnemius than on soleus twitch; however, neostigmine was more effective in antagonizing the effects of neomycin on soleus than on gastrocnemius twitch. These data indicate a difference in responsiveness of fast- and slow-twitch muscles (fast > slow) to the neuromuscular-blocking effects of aminoglycoside antibiotics, and suggest that this may be related to a difference in the predominance of pre- and postjunctional inhibitory actions of these agents in the 2 muscle types.

ANTIBIOTICS structurally related to neomycin (aminoglycoside antibiotics) interfere with impulse transmission at the somatic myoneural junction.[1] The clinical importance of this neuromuscular-blocking effect is usually related to respiratory problems concurrent with the adminstration of neuromuscular-blocking agents and/or general anesthetics. Although Pittinger's group[2] reported an approximate 9% death rate in patients experiencing these problems, the clinical incidence of this adverse side effect is exceptionally low when the magnitude of antibiotic use is considered.

Experiments designed to examine the potency and characteristics of the neuromuscular-blocking effects of antibiotics have used fast-twitch skeletal muscle in nerve-muscle preparations.[3-7] However, some of the muscles that participate in respiratory

Accepted for publication: 12/4/75

movements exhibit slow-twitch characteristics, and studies have shown that neuromuscular-blocking agents can affect fast- and slow-twitch muscle differently.[8-12]

The purpose of the present study was to examine the neuromuscular-blocking properties of the aminoglycoside antibiotics, neomycin, gentamicin, and streptomycin (fig 1), in a gastrocnemius (fast-twitch) and soleus (slow-twitch) muscle preparation in anesthetized cats.

MATERIALS AND METHODS

Healthy adult cats of either sex, weighing between 2.5 and 3.8 kg, were anesthetized with sodium pentobarbital (35 mg/kg IP). Anesthesia was maintained during an experiment by periodic IV injection of small doses (1 to 2 mg/kg) of pentobarbital. The right femoral artery was catheterized for recording of blood pressure (Statham P23 pressure transducer) and the right femoral vein for injection of drugs. The trachea was cannulated and artificial respiration was maintained with room air by a Harvard respirator pump. In designated experiments, cats were allowed to breathe spontaneously and respiratory movements were monitored by use of a bellows-type pneumograph or by use of a thermocouple placed in the tracheal cannula.

Cats were prepared for monitoring indirectly stimulated muscle twitch of the m. gastrocnemius and m. soleus of the left hind limb, using a modification of a previously described technic.[13] The insertion of the m. gastrocnemius was isolated and connected by a stainless-steel wire to the rigid level of a precalibrated[14] force-displacement transducer (Grass FT.10) for recording isometric contractions. The soleus was carefully isolated from the anterior surface of the gastrocnemius mass, and its tendonous insertion was connected by silk suture to a precalibrated[14] force-displacement transducer (Grass FT.03) for measuring isometric contractions (fig 2). Approximately 100 gm resting tension was placed on the gastrocnemius and 25 gm on the soleus muscle.

During all experiments, muscle twitches of the left gastrocnemius and left soleus muscles were examined simultaneously by stimulation of the ipsilateral sciatic nerve. The sciatic nerve was exposed in the mid-thigh region of the hind limb, ligated, and stimulated peripheral to the ligation with shielded bipolar platinum electrodes at supramaximal voltage with shocks of 0.2 msec pulse duration delivered at a frequency of 12 shocks per minute (0.2 Hz) from a square-wave electrical stimulator (Grass S44). The leg was immobilized in extension by placing a stainless-steel intramedullary pin horizontally through the proximal tibia and clamping the pin at each end to stationary rods. The exposed portions of the

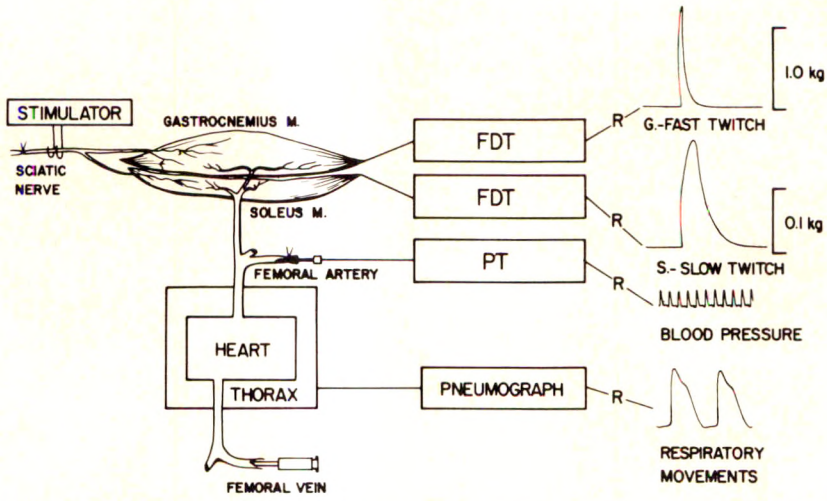

FIG 2. Schematic representation of a sciatic nerve-gastrocnemius and soleus-muscle preparation in anesthetized cats. FDT = force displacement transducer. PT = pressure transducer. R = recorder and amplifier: G. = gastrocnemius. S. = soleus.

muscles and the nerve were bathed in mineral oil and body warmth was maintained with a lamp. All recordings were made on a multichannel Grass model 7B polygraph.

Before proceeding with an experiment, care was taken with each preparation to obtain muscle twitch responses representative of each of the 2 muscle types. If the soleus twitch had an initial fast component or if a secondary slow component (characterized by prolonged relaxation) was observed in the gastrocnemius twitch, additional isolation was attempted at the proximal portion of the muscle bellies. Time was allowed for twitch to stabilize (at least 30 min) before proceeding with an experiment.

Initial studies used 23 cats to determine the dose-response effects of neomycin (n=9), streptomycin (n=10), and gentamicin (n=4). Time was allowed between injections for muscle twitch to return to preinjection values and to stabilize; an additional 20 to 30 minutes was allowed before proceeding with an experiment, to avoid pronounced cumulative effects of an antibiotic.[13] In several experiments, repeated IV injections of neomycin (5 mg/kg) were made at 3 to 4-minute intervals until gastrocnemius twitch was depressed by 90 to 100%. In some experiments, $CaCl_2$ or neostigmine was then administered and the recovery of muscle twitch in cats treated with one of these agents was compared to recovery in the control situation.

In addition, a sciatic nerve-calf muscle preparation was prepared in 11 kittens anesthetized with pentobarbital (28 to 34 mg/kg IP). Stimulation parameters were the same as for the adult cats. Contractions were measured with a Grass FT.03 force-displacement transducer and 25 gm resting tension was placed on the calf muscle. No attempt was made to separate the soleus from the gastrocnemius muscle in kittens. Six kittens were <6 weeks old and weighed between 300 and 430 gm (375.5 ± 21.6 gm, mean ± SE). Five kittens were >7 weeks old and weighed between 439 and 550 gm (477.8 ± 19.9 gm). Dose-response effects to IV administered neomycin (7, 14, and 28 mg/kg) were determined in each kitten and compared between the 2 age groups.

In the dose-response experiments, quantitation of neuromuscular blockade was calculated by measuring the maximum decrease in muscle twitch occurring after administration of an antibiotic and expressing this value in kg of generated tension or as a percent decrease from the preinjection (control) value. The influence of $CaCl_2$ and neostigmine on the effects of neomycin was quantified by normalizing muscle twitch depression, the maximal decrease in muscle twitch observed in each muscle being considered as 100% of the effect in that muscle. All other values obtained over time in that muscle were expressed as a percentage of the maximal effect.

All values are expressed as the mean ± 1 SE. Student's *t*-test was used for statistical comparison.

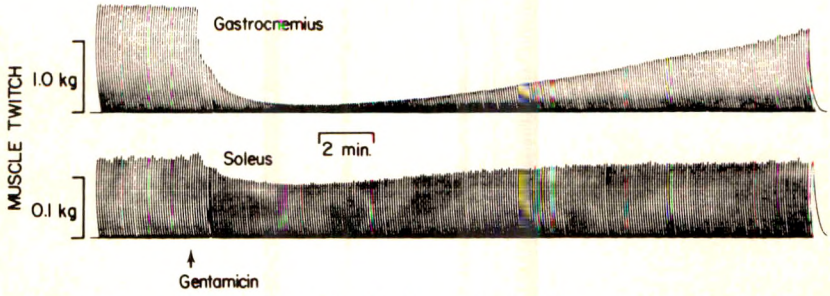

FIG 3. Typical responses of indirectly stimulated muscle twitches of the soleus and gastrocnemius muscles to the neuromuscular blocking effect of gentamicin (3 mg/kg, IV).

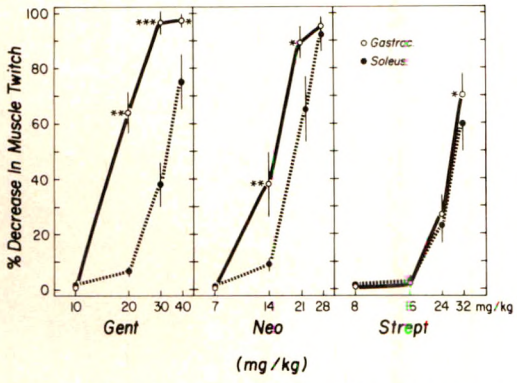

FIG 4. Effects of gentamicin (Gent), neomycin (Neo) and streptomycin (Strept) on indirectly stimulated muscle contraction of the soleus and gastrocnemius (Gastroc.) muscles. Each value is the mean ± SE of responses obtained in 4 (Gent), 9 (Neo), or 10 (Strept) cats. *, **, ***Difference between gastrocnemius and soleus was significant at the $p < 0.05$, $p < 0.005$, and $p < 0.001$ levels, respectively; paired t-test.

RESULTS

Indirectly stimulated contractions of the m. gastrocnemius and m. soleus in the anesthetized adult cat preparations usually exhibited typical fast- and slow-twitch characteristics, respectively. Approximately 10% of the preparations were not used, due to the apparent presence of fast-twitch fibers in the soleus or slow-twitch fibers in the gastrocnemius, even after additional attempts at surgical isolation.

Representative myograms obtained from a typical preparation are included in figure 2. The time to peak tension and total contraction time of 11 gastrocnemius muscles were 34.0 ± 1.1 msec and 260 ± 13.5 msec, respectively, whereas time to peak tension and total concentration time of the 11 corresponding soleus muscles were 100.9 ± 4.8 msec and 445.5 ± 18.1 msec, respectively. The gastrocnemius muscles generated between 1 and 1.5 kg of tension, whereas the soleus muscles generated between 0.1 and 0.4 kg of tension.

Intravenous administration of neomycin, gentamicin, or streptomycin consistently resulted in a decrease in the magnitude of indirectly stimulated muscle twitches of both gastrocnemius and soleus muscles. With each antibiotic studied, the neuromuscular-blocking effects were dose-related in both muscles; and in most cats examined, the effects on gastrocnemius twitch were more pronounced than on the corresponding soleus muscle. In 3 cats tested with streptomycin and in 2 cats tested with neomycin, the soleus was affected more than the corresponding gastrocnemius.

Typical recordings demonstrating the difference in responsiveness of the soleus and gastrocnemius muscles to an aminoglycoside antibiotic are shown in figure 3. Dose-response relationships with each antibiotic are shown in figure 4. In general, the order of potency of the antibiotics was neomycin > gentamicin > streptomycin. The differential effects on the 2 muscles were seen more consistently with neomycin and gentamicin than with streptomycin (fig 4). Absolute values of twitch responses obtained in the experiments with gentamicin are shown in table 1.

Previous studies have demonstrated that administration of Ca^{++} or a cholinesterase inhibitor is reliably effective in antagonizing the neuromuscular-blocking effects of aminoglycoside antibiotics in fast-twitch muscle-nerve preparations.[5-7,13] However, variable success has been reported with the use of these antagonists in clinical circumstances.[5-15] Experiments were included in the present study to determine if $CaCl_2$ and neostigmine were equally effective in antagonizing the effects of neomycin on fast- and slow-twitch muscles.

TABLE 1

Effects of Gentamicin on Indirectly Stimulated Contractions of the Gastrocnemius and Soleus Muscles

Gentamicin, mg/kg	Muscle	Tension, gm ± SE			p*
		Control	Response	Difference	
10 mg	Gastrocnemius	1340.0 ± 116.0	1330.0 ± 123.7	10.0 ± 10.0	>0.05
	Soleus	118.4 ± 9.4	116.0 ± 9.9	2.4 ± 1.1	
20 mg	Gastrocnemius	1386.8 ± 87.4	493.6 ± 66.6	893.2 ± 153.7	<0.005
	Soleus	118.0 ± 10.8	110.7 ± 10.3	7.3 ± 1.3	
30 mg	Gastrocnemius	1560.0 ± 100.6	26.6 ± 26.6	1533.4 ± 113.9	<0.001
	Soleus	122.9 ± 11.6	78.2 ± 6.2	44.7 ± 21.4	
40 mg	Gastrocnemius	1446.0 ± 156.7	26.0 ± 22.0	1420.0 ± 181.4	<0.005
	Soleus	129.3 ± 14.8	32.6 ± 25.7	96.4 ± 25.6

n = 4.

In 13 cats, 5 mg/kg of neomycin was injected IV every 3 to 4 minutes until gastrocnemius twitch was reduced by 90 to 100%. With this schedule, soleus twitch was concurrently decreased by 40 to 60%. Four of the cats served as controls and were not given additional injections. Muscle twitch amplitude at various time intervals was compared in the 4 control cats, in 6 cats given $CaCl_2$ (1.35 mEq Ca^{++}/kg, IV), and in 3 cats given neostigmine (100 μg/kg, IV) at the time of maximum depression of gastrocnemius twitch by neomycin. Since gastrocnemius twitch was consistently affected more than soleus, the effects of Ca^{++} and neostigmine on recovery of the muscles from the effects of neomycin were compared by normalizing muscle twitch depression. With each individual muscle, the maximum decrease in muscle twitch amplitude (90 to 100% in the gastrocnemius and 40 to 60% in the soleus) after injection of neomycin was considered to be 100% of the effect in that muscle. All other values over time of that individual muscle were expressed as a percentage of this maximum. Mean values (figs 5 and 6) show that neostigmine or Ca^{++} antagonized the neuromuscular-blocking effects of neomycin. For example, approximately 1 hour was required for either the gastrocnemius or soleus to recover from the

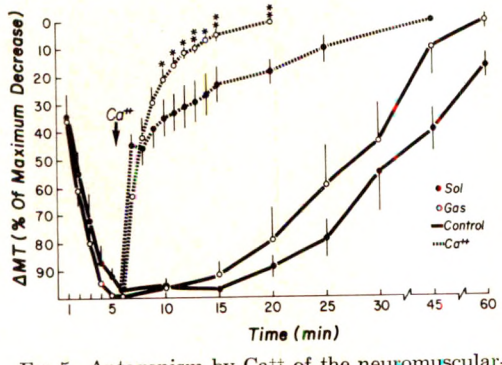

FIG 5. Antagonism by Ca^{++} of the neuromuscular-blocking effects of neomycin on indirectly stimulated contractions of the gastrocnemius (Gas) and soleus (Sol) muscles in anesthetized cats. Neomycin (5 mg/kg) was injected IV every 3 to 4 minutes until gastrocnemius twitch was reduced by 90 to 100%. Saline (solid lines; n = 4) or $CaCl_2$ (dashed lines; 1.35 mEq Ca^{++}/kg; n = 6) was then administered IV. Values are mean ± SE; results are normalized (see text). *, **Difference between gastrocnemius and soleus after administration of Ca^{++} was significant at the $p < 0.05$ and $p < 0.01$ levels, respectively.

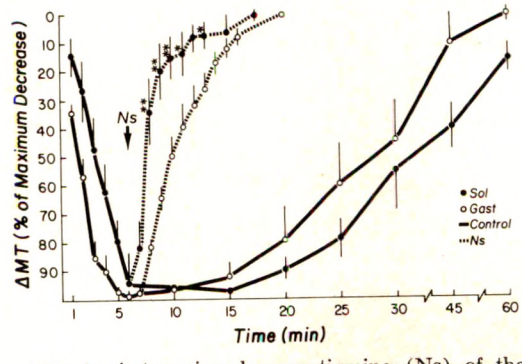

FIG 6. Antagonism by neostigmine (Ns) of the neuromuscular-blocking effect of neomycin on indirectly stimulated contractions of the gastrocnemius (Gast) and soleus (Sol) muscles. Neomycin (5 mg/kg) was injected IV every 3 to 4 minutes until gastrocnemius twitch was reduced by 90 to 100%. Saline (solid line; n = 4) or neostigmine (dashed line; 100 μg/kg; n = 3) was then administered IV. Values are mean ± SE; results are normalized (see text). *, **Difference between soleus and gastrocnemius after administration of neostigmine was significant at the $p < 0.05$ and $p < 0.01$ levels, respectively.

neuromuscular-blocking effects of repeated injections of neomycin, whereas after administration of Ca^{++} or neostigmine, the rate of recovery of muscle twitch height was greatly accelerated.

However, under the present experimental conditions, dissimilarities were seen in the relative effectiveness of Ca^{++} and neostigmine to antagonize the effects of neomycin on gastrocnemius and soleus contractions. Consistently, Ca^{++} was more effective than neostigmine in antagonizing the effects of neomycin in the gastrocnemius than in the soleus, although the gastrocnemius was affected by neomycin to a greater extent than was the soleus. Conversely, neostigmine was more effective than Ca^{++} in restoring normal muscle twitch height in the soleus than in the gastrocnemius (figs 5 and 6).

Four adult cats were allowed to breathe spontaneously and respiratory movements were monitored along with gastrocnemius and soleus twitches. An antibiotic (gentamicin, n=2; streptomycin, n=2) was repeatedly administered until apnea occurred. In each case, respiratory movements gradually decreased with succeeding doses of antibiotic but apnea did not occur until, or after, soleus twitch became completely depressed. A typical recording is shown in figure 7.

Studies in adult cats demonstrated that aminoglycoside antibiotics affected fast-twitch to a greater extent than slow-twitch muscle. This differential potency was examined further by the use of kittens. Skeletal muscles of kittens initially demonstrate slow-twitch characteristics until differentiation occurs during the first few weeks of life.[16] In the present study, the younger kittens were not as susceptible to the muscle twitch depressant effects of neomycin as were the older kittens (table 2).

TABLE 2

Neuromuscular-Blocking Effects of Neomycin on a Sciatic Nerve-Calf Muscle Preparation in Kittens

	Decrease in muscle twitch by neomycin, mg/kg		
Kitten age	7	14	28
	% ± SE		
< 6 wk (n = 6)	1.8 ± 1.2	13.4 ± 2.7	53.8 ± 6.4
> 7 wk (n = 5)	5.6 ± 0.8	52.1 ± 6.8	100.0 ± 0.0
Significance	<0.05*	<0.001*	<0.001*

*Student's *t*-test.

Control muscle twitch of <6-week-old and >7-week-old kittens averaged 127.5 ± 14.5 gm and 132 ± 10 gm, respectively.

DISCUSSION

Although the potential seriousness of antibiotic-induced respiratory paralysis in isolated cases is well established,[2] the incidence of such complications is exceedingly small in relation to the magnitude of antibiotic use. This can be attributed primarily to the low potency of the neuromuscular-blocking effects of these agents when compared to their antimicrobial activity. Aminoglycoside antibiotics have been found even less potent on slow-twitch muscle than on a fast-twitch muscle preparation similar to

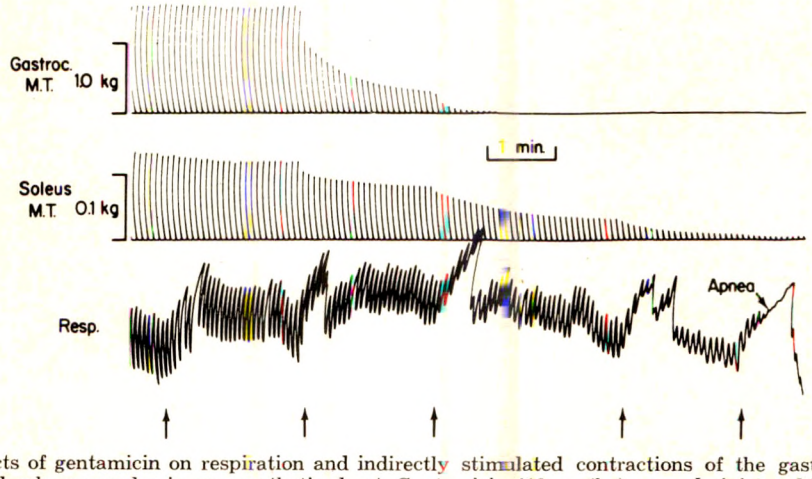

FIG 7. Effects of gentamicin on respiration and indirectly stimulated contractions of the gastrocnemius (Gastroc.) and soleus muscles in an anesthetized cat. Gentamicin (10 mg/kg) was administered IV at each arrow. M.T. = muscle twitch. Resp. = respiratory movements.

those commonly employed to examine these drugs.

In anesthetized adult cats, neomycin, gentamicin, and streptomycin were more effective in decreasing indirectly stimulated twitch of the fast-contracting gastrocnemius than of the slow-twitch soleus muscle. Since paired muscles of the same hind limb were tested concurrently by electrical stimulation of a common nerve trunk, it seems unlikely that observed differences in susceptibility of the gastrocnemius and soleus were due to variations in such factors as nerve stimulation, temperature, blood flow, or other secondary influences.[10] Rather, there seems to be a direct difference in responsiveness of the 2 muscle types to the neuromuscular-blocking effects of aminoglycoside antibiotics. This is further supported by findings in kittens. Skeletal muscle of newborn kittens reacts like slow-contracting muscle. Differentiation into respective slow- and fast-twitch types progresses with age and is usually complete or near complete in kittens >6 weeks of age.[16] In the present study, neomycin was relatively less potent in reducing the strength of indirectly stimulated twitch in kittens <6 weeks old.

Some respiratory muscles, like intercostals,[17] respond to drugs as slow-twitch muscles. In the present study, respiratory-depressant effects of gentamicin and streptomycin were more closely associated temporally with effects on soleus than on gastrocnemius twitch. This seems to support the contention that slow-contracting muscles are more resistant to the antibiotics studied. However, since contractile responses of respiratory muscles were neither individually nor directly examined, it is not known if the gradual diminution of ventilatory movements produced by repeated injection of an antibiotic reflects a decreasing fast muscle component (diaphragmatic)[10] in the presence of continued function of slow-twitch muscles or simply a resistance of respiratory muscles per se to the antibiotics.

Fast- and slow-twitch muscles are known to exhibit different sensitivities to clinically useful peripherally-acting muscle relaxants. With some exceptions, fast-twitch muscle is generally more susceptible to the depolarizing type of neuromuscular-blocking agent, whereas slow-twitch muscle is usually more responsive to the nondepolarizing curariform drugs.[8-12] Aminoglycoside antibiotics act postjunctionally to produce a nondepolarizing desensitization of the motor endplate; however, they are also believed to have a significant prejunctional action.[1,6] Recently, these drugs have been reported to inhibit Ca^{++} uptake in cholinergic nerves[18] and, presumably by this mechanism, to decrease the quanta of acetylcholine discharged from cholinergic fibers.[6,18]

In the present experiments, Ca^{++} had a relatively greater effect on recovery of the gastrocnemius from the effects of neomycin than it did on recovery of the soleus. Conversely, neostigmine hastened recovery of soleus twitch more than it did gastrocnemius twitch. These relative differences were consistently observed despite the fact that, before intervention with neostigmine or Ca^{++}, gastrocnemius twitch was invariably depressed more than the soleus, suggesting that in cats the postjunctional effect of aminoglycoside antibiotics dominates in slow-twitch muscles but prejunctional action is predominant in fast-twitch muscles.

Inhibition of Ca^{++} function in nervous and nonnervous tissues has been recognized as a pharmacologic property of the aminoglycoside antibiotics.[1,18,19-25] We have proposed that, in some excitable cell types, these antibiotics interfere with the uptake or binding of Ca^{++} by "competing" with the cation for negative-charged and superficial binding sites on cellular membranes.[19,20,25] Direct or indirect evidence for this postulate can be interpreted from data obtained from *in vivo* cardiovascular studies,[26] isolated arterial smooth muscles,[19-21,25] cholinergic neurons (sympathetic ganglion),[18] crab muscle fibers,[24] isolated sarcoplasmic reticulum fragments of skeletal muscle,[23] and isolated cardiac muscle.[22]

The difference in susceptibility of slow- and fast-twitch muscles to Ca^{++} and neostigmine during aminoglycoside antibiotic-induced neuromuscular blockade may be related to dissimilarities in prejunctional dependence upon Ca^{++} of respective motor nerves, nerve terminals of motor fibers innervating slow-twitch muscle perhaps being more resistant than analogous structures of fast-twitch muscle to the Ca^{++}-antagonistic properties of the neomycin-streptomycin antibiotics. However, the possibility cannot be excluded that postjunctional cholinergic receptors of fast-twitch muscle are more sensitive to the antibiotics than are receptors of slow-twitch muscle.

A difference in receptor configuration of fast- and slow-twitch muscles resulting in

different sensitivities to neuromuscular blocking agents has been suggested.[12] Although this remains to be established in relation to aminoglycoside antibiotics, present findings may partially explain why variable success has been encountered during attempts to reverse (clinically and experimentally) and even to demonstrate (experimentally) the neuromuscular-blocking effects of these antibiotics with different muscle types.[1,2,15,27] By inference, it seems possible that the difference in responsiveness of fast- and slow-twitch muscles to the clinically useful neuromuscular-blocking agents may also depend, at least in part, upon relative differences in the pre- and postjunctional inhibitory effects of these drugs.

"Acupuncture Anesthesia" — A Clinical Study

JEROME H. MODELL, MD*
PETER K. Y. LEE, MD†
HAL G. BINGHAM, MD‡
DONALD M. GREER, JR., MD§
MUTAZ B. HABAL, MD‖
Gainesville, Florida**

Forty-two patients who were to undergo plastic surgical procedures were asked whether they would accept acupuncture as a substitute for local anesthesia. Eight patients agreed to acupuncture; one of these had 2 operative procedures with acupuncture. Five of the 9 procedures were successful; the remaining 4 required conversion to local anesthesia.

After interviewing the patients, we felt that the success of "acupuncture anesthesia" was largely dependent on patient motivation, and that a patient may experience pain during surgical procedures without any change in facial expression or vital signs. We concluded that "acupuncture anesthesia" is of little value in our patient population at present. Its results are unpredictable; therefore, we anticipate that patient acceptance will be small.

IN 1958, in response to Chairman Mao Tse Tung's suggestion that traditional Chinese medicine is a "great treasure house" and should be combined with Western medicine and elevated to new heights, physicians in the People's Republic of China began using the traditional technic of acupuncture as anesthesia for surgical procedures. Enthusiasm for the technic, even in the People's Republic of China, grew slowly until the proletarian cultural revolution in 1966.†† Since that time there has been a concerted effort by physicians and patients in the People's Republic of China to adopt this combination of traditional and Western medicine whenever possible. Reports of operations performed successfully under "acupuncture anesthesia" in the People's Republic of China are commonplace in the American press.

One of us (Modell) was privileged to be a member of the Acupuncture Anesthesia Study Group of the Committee on Scholarly Communication with the People's Republic of China in May 1974. As such, he was the guest of the Chinese Medical Association for 22 days and observed surgical procedures performed under acupuncture. Some details of that visit have been published elsewhere.[1] Because of the questions raised in that report relating to whether a combination of acupuncture and surgery could be successful for patients in the United States, we conducted the following study.

PATIENT SELECTION AND METHODS

Patients were selected who were to have plastic surgical procedures that could be

converted easily to local anesthesia should acupuncture fail. Each patient was interviewed before the operation and given the choice of having the procedure performed under "acupuncture anesthesia" or under local anesthesia. All patients were told that if they felt uncomfortable at any time during the surgical procedure while under acupuncture, they could request that the acupuncture be terminated and local anesthetics be used. All questions asked by the patients were answered.

None of the patients received any form of premedication. Patients were given acupuncture along traditional meridians appropriate for the site of operation, using needles stimulated electrically with a stimulator capable of producing up to 9 volts at a frequency of 1 to 200 Hz. In general, current intensity and frequency were usually adjusted to the patient's tolerance. Acupuncture induction time was a minimum of 20 minutes. The surgical field then was prepared and draped and the operative procedure begun. The procedures were considered as either a success or failure, according to whether the patient requested that acupuncture be terminated and whether more than 2 ml of local anesthetic was used. In no case were analgesic drugs given.

RESULTS

Of 42 patients interviewed, 8 requested acupuncture. One of these patients had 2 procedures performed under acupuncture.

The first patient was a 20-year-old medical student who was to have a granuloma of the scalp excised. Needles were placed bilaterally at Chuan-Liao (SI-18), Tsu-Lin-Chi (GB-41), and Tsan-Chu (BL-2). In this patient, we did not attempt to increase the intensity of the stimulus to the patient's tolerance. Upon incision of the skin, the patient reported that he was undergoing an experience in "acupain." The acupuncture was terminated and a local anesthetic was infiltrated. The procedure continued without incident.

The second patient was a 45-year-old woman who had contacted one of the authors and requested that a rhinoplasty be performed under acupuncture anesthesia. She said that she had needed a rhinoplasty for a number of years but, because of her fear of both local and general anesthesia, had delayed the procedure. She reported that she was well motivated and wanted to volunteer for the study.

Acupuncture needles were placed bilaterally at Ho-Ku (LI-4), Chu-Chih (LI-11), and Tsu-San-Li (St-36). The patient underwent a 2½-hour rhinoplasty, including bilateral fracture of the nasal bones. Epinephrine (1:200,000) in saline solution was infiltrated from the beginning of the procedure to help control hemostasis.

Throughout the procedure, the patient frequently complained that the electrical stimulus of the acupuncture was too intense. Although she lay quietly on the operating table during much of the surgical procedure, she frequently voiced displeasure, reporting a feeling of intense pressure, particularly when tissues were spread rather than cut. When the nasal bones were to be fractured, the patient reported being quite uncomfortable, and 1 ml of 1% lidocaine with 1:200,000 epinephrine was injected on each side. During the procedure, the patient's pulse and blood pressure remained reasonably stable, despite discomfort.

At the conclusion of the procedure she apologized for any suggestion that she may have been uncomfortable and stated that she had not felt pain, was very pleased with the procedure, and would be happy to undergo a procedure under acupuncture in the future. This procedure, therefore, was considered successful. However, the anesthesiologist and surgeon were more impressed with the patient's endurance than with the analgesia afforded by the acupuncture.

Approximately 3 months later the patient was readmitted for revision of the tip of her nose. This second procedure also was performed under acupuncture but this time without complaint, incident, or changes in vital signs.

Patients 3, 4, and 5 were women, aged 26, 31, and 35, who were scheduled for augmentation mammoplasty. Acupuncture needles were placed bilaterally at Ho-Ku, Nei-Kuan (EH-6), and Tsu-San-Li. When the skin was incised, these patients complained of pain, and soon after the beginning of the procedure requested local anesthesia.

Patient 6 was a 28-year-old woman who had her earlobe reconstructed under acupuncture with no discomfort and no observable signs of pain. Needle placement was bilaterally at Ho-Ku and Shya-Chu (St-6).

Patient 7 was a 24-year-old woman who had needles placed bilaterally at Yang-Pai (GB-14) and Ho-Ku. A foreign body was

removed from the upper eyelid below the level of the levator, also with no reported discomfort or obvious signs of pain.

The 8th patient was a 35-year-old woman who had an augmentation mammoplasty. Needles were placed bilaterally at Ho-Ku, Nei-Kuan, and Tsu-San-Li. Because she complained of some discomfort upon incision through the right nipple, 0.5 ml of 1% lidocaine with 1:200,000 epinephrine was injected into each nipple. No other local anesthetic or analgesic agents were used. The remainder of the 2½-hour procedure was without incident and there was no change in vital signs at any time. The patient appeared calm, relaxed, and comfortable throughout, at times appearing to be dozing.

The patient did request that the intensity of the acupuncture be increased on several occasions but did not report a feeling of pain and did not request local anesthesia. Vital signs at these times were stable. At one point, she asked what was being done. She reported it was as though she were "being touched with a soldering iron," although it did not hurt. This coincided with the use of cautery deep on the chest wall. At the conclusion of the procedure, the patient reported she was comfortable. The surgeon and anesthesiologist considered the procedure an outstanding success. Because the procedure had gone so well, the patient was given a hand-held tape recorder to dictate her thoughts over the next 24 hours.

Pertinent excerpts from that tape are as follows:

"These thoughts have come upon me: 10:25 p.m. What pain I did feel is still vivid at this moment. As sensitive as my breasts—especially the nipple area—are, my greatest anxiety at this moment is fear of a complication that would warrant reopening or any extra surgical measures at this time. In effect, if I had not felt any pain in surgery, I would not fear going back into it.

"At first the entire incision really hurt, then I felt it most at one central point. I was able to tolerate it and from then on there were varying degrees of pain—sharp, short pains which seemed to be snips. I have skinned turkey legs not wanting to peel the film that keeps in the juice. I felt as if this is what was happening when the pockets were being made. It's hard to say why certain areas hurt more than others. Something happened on the left side and the pain was far up near my armpit around the area one would put a thermometer. It was hot and burning and a surprise. Several more times from then on I felt it. I don't think I could have tolerated a lot of it without squawking a little. I wanted to tolerate in silence as much as possible because I knew you would switch to local if I wanted and I didn't want this to happen until I could no longer control my reaction. There were periods of time when all I felt were pressure and pulling. It seems like those points allowed me to face the more painful areas, knowing that the worst would not last too long. As time went by I had such a desire to sleep I would relax and try to alienate the pain from my mind so as to rest and replenish courage. I was weakening. I felt and had such a feeling of dismay, not wanting to relate how I felt any more, just wanting to get it over.

"It is now 12:55 a.m. I am not really sleepy. I am going to relate, as best I can recall at this moment, my feelings mentally, as well as physically, pertaining to all aspects of the operation, as I could see it and feel it. Having never read about acupuncture, I was unaware of how it was done and didn't think electric currents were a part of it until Dr. Modell explained it, and before going to surgery Dr. Lee demonstrated what to expect. After being hooked up entirely and the current started, there were a few minutes of discomfort, ie, a heavy ache and my hand seemed to contract. After only a few minutes the aching subsided and the electrical current was soothing. I found myself wanting to relax and sleep but anxiety would not let me do so. I have described already the feeling through the surgery. As I seemed to feel more pain, I asked for more current. This seemed to help, although I'm not sure if it was the distraction of the surge of electricity or the lessening of the concurrent pain. At any rate it was helpful. At one time I reached a point while asking for current that it seemed too much and I asked for a lessening. Towards the end of the surgery it seemed as if my hands and left leg were getting tired and heavy. However, at no time did I experience anything pertaining to the acupuncture itself as painful."

DISCUSSION

Reports from the People's Republic of China suggest that "acupuncture anesthesia" is successful in over 90% of the patients in whom it is used. To interpret these figures, it is necessary to understand the

Chinese definition of "successful." The Chinese grade the results of "acupuncture anesthesia" in 4 categories: grades I through III are considered successful; grade I is used when the patient has little or no discomfort during the operative procedure and there are minimal changes in vital signs; grade II, when the patient has slight discomfort that can be controlled with small doses of narcotics and local anesthetics. Also, there may be moderate changes in vital signs. Grade III is used when the operation can be successfully completed, but the patient has periods of moderate to severe pain, changes in vital signs, and requires larger doses of parenteral medication and local anesthesia to complete the procedure; and grade IV when acupuncture fails and the operation must be abandoned or the patient given general anesthesia.[1]

The Chinese repeatedly point out that "acupuncture anesthesia" is still an experimental technic and represents an attempt to blend traditional Chinese medicine with Western medicine to improve health care for their people. They acknowledge that some of the present problems with "acupuncture anesthesia" are that many patients suffer incomplete analgesia, that muscle relaxation may be poor, that it does not abolish reflexes, and that patients frequently complain of feeling traction when viscera are manipulated, particularly during operations within the abdominal cavity.

The Chinese also stress the need for proper patient selection. "Acupuncture anesthesia" is not recommended for every patient; it is considered only when an accurate preoperative diagnosis has been established, when the surgical procedure promises to be uncomplicated, and when the patient agrees to have acupuncture after the advantages of "acupuncture anesthesia" and the disadvantages of general anesthesia have been explained. It is estimated that only 20% of patients in the People's Republic of China are operated on with "acupuncture anesthesia."[2]

In some patients, there is considerable preparation; patients who are to undergo thoracotomy must successfully complete a variety of breathing exercises for approximately a week before the operation. The anesthesiologist counsels the patient, and the surgeon and other patients in the hospital ward who have had "acupuncture anesthesia" tell him what they believe its advantages are. Also, each step of the surgical procedure is explained. Patients who are nervous or apprehensive are not considered suitable candidates. It is stressed repeatedly that for "acupuncture anesthesia" to be successful, the surgeon must be precise, rapid, and extremely gentle; tissues must be handled with a minimum of trauma, and retractors are seldom used in the wound. In addition to acupuncture, most patients in the People's Republic of China received approximately 100 mg of phenobarbital and 50 mg of meperidine preoperatively.

Observations in China.—The Acupuncture Anesthesia Study Group had the opportunity to observe, in depth, 48 patients who were preselected to have operations performed under "acupuncture anesthesia." The operations included such diverse procedures as tooth extractions, craniotomy for tumors, ophthalmologic surgery, tonsillectomy, thyroidectomy, pulmonary lobectomy, mitral commissurotomy, repair of ventricular septal defect with extracorporeal circulation, subtotal gastrectomy, ovarian cystectomy, abdominal hysterectomy, inguinal herniorrhaphy, and arthrotomy of the knee. Unfortunately, the Study Group did not observe a sufficient number of procedures in each category to be able to report any statistical significance regarding the success rate in any particular type of surgical procedure.

Of the 48 procedures seen, 25 patients (52%) fell into the category of grade I, and 10 patients (21%) into the category of grade II. The remainder (27%) were classified as grade III or IV.[1] There is no way to predict whether the same statistics would apply to a group of patients similarly selected and prepared in the United States. However, if one assumes that the American patients' responses to surgery and discomfort would be similar to those of the patients observed in the People's Republic of China, grade I results would be applicable to both populations. We also believe that many of our patients would accept a grade II result, but that grades III and IV would be unacceptable. Of the 9 procedures reported in our study, 4 would fit the grade I category. The rhinoplasty would be grade II, and 4 procedures would fit grade III or IV.

It was extremely difficult to interpret accurately the response of some of the patients observed in the People's Republic of China because, since none of them spoke English, the Study Group had to work through an interpreter. Many of the patients

reported a feeling of heaviness, pressure, and traction but denied pain. Because we were unable to question the patient directly, it was difficult to say with certainty whether the words "pain," "pressure," and "traction" were interpreted in the same way by patients and observers. At least 1 patient who had undergone a thyroidectomy described the feeling during operation as "pressure and traction." Upon detailed questioning through an interpreter after the operation, the patient admitted that she was unable to differentiate between what she called "pressure and traction" and what we called "discomfort" or "pain."

This difficulty in communication and the suggestion by some members of the Study Group that political motivation, education, conditioning, or some type of ethnic difference could explain the success of acupuncture in the People's Republic of China led to our current study. Our experience, particularly with patient 2 (rhinoplasty), certainly emphasized the importance of motivation in the success of the procedure. Our experience with patient 8 (augmentation mammoplasty) places considerable doubt on the ability of an observer to determine if a patient is experiencing pain. From all appearances, this patient was comfortable throughout the procedure. She had no change in blood pressure, pulse, respiratory rate or pattern; did not show any facial signs of discomfort; and did not appear to be peripherally vasoconstricted or to perspire. The 2 anesthesiologists who continually observed the patient were not able to detect any evidence of pain. However, the patient obviously felt pain, as evidenced by her very vivid and detailed report.

In spite of extensive research in the People's Republic of China, no definite physiologic mechanism for "acupuncture anesthesia" has been demonstrated.[3] We do not know if it produces anesthesia, analgesia, or hypalgesia. Perhaps hypalgesia is a more accurate description of what the Study Group observed. Another consideration was that needles were placed in traditional meridians and in "new experimental points," some of which were paraincisional, some segmental, and some appeared to be placed directly over or into a major nerve in an attempt to produce "acupuncture anesthesia." Seldom were needles placed in the same location for the same procedure in different patients. One professor in Peking reported, upon questioning, that a Peking surgeon gave the needle to the patient and let him insert and rotate it. He allegedly had a 90% success rate.

CONCLUSIONS

We conclude that the success of "acupuncture anesthesia" is largely dependent on patient motivation. It is well known that each patient's tolerance to pain is different.[4] It is entirely possible that a patient with a high threshold for pain and excellent motivation might be sufficiently distracted by the electrical stimulus of the needles from feeling pain during operation. It also is apparent from our small series that patients may experience pain without producing changes in their vital signs. Thus, it is virtually impossible, by purely clinical observation, to determine if the patient is experiencing pain. Pain appears to be a private experience of the patient which does not always lend itself to objective evaluation by the observer.

Our study suggests that "acupuncture anesthesia," analgesia, or hypalgesia is presently of little value for patients in the United States. Its results are unpredictable and general patient acceptance, therefore, is anticipated to be small. At present, the only clinical application we foresee would be for the patient who is to undergo a superficial procedure in which the risks of general anesthesia are not warranted and who reports a previous true hypersensitivity to a wide variety of local anesthetic agents. If such a patient also is well motivated, has a high pain threshold, and is willing to submit to the procedure, it is possible that he may be successfully operated on under "acupuncture anesthesia."

Perioperative Awareness and Recall

VOLKER EISELE, MD*
AVRON WEINREICH, MD†
STUART BARTLE, MD‡
New York, New York§

This study was designed to introduce a relevant stimulus at successive time intervals during the entire anesthetic period, including the pre- and postanesthetic periods. Using galvanic skin responses, the authors were able to recognize a plane of light anesthesia and arousal, at which time it is considered that sensory input might be perceived. Presenting to the patient a stimulus of some relevance, but one not likely to be psychically traumatic, they investigated the correlation between the ability to maintain an attention span and to recall in the postoperative period. No recall was obtained during the intraoperative period, the first occurrence of recall being in the immediate postanesthetic period and the incidence of recall increasing with increasing time intervals after the end of anesthesia. The authors conclude, however, that since intraoperative awareness without recall is a possibility, care should be taken to avoid emotionally disturbing auditory stimuli throughout the anesthetic procedure.

Is this a dream? Do I wake or sleep?
Keats

THE problem of awareness during anesthesia has existed since Horace Wells' inglorious failure during his first public demonstration of N_2O anesthesia. In 1908, Crile[1] reported a case of complete awareness during N_2O-O_2 anesthesia and recommended morphine and scopolamine as premedication to produce amnesia. In 1950, Winterbottom[2] reported the first case of awareness during a thiopental-muscle relaxant-N_2O-O_2 sequence. Since then, numerous case reports and studies have appeared in the literature.

Many of these retrospective reports were due to obviously inadequate anesthesia. Prospective studies on awareness during general anesthesia have failed to confirm convincingly the occurrence of recall of an intraoperative event.[3]

All studies reported so far have been incomplete in several aspects:

1. They do not indicate at which level of anesthesia a stimulus was presented.

2. The stimulus presented in all retrospective studies (with the exception of Levinson's work[4]) were irrelevant to the patient's well-being, whereas in those reports (including Levinson's) in which recall was reported, the stimulus was generally of a threatening nature.

3. No study has been undertaken in which a series of stimuli were presented systematically at different time intervals during the pre-, intra-, and postanesthetic periods.

The present study was designed to introduce a relevant stimulus at successive time intervals during the entire anesthetic period, including the pre- and postanesthetic periods. Employing the galvanic skin response (GSR),[5,6] we were able to recognize a plane of light anesthesia and arousal, at which time it is considered that sensory input might be perceived. We also presented

to the patient a stimulus of some relevance, but one not likely to prove psychically traumatic. Correlation between the ability to maintain an attention span and recall in the postoperative period was investigated.

METHOD

From June 1974 to January 1975, 250 patients undergoing various elective surgical procedures were studied. Ages ranged from 18 to 88 years. All patients were interviewed either at the time of the preoperative visit or on arrival in the induction room. At this time they were told that they would be given a number to remember either prior to induction, while they were anesthetized, or during the recovery period. Premedications used were atropine or scopolamine in combination with a sedative such as diazepam, secobarbital, Pantopon®, meperidine, or a combination of these agents given in standard doses. Anesthesia was induced in most cases with a sleep-dose of thiopental, in some cases with the addition of diazepam or Innovar®. Anesthesia was maintained by either inhalation agents such as halothane or enflurane or a neurolept technic using Innovar-fentanyl in combination with N_2O-O_2 and a muscle-relaxant (d-tubocurarine or pancuronium).

The 250 patients were divided into 5 equal groups, depending on the stage at which the stimulus was presented:

Group A: Prior to induction

Group B: Intraoperatively

Group C: Pre-extubation

Group D: On arrival in recovery room

Group E: Apparently awake

Group A was given an auditory stimulus; a random double digit number was chosen just prior to induction of anesthesia approximately 45 to 60 minutes after the administration of premedication. When the patients were in the recovery room and clinically awake and oriented to time and place, they were questioned about the number and were again questioned 24 hours later.

Patients in group B were given an auditory stimulus by means of earphones placed with the patients asleep to ensure a given constant amplitude of stimulus. A tape recorder delivered the message in an authoritative manner: "The doctor says you need number . . . ," followed by a double digit number. The message was repeated twice. This method of presentation was believed to be of some relevance to the patient without producing possible anxiety. Forty patients were given this input while clinically anesthetized with varying technics.

Ten patients of group B were considered separately. Atropine was omitted from the premedication because of its autonomic blockade activity; deep curarization was avoided because of its possible ganglionic-blocking effect; and anesthesia was maintained with N_2O-O_2 (70:30) and narcotic supplementation. These patients received their auditory stimuli during a period when GSR indicated autonomic activity. These responses are linearly related to the secretion of sweat and are an early response to stimuli normally absent during deep anesthesia. The autonomic activity as recorded by the GSR correlates with a period of arousal. The GSR was recorded with silver-silver chloride electrodes, placed on the surface of the 2nd and 4th middle phalanges. Input was recorded on a standard Beckman GSR coupler.

After termination of the anesthetic when the patients were clinically awake and oriented to time and place, they were asked: "Do you remember anything unusual the doctor said?" This was repeated on leaving the recovery room and again 24 hours later.

Group C patients were given an auditory stimulus at the termination of anesthesia prior to extubation. This was suggested to them at a time when they were able to follow verbal commands such as "lift your head," "open your eyes," "squeeze my hand." The message was delivered in an authoritative manner: "It is very important for you to remember number . . ." The patients were questioned about the number when they were clinically awake and oriented to time and place, and again 24 hours later.

Group D patients were given both an auditory and a visual stimulus consisting of a giant playing card (at the same time vocalizing the number appearing on the card) approximately 5 to 10 minutes after termination of anesthesia when they arrived in the recovery room. Also tested was their ability to maintain an attention span by having them observe the examiner's finger in front of their eyes as long as possible. The time of the attention span was recorded. These patients were questioned 1 hour later in the recovery room for any recall of either the auditory or the visual stimulus. If they

were not able to recall the number of the card, they were presented with a choice of 3 cards, including the one previously shown to them.

Group E patients were interviewed in the recovery room when they were considered clinically awake with a normal attention span. They were given the same auditory and visual stimulus as described for group D and were questioned about these stimuli approximately 1 hour later.

RESULTS (table 1)

1. All 50 patients in group A recalled the numbers presented prior to induction at 1 hour and 24 hours later, irrespective of the premedication and anesthetic agents.

2. None of the 50 patients in group B given the message by earphones, including the patients to whom the stimulus was given at an arousal period as indicated by GSR, had any recall, irrespective of premedication and anesthetic agents.

3. Four of the 50 patients in group C were able to recall the number given prior to extubation; 46 patients had no recall. All 4 patients with positive recall had thiopental induction followed by N_2O-O_2 with narcotic supplementation (Innovar® and fentanyl, 2 cases; meperidine, 2 cases) and a muscle relaxant (tables 2 and 3).

4. Of the 50 patients in group D, 28 had positive recall for the given number, 22 patients had no recall (tables 4 and 5). Mean attention span in the 28 patients with positive recall was 42.6 ± 13 seconds and in the 22 patients with no recall was 4.3 ± 2.4 seconds.

5. All 50 patients in group E recalled both the auditory and visual stimuli.

DISCUSSION

The formation of a memory involves successive stages of registration: Information input leads to the formation of short-term memory, followed by consolidation and storage of a long-term memory. Whether a given input will lead to the formation of either a short-term or long-term memory (a memory "engram") depends upon the strength of the input and the sensory threshold at the time.[7]

It has been postulated that anesthetic amnesia occurs by impairment of the memory-consolidation process, presumably between the short-term and long-term memory formation and by attenuation of sensory transmission.[7]

When transient lightening of the anesthetic level coincides with an auditory stimulus of a highly emotional content, the possibilitiy of memory consolidation and later recall exists. The problem of recall of an

intraoperative event has never been a feature of deep inhalation anesthesia. Only fairly recently, with the advent of the thiopental-muscle relaxant-N_2O-O_2 technic and the concept of balanced anesthesia, have reports of recall of intraoperative events, usually of an anecdotal nature, appeared. The increased use of the neurolept-muscle relaxant sequence is partly due to its value in high-risk patients and as an alternative to repeated exposure to halothane.

The desire to maintain a high F_{IO_2} during anesthesia contributes to a reduction of the analgesic and amnesic effects of N_2O. In addition, the current concept of maintaining the P_{aCO_2} nearer to physiologic values negates the possible analgesic effects of hypocapnia suggested by Geddes and Gray.[8]

As a consequence, an inherent danger of the neurolept-muscle relaxant technic lies in an uneven anesthetic state, where an adequately anesthetized sensorium alternates with peaks of arousal, without the operator being alerted by the more obvious clinical signs of too-light anesthesia. It is during this period that the patient may be aware of external stimuli, if the stimuli are of a highly emotional or threatening content. They may be stored in some part of memory, producing anxiety, and possibly later emotional disturbance.[9]

While Guedel's stages for ether anesthesia still remain a yardstick for measuring anesthetic depth, and the EEG patterns obtained during anesthesia with other volatile agents provide repeatable levels, the neurolept technics have no equivalent staging; the EEG may even show an awake pattern,[10] while the clinical signs of autonomic activity are often difficult to interpret. In this situation, the GSR is a better indication of anesthetic depth.

None of the patients in group A (preinduction) showed anterograde or retrograde amnesia irrespective of premedication or anesthetic agents used. While previous work has demonstrated profound amnesic effects of scopolamine and diazepam, we were unable to demonstrate any amnesia for the preoperative period. As for diazepam, this may not be surprising, since others[11,12] have shown that dense anterograde amnesia is present only for 10 to 15 minutes after the IV injection, with less severe impairment existing up to one-half hour. We gave diazepam IM ± 1 hour before operation, when an amnesic effect would no longer be expected. The absence of retrograde amnesia following the various anesthetic technics used is in agreement with the findings of Dundee and Pandit,[13] who were unable to confirm the depressant effect of anesthetic agents on a consolidated memory.

We were unable to obtain any recall from patients in group B, whether "adequately" anesthetized or in a state of arousal. This is in contrast to the work of others in the field,[14-22] where seemingly innocuous and irrelevant information has been volunteered in the postoperative period by patients supposedly anesthetized, while undergoing surgical procedures.

Of the 50 patients in group C (pre-extubation period) 25 patients were anesthetized with a volatile agent (halothane or enflurane) and 25 were anesthetized with a thiopental-N_2O-O_2 technic supplemented by a narcotic agent (meperidine or fentanyl). All patients responded to verbal commands. No recall was obtained from patients anesthetized with a volatile agent, whereas 4 patients in the group anesthetized with a neurolept technic had positive recall. One of these 4 patients, on later questioning, was under the impression that the number was given to him during the operation itself.

Where an N_2O-O_2-muscle relaxant technic alone is employed, the incidence of recall has been reported as high,[23] and awakening is prompt upon withdrawal of N_2O. Similarly, with short-acting narcotic supplements, the patient awakes promptly and a high incidence of recall is reported. Those patients anesthetized with volatile agents would be expected to have suppression of memory consolidation for a considerable time after the termination of anesthesia as the agents slowly elute from the extravascular depots, re-enter the circulation, and prolong anesthesia.

These observations hold true in our comparison of results of groups C and D. The more time that elapsed following termination of the anesthetic, the higher the incidence of recall. At the termination of the anesthetic, only 4/50 in group-C patients had recall, while 28 patients in group D had positive recall. Approximately 2/3 of these patients had received neuroleptanesthesia and approximately 1/3, a volatile agent.

The postoperative attention span shows a close correlation with the memory-consolidation process and subsequent recall, those with a short attention span having no recall and those with a normal or long attention span having complete recall. The determination of the postoperative attention span represents a valuable measure of a patient's ability to recall information given at this time and is easily applicable to the clinical situation.

All patients in group E who appeared to be clinically awake were able to retain a memory of their given stimulus.

An anesthetic may be considered to start with the awake and medicated patients and continue through the various stages of anesthesia to the "awake" patient, who may be still emerging from his anesthetic, the results of which may be evident for as long as 2 weeks.[24]

The altered perception may range from total amnesia, dreams, and/or hallucinations, to a loss of 2-point discrimination. Memory, by definition, can only occur during a period of awareness; and where this occurs even momentarily during the course of an anesthetic, it must be regarded as inadequate anesthesia for that period.

We were not able to obtain any recall during the intraoperative period and in some instances even into the postoperative period when the anesthetic had been discontinued for some time. This does not mean that intraoperative awareness without recall is not a possibility. Attention should be given to careful and continuous observation of the patient's face throughout the surgical procedure whenever this is possible. A good anesthetic, light yet to be devised, would be invaluable.

We have been able to demonstrate time and again where a patient grimaces, wrinkles the forehead or moves his head, that where immediate contact is made by stroking the face or speaking reassuringly, the need for

further medication can usually be postponed. Surely this must be regarded as a stage of arousal and should it pass unnoticed either through inattention or because of lack of access to the patient's face, sensory input might be perceived, if not remembered, leading to cases of a Traumatic Neurotic Syndrome.[25]

It is our practice to induce with diazepam alone or supplement the induction of Thiopentone sodium with IV diazepam when a neurolept anesthetic technique is planned. The delay in recovery time is well worth the assurance that the likelihood of awareness and recall will be lessened.[26] Care should be taken during the operation to avoid emotionally disturbing auditory stimuli. Particular care is imperative in the pre-extubation period, and similar discretion is advocated in the recovery room, where confusion may exist for time and place, and events transposed in memory to the intraoperative period.

Severe Hypertension in a Child with Wilms' Tumor: A Case Report

MILTON L. COBB, MD*
ROBERT W. VAUGHAN, MD†
St. Louis, Missouri‡

Problems of management in a child with a large Wilms' tumor and severe uncontrolled hypertension presenting for anesthesia and operation included attempts to determine the etiology of the hypertension; identification of hazards produced by attempted rapid pharmacologic control of blood pressure; need for urgent operative intervention despite uncontrolled hypertension; and choice of anesthetic agent and technic.

THE association of Wilms' tumor (carcinosarcoma, embryoma, nephroblastoma, adenomyosarcoma) with hypertension was first reported in 1938 by Bradley and Pincoffs.[1] However, only 6 cases of severe hypertension (diastolic greater than 120 torr) in the child with Wilms' tumor have been reported.[1-6] No mention of this association or suggested management appears in the anesthetic literature. This report describes the anesthetic management of such a patient.

REPORT OF A CASE

A 27-month-old, 12.7-kg Caucasian boy was referred from another hospital for evaluation of hypertension associated with a large right-sided abdominal mass. During initial evaluation at the referring hospital, a venacavagram and an intravenous pyelogram were performed, revealing an abdominal mass displacing the right kidney downward and the inferior vena cava to the left of the midline. A chest roentgenogram was interpreted as normal, blood pressure was elevated (180/120 torr), and routine complete blood count and urinalysis were normal.

Following transfer, physical examination revealed an irritable thin child with a protuberant abdomen. Supine blood pressure was 210/140 torr in both arms; the pulse rate ranged from 100/minute (resting quietly) to 160/minute while crying. A firm, smooth, immobile mass was palpable in the right upper quadrant, extending vertically from the costal margin to the iliac crest and medially just across the midline. The extremities were warm and the palms of the hands constantly appeared flushed.

Laboratory values on the day of admission, including complete blood count, platelet count, serum electrolytes, blood urea nitrogen, serum liver enzymes, calcium, and phosphorus were all within normal limits. No evidence of mestastasis was found on chest or skeletal radiographs.

Attempts to control the blood pressure were begun immediately; intravenous and oral hydralazine, as well as intravenous diazoxide and furosemide were given. Nevertheless, over the next 36 hours, blood pressure varied from 170/120 torr to as high as 240/170 torr. Serum K^+ had fallen from 3.5 to 2.7 mEq/L in association with vigorous diuretic administration.

Because of concern for the complications of uncontrolled, sustained hypertension (especially a cerebrovascular accident),[3,7] it

Paper received: 11/3/75

Accepted for publication: 12/1/75

was decided to proceed immediately with surgical extirpation of the tumor. Presumptive diagnosis was Wilms' tumor, although neuroblastoma and pheochromocytoma were considered possible. A urine spot test for vanillylmandelic acid had, however, been reported as negative. No premedication was administered because the patient was sedated from a previous injection (meperidine 12 mg) given for planned, but canceled, arteriography.

Upon arrival in the operating room, while resting quietly, the patient's blood pressure was 200/120 torr with a pulse of 100/minute. Anticipating the possibility of either severe hypertension or hypotension requiring pharmacologic control, both phentolamine and norepinephrine drips had been prepared. A careful inhalation induction with halothane-N_2O-O_2 proceeded without difficulty, and endotracheal intubation was easily accomplished without muscle relaxant.

A radial-artery cannula was placed as soon as the patient lost consciousness, and wide-bore intravenous lines (16 gauge) were established in both upper extremities. During induction, the blood pressure gradually decreased to 120/70 torr and remained between 110/60 and 140/80 torr throughout the 4-hour operative procedure. Anesthesia was maintained with halothane (1 to 1.5% inspired concentration) with manually controlled ventilation.

Operative resection included the tumor mass involving the right kidney plus the adjacent, normal-appearing adrenal gland. Five percent dextrose in lactated Ringer's solution was administered at a rate of 8 ml/kg/hr. Operative blood loss (approximately 150 ml) was replaced with warmed whole blood as the loss occurred. Upon completion of operation and discontinuance of halothane, the blood pressure returned to 150/110 torr; hydralazine and subsequently methyldopa were required to maintain diastolic pressure below 120 torr.

Microscopically, the mass proved to be a Wilms' tumor with capsular infiltration. Biopsied adjacent nodes were negative for tumor, as was a biopsy of the opposite kidney. Chemotherapy and radiotherapy were begun, and at the time of discharge, 21 days postoperatively, the patient required continuation of methyldopa for adequate control of his blood pressure.

At the most recent follow-up, 7 months after tumor removal, antihypertensive therapy was discontinued, as the blood pressure had gradually returned to normal.

DISCUSSION

Except in association with pheochromocytoma, no description of the anesthetic management of the severely hypertensive child can be found in pediatric anesthesia texts. In the case of pheochromocytoma, hypertension is generally controlled pharmacologically prior to operation, so that normal blood and ECF volumes can be restored. With a Wilms' tumor, however, no reliable method of preoperatively adjusting vasomotor tone or blood volume toward normal has been reported.

Presumed mechanisms for the hypertension associated with Wilms' tumor include elevated renin levels secondary to renal ischemia produced by mechanical compression of the renal artery, secretion of renin by the tumor itself, and a possible unidentified pressor substance secreted by the tumor.[2] However, none of these possibilities would fully explain the observed course in this patient; he remained hypertensive for several months postoperatively, as have 2 previously reported patients.[2,5] Causes for continued renin production or pressor substance secretion in our patient were not apparent; there was no demonstrable residual or metastatic tumor tissue and the contralateral kidney was normal. Elevated blood-renin levels were present intraoperatively, but these values fell to normal by the day after operation. In spite of normal renin levels, antihypertensive medication was still necessary for pressure control.

Problems may be posed by therapy aimed at lowering blood pressure preoperatively. In 2 reported instances,[3,7] attempted preoperative control with antihypertensive drugs has not been successful; both children died preoperatively of hypertension-related complications. Of added interest, if renin is indeed a factor in the production of hypertension with Wilms' tumor, acute diuretic administration and vasodilating antihypertensive drugs may further increase renin activity.[8] Propranolol has been recently reported to cause a fall in renin activity,[8] so that one might be presented preoperatively with a child acutely treated with propranolol. The consequences of acute and possibly intense beta-blockade just prior to anesthesia have not yet been fully demonstrated.

Aggressive diuretic therapy may also alter serum electrolytes significantly. In our patient, serum K^+ fell from 3.5 to 2.7 mEq/L preoperatively. Use of nondepolarizing muscle relaxants could, therefore, result in a neuromuscular block which could not be predictably antagonized. Dangerous ventricular arrhythmias could be produced by halothane anesthesia administered in face of hypokalemia and hypertension. In addition, the possibility of acute ECF depletion consequent to potent diuretics might be masked by a marked degree of systemic vasoconstriction. In that situation, precipitous falls in blood pressure from anesthetic-induced vasodilation and myocardial depression could be predicted.

Presented with a child with severe, uncontrolled hypertension, we chose halothane for its controllability in lowering blood pressure to the desired level. We were concerned that sustained systolic levels of 150 to 200 torr would contribute to massive blood loss during resection. Equally worrisome was the possibility of a cerebrovascular accident if a further increase in blood pressure ensued during manipulation of the tumor. The possibility of a catecholamine-secreting tumor also was considered, despite a single preoperative negative urine spot test for vanillylmandelic acid.

Pharmacologic preparation for treatment of sudden hypotension and/or hypertension during extirpation of the tumor seemed prudent. However, the ease with which the blood pressure was controlled intraoperatively in this child was a pleasant surprise; this finding is consonant with the experience of at least 1 other pediatric anesthesia group.*

Clinical Evaluation of Injectable Lorazepam as a Premedicant: The Effect on Recall

CASEY D. BLITT, MD*
W. CLAYTON PETTY, MD†
WILL A. WRIGHT, MD‡
BARBARA WRIGHT§
Tucson, Arizona‖

A double-blind comparison of lorazepam and placebo, lorazepam and pentobarbital, and a comparison of lorazepam IV drip versus lorazepam IV bolus as a premedicant showed this new agent to offer promise as a sedative premedicant. However, the potency of the drug demands caution, and its use for outpatient premedication is not recommended.

LORAZEPAM¶, a 1,4-benzodiazepine sedative, has been reported to have antianxiety and antirecall effects.[1,2] The purpose of this study was to evaluate the efficacy of lorazepam as a preanesthetic medication in producing lack of recall for specific events prior to and after anesthesia and operation.

METHODS

Adult patients (n=140) in ASA classes I and II, weighing between 45 and 90 kg, were studied; all gave written informed consent before entering the study. None were receiving monoamine oxidase inhibitors or had a known sensitivity to barbiturates or benzodiazepines. No other sedatives or psychotropic durgs were permitted during the study, but no restrictions were placed on the technic of anesthesia selected. Neurosurgery, open-heart surgery, and organ-transplant surgery were specifically excluded.

The study was carried out in 3 parts. In part I, 50 patients were studied in a double-blind controlled manner, to document the differences between lorazepam (4 mg) and placebo (propylene glycol vehicle) administered IV. Meperidine (50 mg) and atropine (0.6 mg) were given IM to all patients approximately 1 hour before injection of lorazepam or placebo. Fifteen minutes after injection, a memory card consisting of a large dollar bill was displayed to obtain the patient's verbal response.

Patients were visually and verbally oriented to events and objects from the time they were transported from their hospital room until induction of anesthesia. Blood samples were analyzed for plasma concentrations of lorazepam. Twenty-four hours postoperatively, the following questions were asked:

1. Do you remember anything on the way to the operating room? 2. Do you remember entering the operating room? 3. Do you remember being moved from the stretcher to the operating table? 4. Do you remember seeing the operating room surgical light?

5. Do you remember being shown a card yesterday? (If the patient could not remember being shown the card, he was reminded that he had been, and was asked to pick it out of a composite of 8 different cards.) 6. Do you remember leaving the recovery room? 7. Do you remember the physician cleansing your skin for anesthesia? 8. Do you remember the physician sticking you with a small needle and asking you when you could feel the needle? 9. Do you remember the anesthesia mask being placed over your face? 10. Do you remember doubling up your knees in preparation for the anesthesia? 11. Do you remember the physician starting the IV? 12. Did the injection make you sleepy or drowsy? 13. Do you remember leaving your hospital room?

Part II of the study was a double-blind controlled study of 50 patients to determine the difference between lorazepam (4 mg) and pentobarbital (100 mg), administered IM as the sole premedicant the morning of operation. About 2 hours later, the memory card was shown. Patients were visually and verbally oriented to events and objects from the time they were transported from their hospital room until induction of anesthesia. The standard 24-hour interview was performed to determine the patient's recall ability.

In part III of the study, 40 patients were given lorazepam, either by IV drip or by an IV incremental bolus, 60 minutes after 50 mg of IM meperidine and 0.6 mg of IM atropine, to determine if some clinical evidence other than drowsiness would act as an endpoint for the drug administration. Patients were visually and verbally oriented to events and objects from the time they were transported from their hospital room until induction of anesthesia. Fifteen minutes after administration of lorazepam, a memory card was shown and a 24-hour interview to test recall ability was conducted.

Age, weight, and height differences in all groups were analyzed using a 1-way analysis of variance. Race proportions in all groups were compared by chi-square. Sex proportions, anesthetic agents, muscle relaxants, other intraoperative medication received, medication received in the recovery room, supplemental anesthetics, and surgical procedure classification were compared in all 3 groups by Fisher's exact test.

A subjective response by the patient and physician regarding sedation and patient acceptance (excellent, good, fair, not acceptable) was also elicited and subjected to chi-square testing in all 3 groups. The Fisher test was used to compare results of the 24-hour interview and to compare the incidence of adverse effects in all groups.

RESULTS

The drug groups (stratified by general and regional anesthesia types) were found to be homogeneous with respect to age, weight, height, sex, race, anesthetic agents, intraoperative muscle relaxants and other medication received, medication in the recovery room, supplemental anesthesia, and surgical procedures.

Group I: Lorazepam Versus Placebo (IV).—The sedative effect of lorazepam was observed by both the patient and the physician and was well accepted by the patient. These effects were not always evident in the placebo group. Recall for specific events as elicited by questions asked in the 24-hour interview is shown in table 1. In the lorazepam group, 85% of the patients tested and

*$p<0.01$.

†$p<0.05$.

( ) Percent failure to recall.

groups. ("Did the injection make you feel sleepy or drowsy?") No significant differences were noted regarding patient acceptance of medication or the physician's clinical judgment of premedication. Patients given lorazepam showed significantly less ability to recall events than those given pentobarbital, as evidenced by the results of the 24-hour interview (table 3). Sixty-eight percent of the patients in the lorazepam group could not recall the memory card and 47% failed to recognize the card from the composite picture. Only 16% in the pentobarbital versus 68% in the lorazepam group ($p<0.01$) failed to recall the card, and all recognized the card from the composite picture.

Part III: Lorazepam Drip Versus Bolus.—Drowsiness appeared at a mean dose of 0.053 (± SD 0.0268) mg/kg and at a mean time of 8.15 (± SD 3.4) minutes with the IV continuous drip method and with a mean dose of 0.059 (± SD 0.0268) mg/kg and a mean time of 6.9 (± SD 3.19) minutes by bolus. However, lack of ability to recall specific events was equally evident by both technics, as 82% could not recall the memory card and 64% failed to recognize the card from the composite picture. With sedation as an endpoint, 32/38 patients said they felt sleepy or drowsy following the injection. Euphoria was seen in 1 patient and hallucinations, with difficulty in depth perception, were reported by another. Acceptance of the medication by physicians and patients was good.

DISCUSSION

Our study indicates that lorazepam is a satisfactory preanesthetic sedative. Additionally, it effectively prevents recall of events surrounding the operative period, an effect certainly beneficial in some patients. The drug is well accepted and well tolerated by patients but is extremely potent and may prove difficult to learn to use effectively, since it is easy to "severely obtund" a patient for a long time in the postoperative period if too much is given. We recommend that it not be used for premedication of outpatients.

It became obvious at the end of our study that the dosage of lorazepam necessary to produce lack of recall may not necessarily correlate with the dosage necessary to produce an easily recognizable clinical effect, but the agent appears compatible with current anesthetic agents and technics. Although 3 patients exhibited CNS excitation following its administration, all were easily reversible with physostigmine.[3]

The benzodiazepine tranquilizer, diazepam, has been used successfully as an amnesic in combination with the N_2O-narcotic-muscle relaxant technic.[4,5] Ghoneim's group[6] attempted to relate plasma levels of diazepam and a diazepam metabolite, desmethyldiazepam, to mood levels. Correlation was found between plasma levels of diazepam and some of the mood ratings, but these authors concluded that plasma levels cannot be meaningfully related to cerebral effects without further studies. We have not seen any correlation between plasma levels of lorazepam and recall ability.

Intraoperative Awakening for Early Recognition of Possible Neurologic Sequelae During Harrington-Rod Spinal Fusion

K. G. SUDHIR, FFARCS*
ROBERT M. SMITH, MD†
JOHN E. HALL, MD‡
DOLLY D. HANSEN, MD§
Boston, Massachusetts‖

To permit early recognition of possible cord trauma due to spinal fusion with Harrington-rod instrumentation, 42 patients were awakened intraoperatively for testing voluntary motor function of the limbs. N_2O-O_2-curare and morphine were used for anesthesia in all patients. In 5 patients, who refused IV induction, halothane was given for induction only. Only 1 patient had any complaint referrable to being awakened intraoperatively. The awakening caused no displacement of Harrington rods in any patient. No neurologic sequelae were found.

POSTERIOR spinal fusion with Harrington-rod instrumentation for correction of scoliosis is increasingly common. One of the complications of this operation is paraplegia, with a reported incidence of 0.1%.[1]

To prevent this complication, Vauzelle and associates[2] awakened patients intraoperatively to check voluntary motor power of the limbs. The anesthetic agents used were hydroxydione, sodium succinate, succinylcholine, and diallylnortoxiferine (Alcuronium®) plus a narcotic (unnamed). Intraoperative check disclosed loss of voluntary leg motion following rod placement in 3 patients. In the first, motion returned within 5 minutes of rod removal. When the rod was replaced with less distraction, voluntary leg motion was lost again, but was regained on rod removal. In the second, the authors were able to replace the rod later, after halo traction. In the third, reduction of the distraction was sufficient to bring about return of function without removal of the rod.

At the Children's Hospital Medical Center of Boston, 340 patients were operated on for spinal fusion during the year October 1974-September 1975. Of this series, 2 patients are known to have had postoperative neurologic deficits. The loss of motor function in one was related to spinal operation but not to Harrington-rod instrumentation. The second case is reported here as an example of transient neurologic deficit due to use of a Harrington rod; this was detected early and countermeasures were taken which prevented permanent neurologic damage. The anesthetic technic employed for patients to be awakened intraoperatively is also described.

CASE REPORT

A 15-year-old girl was admitted with a diagnosis of idiopathic scoliosis which had been detected during a routine physical examination. She had no cardiorespiratory symptoms attributable to scoliosis. Neurologic findings were benign. Standing roentgenograms showed a right thoracic curve of 57° from 6th dorsal to 1st lumbar vertebras and a left lumbar curve of 43° from 1st lumbar to 5th lumbar vertebras. Hematocrit was 43.3% and urinalysis, electrolytes,

prothrombin time, and partial thromboplastin time were normal. Chest x-ray and pulmonary-function tests showed moderate restrictive lung disease.

The patient was scheduled for posterior spinal fusion from 5th dorsal to 3rd lumbar vertebras with iliac bone graft and Harrington-rod instrumentation. Premedication consisted of pentobarbital, 2 mg/kg orally at 0500 hr, and atropine (0.015 mg/kg), and morphine (0.15 mg/kg) IM, 90 minutes before operation , which was at 0800 hr. Anesthesia was induced with thiopental (5 mg/kg) and succinylcholine (1.5 mg/kg) IV, followed by endotracheal intubation with a 7-mm cuffed tube. Anesthesia was maintained with N_2O-O_2-curare and morphine. Anesthetic course throughout the operation was uneventful.

At the end of the procedure, the patient was turned supine on a Striker frame, with the endotracheal tube in place. Muscle relaxants were reversed with atropine and neostigmine. The N_2O was discontinued and 100% O_2 was administered. The patient opened her eyes and was awake within a few minutes.

As the anesthesiologist was preparing to extubate the patient, one of the surgeons asked the patient to move her feet. She was able to move her right foot but not her left. A sensory deficit was noted on the right side up to the midthoracic level. The patient also had urinary incontinence. At this time, she was conscious enough to raise her head, both arms, and right foot, but still could not move her left foot.

With the patient reanesthetized and placed prone on the operating table, the surgical incision was reopened and the Harrington rod removed. Fifth dorsal to 3rd lumbar interspaces were explored, but no abnormality could be detected. The incision was closed and the patient was again awakened in the supine position, but was still unable to move her left foot. Immediate postoperative neurologic examination demonstrated a band of sensory loss below the left nipple, loss of motor function in the left lower limb, and sensory loss in the right lower limb.

Progressive neurologic improvement was noted over the next 12 hours. A myelogram on the 1st postoperative day was negative. The patient remained incontinent of urine for the next 8 days and required intermittent catheterization (12 hourly). On the 9th postoperative day, urinary residual increased, and a cystometrogram showed a hypotonic autonomous bladder with denervation hypersensitivity to bethanechol chloride (Urecholine®). Intermittent catheterization was continued.

Treatment by localizer cast reduced her dorsal curve to 37° and lumbar curve to 23°. She was discharged to recumbency at home on the 23rd postoperative day. At followup 3 months later, a repeat cystometrogram was normal and the patient was found to have complete motor and sensory recovery except for a patch of sensory loss on the left side of the chest.

CASE DISCUSSION

The most likely cause of neurologic deficit after Harrington-rod instrumentation is the stretching of the arteries supplying the spinal cord. It is known that transient spasm or prolonged occlusion of the artery of Adamkiewicz will cause paraplegia at the 8th dorsal level.[3] Most paraplegias resulting from correction of scoliosis are at the 8th dorsal level, in curves measuring over 100°.[4] Other causes could be accidental surgical trauma to the spinal cord or compression of the spinal cord due to hematoma formation. In this patient, exploration of the wound did not reveal any visible damage to the cord, and the postoperative myelogram ruled out hematoma. Neurologic improvement during the 24 hours postoperatively indicated that the trauma to the spinal cord was of a transient nature.

Awakening Technic.—To prevent recurrence of the above complication, the practice of awakening patients during Harrington-rod instrumentation was adopted at Children's Hospital Medical Center and applied to 42/46 patients between January and May 1975. Of the 4 patients not awakened, 2 were mentally retarded and 2 were considered too young to cooperate (1 and 3 years of age). Preoperatively, all parents and all older children and adults were informed of this procedure, but younger children, under age 12, who might be frightened, were not so informed.

Preoperative medication for all patients consisted of pentobarbital (2 to 4 mg orally on the morning of operation) and atropine (0.015 mg/kg) with morphine sulfate (0.1 mg/kg IM) 90 minutes before operation. In 41/46 patients, anesthesia was induced by IV thiopental (3 to 5 mg/kg) followed by

1 mg/kg of succinylcholine and tracheal intubation. Five patients who refused IV injection were induced with N_2O-O_2-halothane. The halothane was used only for induction and was discontinued after an IV infusion was established. Anesthesia was maintained with N_2O-O_2-curare and morphine in all patients. Dosage of morphine during the operation varied from 0.1 to 0.2 mg/kg and curare from 0.35 to 0.5 mg/kg initially, with supplemental doses of 0.01 to 0.05 mg/kg morphine and 0.1 to 0.3 mg/kg curare, when necessary.

No special attempt was made to keep patients under light anesthesia for the sake of intraoperative awakening. Intervals from the induction of anesthesia to intraoperative awakening varied from 2½ to 6 hours and intervals from the last dose of curare to the time of intraoperative awakening ranged from 10 minutes to 4 hours.

To test spinal function after the Harrington rods were in place, N_2O was discontinued and patients were hand-ventilated with O_2. At this time, we insisted that the operative procedure be stopped and silence be maintained in the operating room while patients were awakened and until they were reanesthetized. A member of the anesthesia team observed the patient's feet under the drapes. Within 1 minute, the anesthesiologist called the patient by name and asked him to move his hands and feet. The *maximum time* to awaken after the N_2O was turned off was 5 minutes, and in most patients was less than 2 minutes.

Increases in blood pressure of 10 to 20 torr and pulse rate of 10 to 20/minute were noted in all patients at this time. In 1 patient, the curare had to be reversed with atropine and neostigmine before the patient was able to move his hands and feet on command. His last dose of curare had been given 20 minutes prior to intraoperative awakening. In 1 other patient, naloxone hydrochloride was needed to reverse the morphine. As soon as movement of the hands and feet was noted, patients were reanesthetized with 70% N_2O and 30% O_2, followed by thiopental (1 to 2 mg/kg) and supplemental doses of curare and morphine. Diazepam (0.1 mg/kg) was given to provide retrograde amnesia.[5]

In most instances, curarization was reversed and patients extubated in the operating room. In patients whose preoperative pulmonary-function tests showed less than 50% of predicted value, curare reversal has not been attempted. These patients have been supported by mechanical ventilation for 24 hours after operation, then weaned by intermittent mandatory ventilation and extubated when their vital capacity was more than 10 to 15 ml/kg and their inspiratory force more than 25 to 30 cm H_2O. In postoperative interviews, 41/42 patients who were awakened intraoperatively did not have any complaints related to anesthesia.

No leading questions were asked regarding intraoperative awakening, and in only 1 patient was there any recollection of the event. This patient, a 30-year-old woman who previously had required tranquilizer therapy, complained that she remembered hearing the surgeons talking about her during the operation. She recalled music being played in the operating room and could also feel the surgeons working on her back, stating that she did not feel pain but complaining that it was unpleasant. She had undergone a posterior spinal release 2 weeks before the Harrington-rod fusion and had required high doses of morphine for pain postoperatively. During the operation for spinal release, no difficulty was encountered during anesthesia, but during the operation for Harrington-rod fusion, she required more frequent and higher doses of morphine and curare than during the preceding operation, possibly through development of acute tolerance to opiates.

In no patient in whom this technic was used were there any neurologic sequelae. This does not mean that there might not be in the future, but it does offer a means of early recognition and treatment. Awakening and movement of patients intraoperatively did not dislodge the Harrington rod in any patient.

Fluroxene (2, 2, 2-Trifluoroethyl Vinyl Ether) Toxicity: A Chemical Aspect

G. G. HARRISON, MD, FFARCS*
K. IVANETICH, PhD†
L. KAMINSKY, PHD‡
M. J. HALSEY, D PHIL§

Fluroxene is highly toxic to several animal species. This toxicity is enhanced by induction of raised levels of hepatic microsomal enzymes. Experiments in rats are described which seek to assess the relative contribution to this toxicity of the individual component groups of the fluroxene molecule. Though results point to the trifluoroethyl moiety of fluroxene as that aspect of the molecule most responsible for the observed mortality, reduction of the vinyl group modifies the pattern of liver injury. That the liver necrosis, manifest following fluroxene anesthesia in the presence of microsomal induction, is alone the direct cause of the acute death of experimental animals is questioned.

THE anesthetic, fluroxene, has recently been demonstrated to be toxic to several animal species under certain circumstances.[1] Rats, guinea pigs, and mice have been shown to display toxic effects when chronically exposed to concentrations of fluroxene as low as 30 parts per million (1/2000 MAC).

That this toxicity is the result of some aspect of fluroxene biotransformation, rather than an effect of fluroxene itself, is suggested by the demonstration of increased manifestations of toxicity following hepatic microsomal enzyme induction, with a decrease in these when microsomal enzyme activity is suppressed.[2,3]

There is some evidence to suggest that formation of the highly toxic trifluoroethanol from the fluorinated ethyl moiety of fluroxene is responsible for these toxic effects.[4,5] But, whereas fluroxene anesthesia in the presence of enhanced hepatic microsomal mixed function oxidase levels resulted in florid liver necrosis,[6] direct exposure of animals to trifluoroethanol resulted in the death of the animal without similar histologic changes in the liver.[5] We questioned, therefore, the contribution to the manifest toxicity that might result from the catabolism of the vinyl moiety of fluroxene.

To this end, we exposed groups of rats in

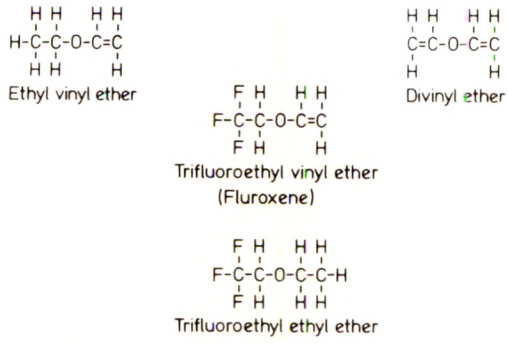

FIG 1. Structural formulas of fluroxene and the 3 related compounds studied.

which levels of microsomal enzymes had been increased (together with appropriate control groups) to fluroxene anesthesia and to 3 related compounds, each of which comprised some aspect of the fluroxene structure. We noted thereafter manifestations of toxicity as determined by (1) death or survival of the animal and (2) examination of liver histology.

The structural formulas of fluroxene and the 3 other anesthetic compounds exemplifying modifications of aspects of this structure (fig 1) are as follows:

1. Fluroxene: 2,2,2-trifluoroethyl vinyl ether.*

2. Vinamar, or ethyl vinyl ether, the nonfluorinated analog of fluroxene.†[7]

3. Vinesthene, or divinyl ether.‡[8]

4. Trifluoroethyl ethyl ether (TFEE), a chemically reduced form of fluroxene in which the vinyl moiety is hydrogenated to an ethyl group.

METHODS

The experimental animals were 200 to 300-gm male Sprague Dawley rats. Liver microsomal enzyme levels were enhanced by the daily intraperitoneal administration of phenobarbital (80 mg/kg/day) for 3 days preanesthetic. The concentration of phenobarbital sodium in saline solution used was 10 mg/ml, giving injection volumes of approximately 2 ml. Control rats were injected with similar volumes of physiologic saline solutions.

Having been allowed food and water ad lib until then, rats were starved for 24 hours after the 3rd phenobarbital injection, at which time (day 4) they were anesthetized. In the event of survival, this program was repeated. Survivors were then sacrificed by cervical dislocation on the 3rd day thereafter.

Animals were anesthetized in groups of 5 for periods of 3 hours in a standard dessicator 28 cm in diameter with a volume of 27.3 L, of which 4 L, the volume below the grid, was filled with standard anesthetic soda lime. Additional chemical CO_2 absorption was provided for by the placement of extra vertically standing perforated containers of soda lime between the animals.

The anesthetic agents were carried by a flow of O_2 (5 L/min) passed through a vaporizer and the anesthetic chamber in series. In such circumstances, the level of ambient CO_2 in the anesthetic chamber was less than 1%. In the case of ethyl vinyl ether and divinyl ether, because of their limited availability, a lower O_2 flow (2 L/min) was used.

Animals were exposed to anesthetic and subanesthetic concentrations of fluroxene (3 and 0.5%) delivered from a Fluoromartec® vaporizer, or to concentrations of the other agents sufficient to maintain a very light level of anesthesia, in equianesthetic concentrations. This level of anesthesia was defined as that at which response to paw-pinching became obtunded. TFEE, which produced anesthesia in rats, was synthesized in our laboratory by reduction of commercially available fluroxene with hydrogen in the presence of a palladium catalyst. Reduction of the vinyl function was checked by IR spectrophotometry, the material being treated to remove peroxides and redistilled before use.[9] All agents were screened to exclude the presence of peroxides.

After the death or sacrifice of experimental animals, the livers were immediately excised and fixed in formalin. Thereafter, sections of liver were stained with hematoxylin-eosin (H & E) and submitted to light microscopy.

RESULTS

The tabulated results, in terms of anesthetic agent, number of 3-hour exposures, mortality, and histology (table) reveal that all enzyme-induced rats exposed to fluroxene, both in anesthetic and subanesthetic concentrations, died after a single 3-hour exposure. Similar mortality followed expo-

TABLE

Anesthetic	Microsomal state: + = with induction 0 = no induction	Duration of anesthetic, hours	Number of exposures	Mortality	Histology
Fluroxene 3%	+	3	1	20/20	Periportal congestion, gross centrizonal necrosis or marked cell damage in all.
0.5%	+	3	1	10/10	Periportal congestion, gross centrizonal necrosis or marked cell damage in all.
3%	0	3	2	0/20	Periportal hydropic changes, 8/20.
0.5%	0	3	2	0/10	Normal histology.
TFEE	+	3	1	12/12	Frank centrizonal necrosis, 2/12. Marked fatty infiltration ± areas of focal necrosis and cell damage, 10/12
	0	3	1	0/12	No centrizonal necrosis. Miliary fatty infiltration and periportal hydropic degeneration, 6/12.
Vinamar	+	3	2	0/9	No necrosis. Periportal hydropic degeneration, 2/9.
	0	3	2	0/10	No necrosis. Periportal hydropic degeneration, 5/10.
Vinesthene	+	3	2	0/5	No necrosis. Periportal hydropic degeneration, 4/5.
	0	3	2	0/5	No necrosis. Periportal hydropic degeneration, 4/5.

sure of enzyme-induced rats to TFEE. This mortality, which occurred during or shortly after anesthesia, was associated with histologic evidence of severe centrizonal liver damage: frank necrosis, chromatolysis, fatty infiltration, pyknosis, and cloudy swelling (figs 2 and 3). Congestion, especially in the periportal areas, was a marked feature, particularly of those enzyme-induced animals anesthetized by fluroxene. The incidence of frank necrosis was much lower in enzyme-induced animals after anesthesia with TFEE, in which circumstance marked fatty infiltration with centrizonal pallor was the most consistent finding (fig 4). The magnitude of histologic liver damage in some animals after TFEE did not appear sufficient to account for death.

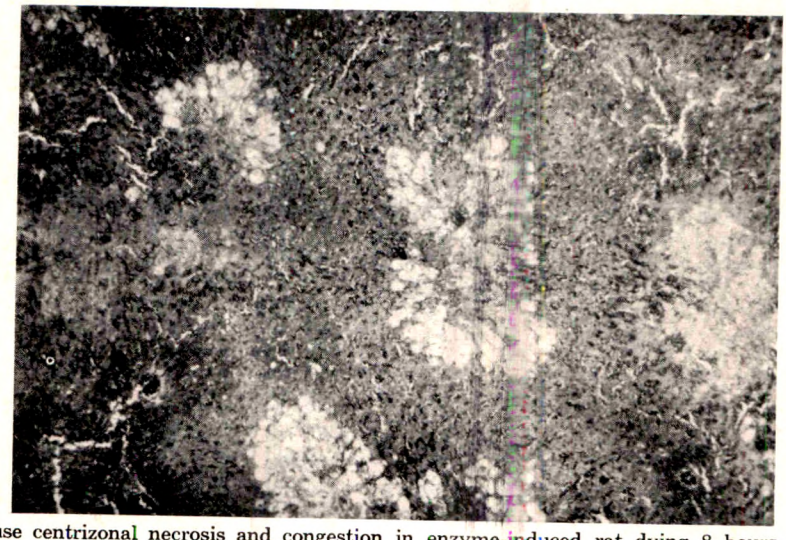

FIG 2. Diffuse centrizonal necrosis and congestion in enzyme-induced rat dying 8 hours after 3-hour exposure to 0.5% fluroxene. H & E x 160.

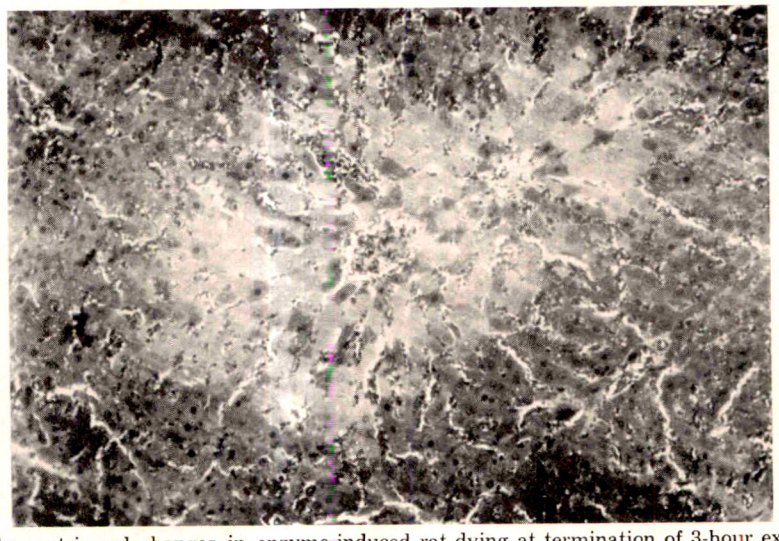

FIG 3. Early centrizonal changes in enzyme-induced rat dying at termination of 3-hour exposure to 3% fluroxene. Note chromatolysis, pallor, congestion, and occasional pyknotic cells. H & E x 400.

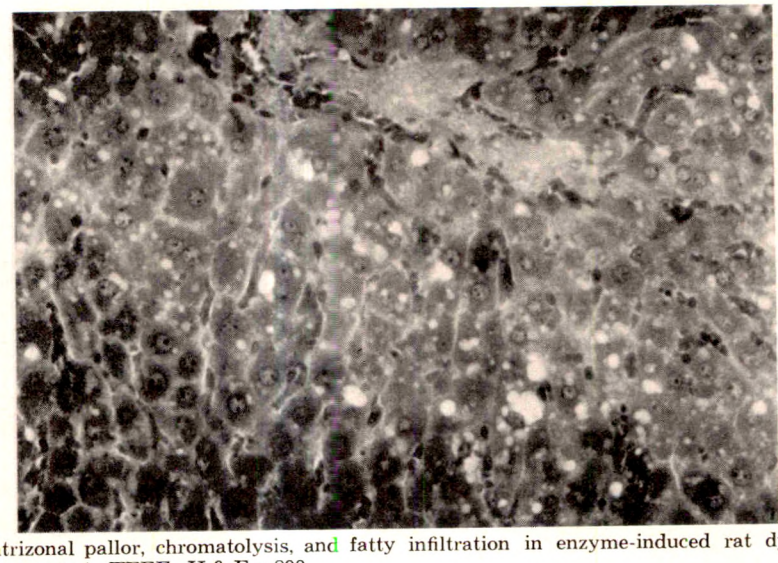

FIG 4. Centrizonal pallor, chromatolysis, and fatty infiltration in enzyme-induced rat dying 12 hours after 3-hour exposure to TFEE. H & E x 800.

No mortality occurred in the relevant fluroxene- or TFEE-anesthetized, uninduced controls, nor in any induced or uninduced animal exposed to vinamar or vinesthene. Nor was there evidence of centrizonal necrosis in any of these animals. However, the livers of some showed a nonspecific periportal hydropic change, apparent in both enzyme-induced and uninduced control animals.

DISCUSSION

Following phenobarbital induction of microsomal enzymes—

1. Fluroxene, even in subanesthetic concentrations, causes florid liver necrosis and death.

2. Modification of the vinyl group of fluroxene to an ethyl moiety does not lessen this mortality, though it does produce a different and less extreme pattern of liver damage.

3. Neither mortality nor histologic liver necrosis followed repeated exposures of animals to ethyl vinyl ether or divinyl ether.

Considering as the index of toxicity the mortality which occurred in the presence of enzyme induction following exposure of rats

to the test agents, it is immediately apparent that the trifluoroethyl moiety is the common denominator, no mortality resulting in its absence. However, the modification of the histologic pattern of liver injury following the use of TFEE rather than fluroxene suggests that the vinyl group must in some way be involved in the induction of the liver damage which, in itself therefore, may not be the direct cause of death in the experimental animals. This is in agreement with our earlier report that catabolism of the vinyl group of fluroxene, *in vivo* or *in vitro*, results in the destruction of hepatic cytochrome P450.[3,9] It is surprising, in view of the apparent damage caused to the liver by the biotransformation of the vinyl group in fluroxene, that neither ethyl vinyl ether nor divinyl ether produces similar liver damage. This aspect is presently under investigation.

ACKNOWLEDGMENT

Liver sections in this study were cut by Mr. Stan Abbott of the Department of Surgery, University of Cape Town, South Africa, and Mr. Christopher Sowter of the Department of Pathology, Clinical Research Centre, Northwick Park, Harrow, England. Technical laboratory assistance was provided by Mrs. I. Zietsman and Mr. Brian Sasman of the Department of Anaesthetics, University of Cape Town, and Mr. Peter Bateman of the Department of Anaesthetics, Clinical Research Centre. To these we express our thanks.

Editors share the belief that medical writing is capable of vast improvement. This article is one of a series of personal communications from Charles G. Roland, M.D., former Senior Editor of JAMA, to John T. Martin, M.D., Associate Editor of Anesthesia & Analgesia . . . Current Researches. Dr. Roland is Chairman, Department of Biomedical Communications, Mayo Clinic, Rochester, Minnesota 55901.

Thoughts About Medical Writing

XXXVI. Writing an Editorial

Dear Tom:

Some time back I wrote about the case report and the letter-to-the-editor. So now, I thought I might write about that powerful medium, the editorial.

We need more editorials, and more effective editorials, in our journals. Through editorials we can disseminate informed opinion without immobilizing it in the plaster cast of the conventional medical article with its fixed format and rigid demand for statistical significance and controls.

You don't have to be an editor to write an editorial. Journals often request editorials from authors outside their staff. Moreover, the old idea that an editorial must express the official viewpoint of the editorial board or of the society or association that owns the journal has largely disappeared. Consequently, the editorial "we" is becoming archaic. Most often, editorials clearly express the opinions or sentiments of one person; and most often, editorials now are signed.

I believe that identifying the author of an editorial advances the cause of responsible medical journalism. But that policy puts extra pressure on the author because he or she cannot use anonymity as a shield. And you should keep this fact in mind; if you write an editorial and you are challenged, you may find opinion harder to defend convincingly than you would dry but verifiable fact.

What is a medical editorial? It is a brief article—typically 400 to 1,000 words—that expresses opinion or interprets the facts or opinions of others; the subject matter can be any aspect of medicine (or of any related subject approved by the journal's editor). A former colleague of mine once said that an editorial was whatever an editor wrote for the editorial page. Adding the clause "or asked to have written" would satisfy me.

Suppose an editor asks you to write an editorial but doesn't specify the topic. What should you write about? Davidson[1] identified 10 "tangential items" that would lead to suitable editorial themes; I have taken his list, revised and reworded it, and added the 11th item, which I believe is one of the commonest sources of editorial ideas.

1. Historical material
2. Public relations
3. Legislation and governmental activities
4. Economic considerations
5. Ethics and morality
6. Professional organizational matters
7. Relations with related groups
8. Semantic and terminologic problems
9. Philosophic excursions
10. Research and training
11. Critical commentary on scientific articles or books

You probably can supplement this list, but it makes a suitable starting point. Using the list, plus your daily newspaper or the latest issue of this journal, you should have no difficulty creating a substantial list of potential topics for editorials.

An invitation to write an editorial carries with it the opportunity to write more imaginatively and creatively than you can when writing a journal article. Certainly, you should try. The opportunity to use metaphor, humor, and other rhetorical devices awaits you. But remember not to overdo it. Ration yourself to one metaphor per editorial. Don't bore your reader with humor by straining too hard.

As is true for most kinds of nonfiction writing, editorial writing can be improved by studying the work of the experts. The journals I would recommend are the *Annals of Internal Medicine*, the *New England Journal of Medicine*, and *JAMA*—but remember that not everything you find there will be top quality; that would be expecting too much. You must read selectively. Singling out particular editorial writers carries even more danger, although the editors-in-chief of the first two journals I mentioned regularly achieve a high level. I identified a few others in an anthology that appeared a few years ago.[2]

You should be able to state the message of your editorial in one sentence. Indeed, I believe that you should *make* yourself do that before you actually begin writing the editorial. Once you have that statement in hand, the editorial itself should present a reasoned and logical argument to persuade your readers to accept your view or, at least, to acknowledge its plausibility.

Please remember the special importance of the opening sentence.[3] Your first sentence plays an enormous, if immeasurable, role in convincing your reader that he needs to take the time to read what you have written. Consider these opening sentences:

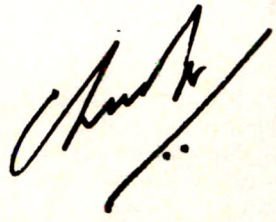
"Perhaps the most important sequel to the Arab oil embargo has been movement toward widespread adoption of nuclear energy."[4] (This plain but direct and effective sentence began an editorial on the recent rush to produce nuclear energy.)

"We live in a 'mammoriented' world."[5] (In this editorial, the writer discussed the FDA control of silicone materials proposed for use in augmenting the size of the female breast.)

"A little over a year ago my Aunt Martha died, but under the circumstances no one sent any flowers."[6] (This essay dealt with the burgeoning number of life-support devices available and the questions their use introduces about life and death.)

Your critical reading will reveal many additional examples. Once you can epitomize the gist of your editorial message in a thematic sentence, and once you have written an interesting, attention-gaining opening sentence, you are a long way toward preparing a good editorial. Now let's hope some editor has the good sense to invite you to write it.

Regards,



[Charles G. Roland, M.D.]

Electroanesthesia (EA) Studies: EA Produced By Stimulation of Sensory Nerves of the Scalp in Rhesus Monkeys

TATSUHIKO KANO, MD*
GEORGE S. M. COWAN, MB, ChB†
ROBERT H. SMITH, MD‡
San Francisco, California§

After it was learned that electroanesthesia (EA) could not be produced in a Rhesus monkey which had undergone a circumferential scalp block with 0.25% lidocaine, it was postulated that EA could be produced by electrostimulation of the sensory nerves of the scalp in the rhesus. The work reported here verifies that EA can be produced by this method in this species; it is not necessary to pass current through the head.

WE HAVE been engaged in a continuing inquiry into the possibility of producing a state of clinical anesthesia solely by the application of electric currents, without supplementary drugs.[1-9] Our objective has been to get adequate current into the thalamus and to so overstimulate it as to prevent transmission of "pain-impulses" through the area.[3,9] Pathways for current were studied, and the most effective, in terms of minimal current requirements, was found to be between the orbits and the foramen magnum.[3]

Studies on blind human subjects, in whom the pathway between the orbits and foramen magnum was used, revealed that electrostimulation of the maxillary branch of the trigeminal nerve in the orbit produced aching in the maxillary teeth when over 30 ma was applied. In monkeys, that current magnitude is not required and we have seen no evidence of toothache in this species, so we have continued the use of the pathway between the orbit and the foramen magnum.

In the course of animal studies using this pathway, we discovered that a monkey could not be anesthetized by current after a circumferential scalp block was effected with 0.25% lidocaine without epinephrine.[1] This finding suggested that we might produce EA by electrostimulation of the sensory nerves of the scalp in monkeys.

The present study was designed to ascertain: (1) whether simple electrostimulation of the scalp overlying sensory nerves would produce EA, (2) how many of such scalp areas had to be stimulated, and (3) if electrostimulation of the posterior 2/3 of the scalp alone would produce EA. This seemed to us to be a possible means of producing EA without using the orbit-foramen magnum route and, in doing so, to eliminate risk to the eyes and stimulation of the V-2 nerves in the orbit.

METHOD

Twenty-five tests were made on 5 adult

Rhesus monkeys over a 1-month period. The animals were restrained in a chair so devised as to leave the head, hands, legs, and tail accessible. Each animal had a nasotracheal catheter in place during each test. (This measure is necessary because the restrained Rhesus will hold its breath when current is applied; the nasotracheal tube permits ventilation of the animal with air for a few breaths, to break the pattern of breath-holding.)

The patterns of electrode placement are depicted in figures 1 and 2. The current was applied between electrodes straddling specific nerves: the greater occipitals, the supraorbitals, and the greater auriculars.

The electrodes were subcutaneous safety pins or 2.5 cm diameter agar-saturated sponges. The distance between electrodes varied from 2 to 5 cm. No local anesthetic was used in the placement of subcutaneous electrodes. The usual pattern was the insertion of an 18-gauge needle through the skin into the subcutaneous tissue, then bringing the tip out through the skin 2.5 cm lower. The safety pin, with its tip in the needle lumen, followed the needle as it was withdrawn. Safety pin electrodes were sterile #1 standard stainless-steel, with the pin portion coated with a dielectric substance except for 1 cm in the center; there was no bare metal against the skin. Sponge electrodes were applied in plastic electrode holders taped in place.

The anterior pair of electrodes, which straddled the supraorbital nerve, was used in the first part of the study but was omitted when it was learned that it was not needed. The current form was bidirectional square pulse. The duty cycle (percentage of pulse duration that current is flowing) was kept in the 20 to 40% range. The generators are so constructed as to produce a bidirectional square pulse. Frequency range is 100 Hz to 200 kHz. Duty cycle ranges from less than 1 to 50%. Peak current limit is 500 ma and is constant for a given average current; at a given average current meter reading, changing the duty cycle will change the average current leaving the peak current constant.

Basic frequency ranges were from 500 to 10,000 Hz. There were no mixtures of high (10,000 Hz) and low (500 Hz) frequencies

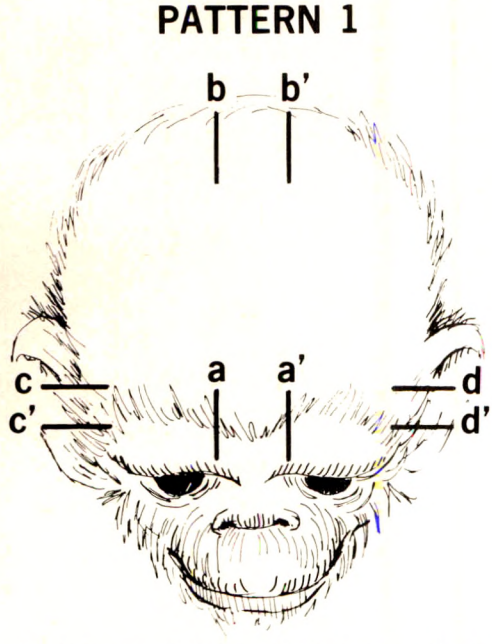

FIG 1. Pattern I. Using subcutaneous needle electrodes, the electrodes a and a′ straddle the main trunks of the 2 supraorbital nerves; b-b′ straddle the c-2-3 greater occipital nerves; c-c′ and d-d′ straddle the right and left greater auricular nerves, respectively. Milliamperage figures are average current; 20% duty cycle produces a peak current 5 times higher than the average current value.

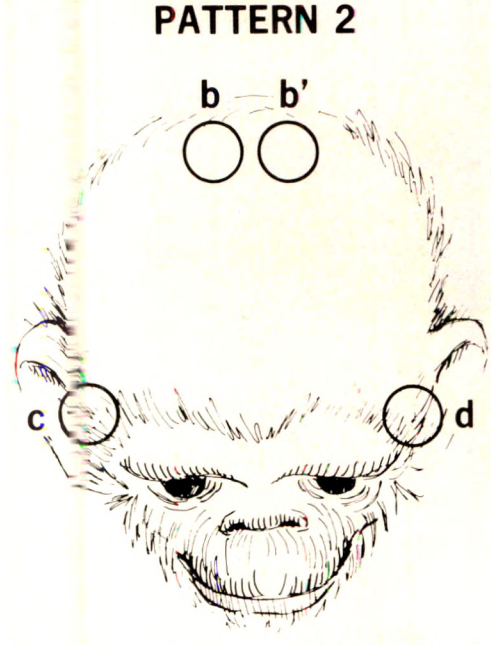

FIG 2. Pattern II. Using agar sponges 2.5 cm in diameter on the skin surface: electrodes b and b′ straddle the greater occiptal nerves c-2-3; electrodes c and d overlie the greater auricular nerves on their respective sides, anterior to the ear and about 3 cm lateral to and behind the lateral canthus of the eye. Milliamperage figures are average current; 20% duty cycle produces a peak current 5 times higher than the average current value. In none of the studies were the streams of current crossed, as in the interference pattern.

in any single application. The frequency between any pair of electrodes was 50 to 100 pps (pulses/sec) different from the frequency between any other pair.

The test for anesthesia in this series was the response to the application of pain to the tail by an electric device which produces a low-frequency square pulse. When a strong stimulus, applied for 30 seconds, evoked no response such as body movement or tail twitching, an anesthetic state was assumed to be present. To avoid a "startle" effect which resembles moving in response to pain, current applied for pain production was applied cautiously, intensity being started at zero and increased slowly and steadily to a predetermined level, usually 50 ma. The electrodes for the pain stimulator were subcutaneous needles 7.6 cm apart, in the tail. This pain-producing device was developed on human subjects to "measure" anesthesia.* It does no injury to tissues, and the pain ends instantly when the current flow is stopped.

Monkeys were rested at least 2 hours between current application and were used no more than 2 days per week. With each current application, an evaluation was made of pupil size and response to a strong light.

RESULTS (tables 1 and 2)

In the Rhesus, EA can be produced by electrostimulation of the nerves about the ears and the greater occipitals; it is not necessary to stimulate the supraorbital nerves. When EA is produced by electrostimulation of the nerves in the posterior 2/3 of the scalp, meiosis does not develop during the current application, and pupillary light reflexes are normal.

Subcutaneous pairs of electrodes carrying 30 ma of current produced 3rd-degree burns between the electrodes in one animal. No burns were produced by surface electrodes. EA can be produced by passing current from the skin in front of the ear to the skin overlying the greater occipital nerves.

DISCUSSION

It is not necessary to pass current through the head to produce EA in Rhesus monkeys, nor is it necessary to subject the eyes and trigeminal branches to electrostimulation to produce EA in these animals.

In the Rhesus, in all applications of current where the current path is through the orbits, meiosis develops as the current intensity approaches that required to produce EA. In this study, when meiosis was not present, the pupillary light reflexes were intact, findings interpreted as indicating that the eyes are not being stimulated by current. This absence of change was noted when anteriormost preauricular electrodes were more than 2 cm behind the lateral canthus of the eyes.

In all these studies, the current was applied across the nerve path; studies in other species are needed to learn whether this is the most efficient application pattern. These pathway studies and those of the effects of distances between electrodes are difficult in the Rhesus because the head surface is so small, making surface electrodes, which must be 2.5 cm in diameter, to avoid current-density burns, difficult to position effectively.

Pattern II (fig 2) was developed because pattern I (fig 1), based on subcutaneous electrodes, could not be duplicated with sponges on the surface, and we wanted to test high frequencies which require higher amplitudes than subcutaneous needle electrodes will carry without burning.

The subcutaneous electrodes did not produce burns at low frequencies which required low intensities. In the 10 kHz range, the amplitude required for EA production was so high that the small amount of tissue (1 x 2 cm) could not dissipate the heat produced, and burns developed in 1 monkey. When we found the burns, we duplicated the electrodes and current application on the arms of 2 investigators. A burning sensation developed in 8.5 minutes (1 subject) and in 10 minutes (the other subject). This finding suggests that the lack of reaction from the monkey was because it was under anesthesia when the burn developed.

In the pattern of current application reported here, EA "fades," as it does when the current is applied through the head. The fading is managed, as reported earlier,[6] by reducing the frequency and amplitude. Relatively comfortable high frequencies, with the higher required amplitude, will produce EA. When an anesthetic state is produced, the frequency can be turned down into more efficient ranges (500 to 1000 Hz), and the amplitude can be reduced as well. Note that in monkey 601 (table 2) 10 kHz required 50 ma but 200 Hz required only 5 ma.

All in pattern II. Agar sponges situated to move current between c and b and d and b'. Intersponge distance over 3 cm.

We have not tested in Rhesus monkeys the efficiency of EA by the parallel tests: surgical procedure and pain-stimulator, as was done in acute experiments on dogs, in which it was learned that the stimulator was a reliable means of predicting whether the animal would tolerate abdominal surgery without moving.

The anesthesia produced in this study was in no way different from that produced by the passage of current through the head. The items compared were reaction to the stimulator, fading, respiration and pulse, and muscle tone.

In these current applications, as in all others, the induction period is 1 to 5 minutes. The rate of increase in the current depends on the animals' respiratory rate. The struggling Rhesus frequently strains (Valsalva maneuvers), with slowing of the heart. When this occurs, the current is reduced slightly and the animal is ventilated 2 or 3 times, via endotracheal tube, with room air and a hand ventilator; then current buildup proceeds. When unconsciousness develops, the pulse rate and respiratory activity remain within normal range. A low-grade metabolic acidosis is present for the first 20 minutes, but Po_2 and Pco_2 are within normal limits. Muscle tone is not impaired, and the animal appears to be in the plane 3 of stage I of anesthesia.

We have learned, in the course of human experiments, that it is not possible to use 1 frequency output and divide it to energize 2 pairs of electrodes, even if the division is so adjusted as to be equal. Severe discomfort ensues: a form of vibration. Each pair of electrodes must have a frequency different from all other pairs, 50 to 100 pps being the usual difference. This finding necessitates 3 separate output channels for 3 pairs of electrodes.

The mechanism for the findings in this study is not clear. Earlier studies indicated that the "target area" probably was the thalamus,[3,9] or perhaps more properly, the thalamic area. We found some evidence that the EA state probably was consequent to depolarization. Our efforts for several years have been based on trying to get enough current into the critical area to produce the effect of continuous depolarization.

When current was being passed through the head in the usual manner of producing EA, an appropriate current density in some critical area was the objective. The discovery that a simple sensory nerve block prevented EA production changed the point of view on the necessity for an appropriate density. Now this discovery, that the passage of current across sensory nerves will produce EA, again raises the question of the necessity for a specific current density in the thalamic area.

Assume a monkey's head is 7.6 cm in diameter and 25 cm in circumference. If 3 electrode pairs are used, with 2 cm between each pair, there is some current getting into the brain center, but not much. If the interelectrode distance is 3 or 4 cm, a great deal more of the current is reaching the center of the brain. It is easy to assume that the portion reaching the brain center is responsible for the EA produced. However, if the sensory nerve is blocked with

a local anesthetic, the animal cannot be anesthetized with electric current. When surface electrodes were used, the distance between the electrodes was such that a great deal of current must have reached the brain center. Still, when the interelectrode area was infiltrated with local anesthetic, EA could not be produced.

It may be that the findings described here simply represent another means of providing the required stimulus in the appropriate area, in this case by overstimlation of the thalamus via high sensory-nerve input. Further neurophysiologic evaluation will be required for a more precise explanation.

Our laboratory has for over 9 years recommended that new electric current effects be evaluated by application to humans before application to animals. The pain-stimulator, the subcutaneous electrode introducer, and the crossover pattern of high frequencies were all developed in and on human subjects before being used on animals. Their acceptance in humans attests to their humane quality in lower animals.

Post-Thoracotomy Intercostal Block: Comparison of Its Effects on Pulmonary Function With Those of Intramuscular Meperidine

RONALD J. FAUST, MD
LEE A. NAUSS, MD
Department of Anesthesiology
Mayo Clinic and Mayo Foundation
Rochester, Minnesota 55901

Study of 34 patients who had undergone thoracotomy revealed that the group given intercostal nerve block analgesia had a significantly smaller decline in vital capacity after operation than did the group given narcotic analgesia only. The postoperative increase in arterial CO_2 tension of the nerve block group also was significantly smaller than that of the narcotic group. The study suggests that intercostal nerve block for post-thoracotomy analgesia offers some advantage in preserving effort-dependent pulmonary function when compared with postoperative narcotic analgesia.

ABBREVIATIONS

Pa_{O_2} = arterial partial pressure of O_2 (torr)

Pa_{CO_2} = arterial partial pressure of CO_2 (torr)

VC = vital capacity

MMFR = maximal mid-expiratory flow rate

MVV = maximal voluntary ventilation

$(A\text{-}a)D_{O_2}$ = alveolar-arterial difference of oxygen tensions

PA_{O_2} = alveolar partial pressure of O_2 (torr)

P_{IO_2} = inspired partial pressure of O_2 (torr)

PA_{CO_2} = alveolar partial pressure of CO_2 (torr)

R = respiratory quotient

F_{IO_2} = fraction of O_2 in inspired air

AFTER thoracotomy or surgery of the upper abdomen, pain produces a sequence of undesirable effects on respiratory function. Splinting and the inability to cough effectively cause retention of sputum and progressive atelectasis. These, in turn, may lead to ventilation-perfusion inequality, shunting, and hypoxemia.[1] More recent work implicates a decrease in functional residual capacity and airway closure in this process.[2]

Although narcotics make the pain more bearable and decrease the splinting of the chest wall, they depress the reflex urge to sigh. Even with narcotic doses that do not depress ventilation, the natural sigh mechanism is obtunded, thereby contributing to atelectasis.[3]

For more than 30 years, attempts have been made to overcome this postoperative pain problem by using regional analgesia.[4,5] Because afferent pain fibers can be blocked completely, local anesthetics may provide more nearly complete analgesia than systemically administered narcotics. If chest and abdominal wall movements are less painful after regional block, the postoperative patient might be able to breathe more deeply. Epidural and intercostal techniques have been used to achieve this analgesia, but studies comparing the pulmonary effects of narcotic analgesia with the pulmonary effects of regional techniques have shown conflicting results. In comparisons between groups receiving epidural analgesia and groups receiving narcotics, several investigators have found significant improvement in arterial oxygen tension but conflicting changes in dynamic lung volumes.[6-8] One recent study found similar decreases in Pa_{O_2}, Pa_{CO_2}, vital capacity, and peak expiratory flow rate when it compared groups given peridural analgesia with those given morphine after upper abdominal surgery.[9]

Regional analgesia has been studied less often after thoracotomy than after upper abdominal surgery. In 1966, Bergh and others[10] found significant improvement in peak expiratory flow rates in patients who were given an intercostal block the morning after thoracotomy. When compared with patients given narcotic analgesics only, the patients given intercostal block had significant changes in arterial oxygenation. More recently, Galway et al. found no improvement in lung volumes and no significant analgesic effect in patients given a transpleural intercostal block during thoracotomy.[11]

The purpose of our study was to compare pulmonary function in postoperative thoracotomy patients given either intercostal block or parenteral narcotics for analgesia.

METHODS

Thirty-four patients scheduled for thoracotomy were randomly allocated into two groups for postoperative analgesia: an intercostal nerve block group and a narcotic group.

Preoperative pulmonary disease and the specific surgical procedure planned were not determinants in group allocation, as long as a thoracotomy incision would be used. After obtaining informed consent, arterial blood gases were drawn the evening before surgery. Vital capacity, maximal mid-expiratory flow rate, and maximal voluntary ventilation were measured with a 9-liter Collins spirometer. All measurements were performed with the patient breathing room air and in a 45° semi-sitting position. No changes were made in the routine preoperative, surgical, or anesthetic management of the patient.

After surgery, each patient received routine nursing care until relief of pain was requested. The patient was then given either an intercostal nerve block or an intramuscular injection of a narcotic depending on the preoperative group assignment. Patients in the nerve block group had injections into seven intercostal spaces, according to the technique described by Moore.[12] A dose of 4 ml of bupivacaine (0.5%) with epinephrine (1:200,000) was placed into each of the five interspaces that were closest to the intercostal incision and into two interspaces at the level of the insertion of the chest tube. Patients in the narcotic group were given meperidine intramuscularly in a dose based on the surgeon's clinical estimate of the needs of the patient. The mean meperidine dosage was 0.92 mg/kg in these 17 patients (SE 0.09 mg/kg; range 0.61 to 1.47 mg/kg). Although it would be ideal to study the post-thoracotomy patient before and after he was given analgesia, the severity of the pain in these patients precluded accurate spirometry before analgesia. Thus, each patient was studied preoperatively and 45 minutes after the first administration of analgesia. Each measurement consisted of an arterial blood sample and spirometry. All measurements were performed with the patient breathing room air for at least 25 minutes and in a 45° semi-sitting position. All patients received chest physiotherapy and frequent cough encouragement throughout their postoperative course. Both groups of patients were followed to determine postoperative course, complications, and length of hospitalization.

Arterial gas results and results of spirometry were corrected for patient temperature. The alveolar-arterial difference of oxygen tension [$(A\text{-}a)D_{O_2}$] was calculated from the alveolar air equation: $P_{A_{O_2}} = P_{I_{O_2}} - P_{A_{CO_2}} \left(F_{I_{O_2}} + \frac{1 - F_{I_{O_2}}}{R} \right)$, in which R was assumed to be 0.8.

RESULTS

Thirty-four patients were studied; 17 were allocated to the intercostal nerve block group and 17 to the narcotic group. Patients requiring mechanical ventilation after operation were excluded. A higher incidence of females was noted in the narcotic group than in the nerve block group (8 of 17 patients compared with 3 of 17 patients). The average age of the patients in the intercostal block group was 63 years and of patients in the narcotic group, 61 years. When preoperative spirometry values were compared with the predicted normal value for each patient, the narcotic group had slightly higher mean vital capacity, maximal mid-expiratory flow rate, and maximal voluntary ventilation values than did the intercostal block group (Table 1), but the differences were not significant. Eighty-eight percent of the intercostal nerve block group and 65% of the narcotic group had resection of lung parenchyma during thoracotomy; in the remaining patients, the thoracotomy was performed for repair of a hiatal hernia or resection of an esophageal malignancy.

TABLE 1

Preoperative and Postoperative Spirometry* and Arterial Blood Gas Results for Intercostal Block Group and Narcotic Group (Mean ± SE)

	Intercostal block group (17 patients)			Narcotic group (17 patients)

*VC, MMFR, and MVV are expressed as % of predicted value; predicted values for each patient were derived from tables of normal spirometry data for our institution.

†Significant preop-postop difference within group ($p<0.05$).

‡Significant difference between groups ($p<0.05$).

Mean vital capacity, mean maximal mid-expiratory flow rate, and mean maximal voluntary ventilation were significantly decreased in both groups after operation ($p<0.05$, Student's *t*-test for paired data). Pao_2 decreased and $Paco_2$ increased in each group after operation, and these changes were also significant ($p<0.05$). In each of the three variables measured by spirometry after operation, the narcotic group had a greater decrease than did the intercostal block group, but the difference was statistically significant ($p<0.05$) only for vital capacity (fig 1). In spite of a slightly larger mean vital capacity before operation, the narcotic group had a mean decrease of 78% in vital capacity after operation. The mean decrease for the intercostal nerve block group was only 60%, however, and this was a significant difference between groups ($p<0.05$, Student's *t*-test).

The narcotic group showed slightly greatmean maximal voluntary ventilation before operation, but function decreased 58% after operation (fig 2). The intercostal nerve block group had a decrease of only 45% after operation, but the difference between groups was not statistically significant.

The narcotic group showed slightly greater maximal mid-expiratory flow rate before operation but a greater decline after operation—30% as compared with 22% for the intercostal nerve block group (fig 3).

Mean Pao_2 declined 13 torr in the intercostal block group and 10 torr in the narcotic group after operation (fig 4). $Paco_2$ increased 6 torr in the narcotic group and

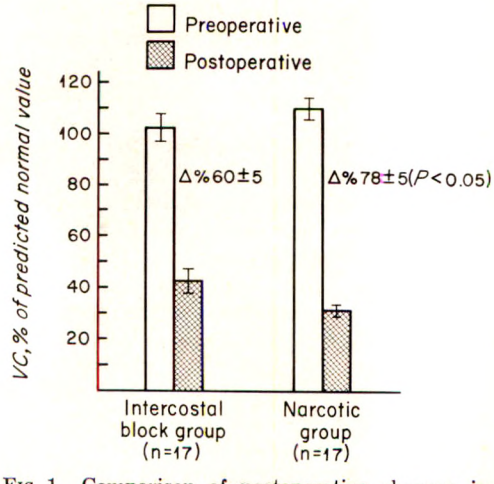

FIG 1. Comparison of postoperative changes in mean vital capacity (VC) between intercostal block group and narcotic group.

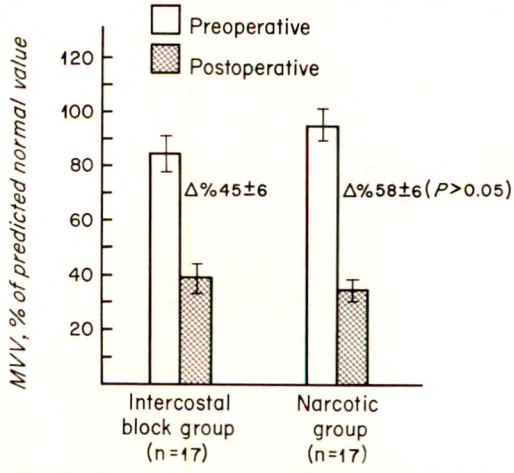

FIG 2. Comparison of postoperative changes in mean maximal voluntary ventilation (MVV) between intercostal block group and narcotic group.

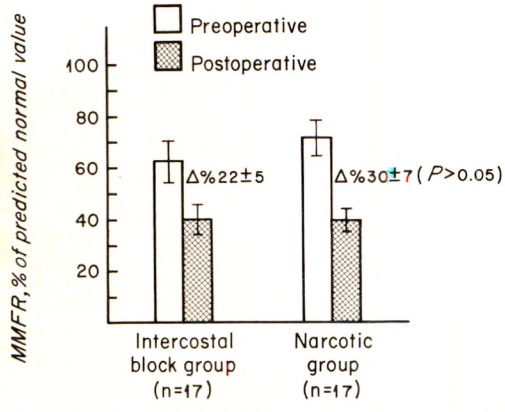

FIG 3. Comparison of postoperative changes in mean maximal mid-expiratory flow rate (MMFR) between intercostal block group and narcotic group.

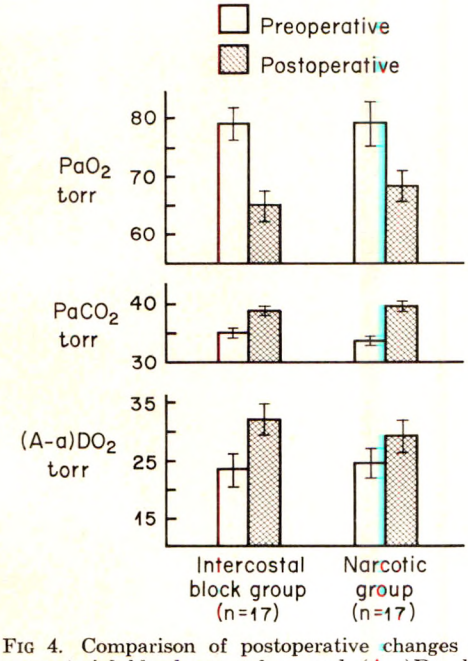

FIG 4. Comparison of postoperative changes in mean arterial blood gas values and (A-a)Do_2 between intercostal block group and narcotic group.

3 torr in the intercostal block group, and this difference between groups was statistically significant ($p<0.05$), although neither group showed postoperative CO_2 retention. The (A-a) Do_2 increased in each group after operation, but the difference was not significant between the groups.

Comparison of the length of hospitalization for the two groups showed no significant difference. There was one death in the nerve block group, death being due to nonpulmonary complications. Two patients in the narcotic group developed postoperative atelectasis that was evident roentgenographically. No complications were attributable to the intercostal nerve blocks themselves.

DISCUSSION

Our spirometry data reveal that one parameter of pulmonary function could be significantly improved after thoracotomy with intercostal nerve blocks. The significant improvement of vital capacity between the nerve block group and the narcotic group is perhaps explained on the basis of the vital capacity being an effort-dependent test of pulmonary function. The patients in the intercostal nerve block group may have been more capable of cooperating with our requests at the time of spirometry. The intercostal nerve block likewise probably improved the ability of these patients to cooperate with the cough and deep-breathing requests. Nevertheless, our data for maximal mid-expiratory flow rate and maximal voluntary ventilation did not show a statistically significant difference between groups. Our data agree with those of Bergh et al.,[10] who found a significant improvement in peak expiratory flow rates in patients who were given a single intercostal nerve block the morning after thoracotomy. Peak expiratory flow rate is another effort-dependent test of pulmonary function.

Our arterial blood gas data also agree with those from Bergh and associates' study, that is, no change in Pao_2 but a decrease in $Paco_2$ 2 hours after intercostal block the morning after thoracotomy. Our results differ from those of several investigators,[6-8] who found improved arterial oxygenation when regional analgesia was used after upper abdominal surgery.

Although we did not evaluate subjective pain relief, we have the clinical impression that intercostal block gave superior analgesia. Patients who have had both forms of analgesia frequently commented that the intercostal nerve block gave more effective pain relief. Although we considered an increase in vital capacity as an indication of improved pulmonary function, Bromage[5] interpreted increased vital capacity in itself as evidence of more effective analgesia. After the initial postoperative block, our patients were allowed to choose either a repeat block or a narcotic injection. Five of the 17 patients in the intercostal block group required no narcotics throughout their postoperative course, but these 5 requested repeat of their intercostal blocks an average of three times.

The patient who has had thoracotomy is an ideal candidate for intercostal block because the use of chest tubes decreases the danger of a pneumothorax, the most common complication of intercostal nerve block. This and the safety and long duration of action of bupivacaine itself have made intercostal nerve block a practical and safe approach to analgesia in the patient who has had thoracotomy.

Unlike that noted in a recent series from Seattle,[7] we found no significant difference in length of hospitalization between our two groups. A larger series might indicate whether hospitalization time or complication rate has been significantly altered by use of intercostal nerve block after thoracotomy.

Changes in Blood Chemistries Following Prolonged Enflurane Anesthesia

E. I. EGER, II, MD*
R. K. CALVERLEY, MD†
N. T. SMITH, MD‡

Blood chemistries revealed minimal or no injury to the kidney or liver in 12 young healthy male volunteers subjected to 9.6 MAC hours of enflurane anesthesia without surgical stress. The results were similar to those previously obtained with halothane, isoflurane, fluroxene, and diethyl ether.

THE evaluation of the toxic effects of anesthetics in man usually is compromised by the (1) superimposition of surgical stress, (2) presence of preexisting hepatic or renal disease, and (3) clinical requirements for the use of adjuvant drugs. These additional factors can induce their own effects which may obscure the actions of the anesthetic. Studies in volunteers circumvent these limitations and therefore are of particular value since they allow the direct correlation of the changes seen with the anesthetic stress alone.

We recently obtained blood chemistries from 12 young (20 to 26 years) healthy male volunteers who underwent prolonged and occasionally deep (2 MAC) enflurane anesthesia in the course of cardiorespiratory studies. The following is a report of these studies and their results.

METHODS

Prior to anesthesia, blood specimens were drawn from the volunteers for the analyses listed in the table. Anesthesia was induced and maintained at 1.0, 1.5, and 2.0 MAC (infrared analysis) with enflurane in O_2 (9.6 ± 0.4 SEM MAC-hours§) with a brief addition of N_2O (an additional 0.6 MAC-hours) midway during the anesthesia. Except for the use of succinylcholine to facilitate endotracheal intubation, no other drugs were given. Anesthetic dose was reduced if systolic arterial pressure fell to 45 torr. Ventilation was controlled to maintain a normal $Paco_2$ for about 2/3 of the study and was spontaneous the remainder of the time. With spontaneous ventilation, $Paco_2$ sometimes reached 80 torr.

Blood specimens again were obtained the 1st and 5th days after anesthesia and were compared (paired *t*-test) with the preanesthetic results (table). We accepted as significant a p value of <0.05. Complete values were not obtained in all cases.

§MAC-hours were obtained by taking the sum of all doses times duration of exposure at each dose for a given subject and dividing by MAC[1] corrected for age[2] (.89% enflurane).

RESULTS AND DISCUSSION

Although enflurane undergoes slight biodegradation to products which include fluoride ion,[3] there was little change in creatinine, blood urea nitrogen, or serum electrolytes, all of which remained within normal limits. The statistically significant (but clinically insignificant) rise in uric acid was nearly identical to that seen after prolonged halothane anesthesia in a similar group of volunteers.[4] Although the lower serum K^+ at 2 days was within normal limits, this decrease was not seen in previous studies following prolonged isoflurane or halothane anesthesia.[4]

Liver function studies gave somewhat conflicting results. Like isoflurane, enflurane did not significantly affect BSP retention at 1 day following anesthesia (table). This contrasts with the effects of halothane, fluroxene, and diethyl ether, which under similar circumstances of anesthetic duration and dose produced average values of 10, 8, and 10% retention, respectively (fig 1).[4] However, neither halothane nor isoflurane consistently increased SGOT or LDH in previous studies, whereas we found that enflurane did and, in the case of SGOT, enflurane gave an average value well above the normal range (table, fig 2).

Finally, in the 4 volunteers in whom it was measured, CPK rose consistently. The small sample size and variability of the increase precluded determination of statistical significance, but the results suggest the need for further study of this enzyme change.

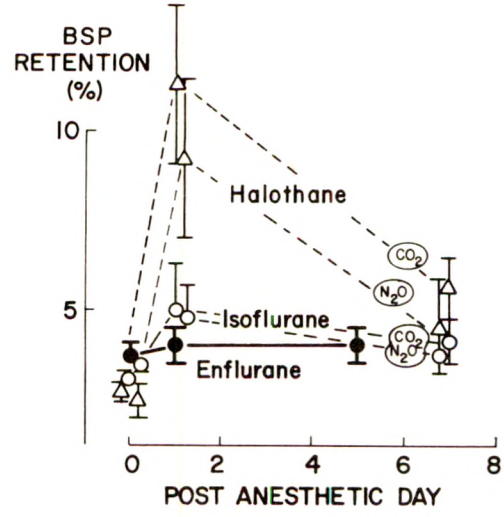

FIG 1. Data for enflurane for BSP retention (dark lines, filled circles) from this study are contrasted with data from previous studies[4] for halothane (dashed lines, open triangles) and isoflurane (dashed lines, open circles). Two groups of subject results are shown for both halothane and isoflurane. As indicated on the graphs, N_2O was added to the anesthetic regime in 1 case and CO_2 (to determine responsiveness to CO_2) in the other. All values are means ± SEM.

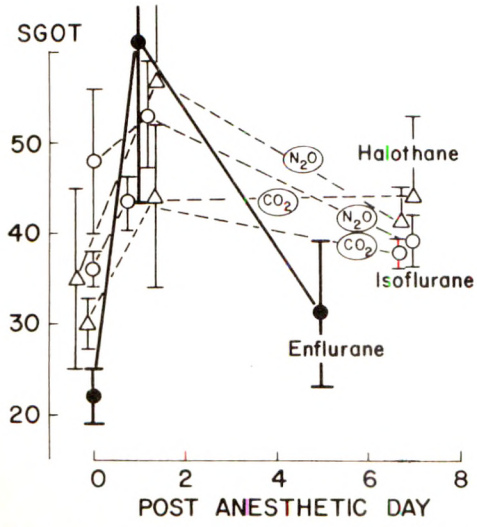

FIG 2. Comparisons from figure 1 are repeated here for SGOT. In contrast to the absence of an effect on BSP retention, enflurane (solid line) caused a significant rise in SGOT on the 1st post-anesthetic day. The increases in SGOT seen with halothane or isoflurane were not statistically significant.

CPK values are not available from previous similar studies. However, we recently have found* that halothane anesthesia in volunteers also is followed by an increase in CPK.

We conclude that prolonged and sometimes profound enflurane anesthesia in young healthy volunteers produces minimal changes in blood chemistries that reflect renal and hepatic function.

San Francisco, California

Efforts by clinical studies to distinguish among the potent inhaled agents with respect to their toxicity to liver and kidney have not proven too fruitful. Perhaps this is good. For, put another way, all are quite safe. Anesthetic-induced depression and accompanying hypotension, even when severe as it was with all of the agents tested, did not result in injury sufficient to alter hepatic or renal function persistently. The rise of SGOT with enflurane, which had returned to control levels by the 5th post-operative day, might not be indicative of hepatic injury, since this enzyme is found in many tissues other than liver. Perhaps the absence of abnormality in somewhat more specific tests such as the BSP, SGPT, and LDH support this idea.

Studies such as these are important even though the results are not very exciting. For one thing, the anesthetic exposure was unusual in that no surgical stress occurred, yet prolonged anesthesia and the stress of elevated P_{CO_2} were imposed. Certainly the anesthetic exposure was as great as the vast majority of patients will encounter. Therefore, one can have reasonable confidence that injury from enflurane will not follow a simple dose-response relationship as a classic hepatotoxin or nephrotoxin should—confidence at least within the limits of the doses Dr. Eger administered.

Another feature of such broad testing is that a significant event may occur which warrants further tests. Since we are puzzled so frequently about the pathogenesis of anesthetic toxicity, no reasonable lead should be overlooked. In the current study, an elevation of CPK occurred. As Dr. Eger indicated, comparative data are not available to determine if this finding is unique to enflurane.

This study is encouraging specifically because no renal abnormality occurred. Both the type and quantity of metabolite produced by anesthetic metabolism are important in anesthetic toxicity. Enflurane metabolism yields inorganic fluoride. These long MAC-hour exposures did not produce sufficient free fluoride to result in hypernatremia or azotemia.

These studies can give us no confidence that enflurane will not produce a rare, serious hepatic injury such as occurs with halothane, but I am sure the authors would not expect such certainty from these studies. We will have to wait for information on which patients are at risk and/or what the anesthetic metabolites are which produce halothane's hepatotoxicity. Then we can predict what may happen with a new compound.

Spinal Anesthesia for Lumbar Disc Surgery: Review of 576 Operations

DAVID J. SILVER, MD*
REMBRANDT H. DUNSMORE, MD†
CHARLES M. DICKSON, MD‡
Hartford, Connecticut§

Neurologic complications accompanying spinal anesthesia were examined in 576 lumbar disc operations on 507 patients. The single serious complication did not seem attributable to the choice of anesthetic method. Minor neurologic complications, with the exception of spinal headache, could be explained by surgical manipulation. The authors conclude that spinal anesthesia is safe for surgical operations on the laterally herniated lumbar disc.

NEUROLOGIC complications associated with spinal anesthesia are rare and generally minor.[1-4] Controversy exists, however, over the use of spinal anesthesia for lumbar disc surgery. Vandam and Dripps[2] suggest that spinal anesthesia may exacerbate existing neurologic disease and recommend against its use for lumbar disc surgery. Others have found spinal anesthesia safe and effective.[5-8] Spinal anesthesia has been used at Hartford Hospital for more than 9000 disc operations during a 35-year period. We report here the results of a study of a sample of this patient population.

MATERIALS AND METHODS

From 918 lumbar disc operations at Hartford Hospital during 1969-70, the charts of 575 patients were selected randomly for study; 68 were eliminated because follow-up study was less than 6 weeks. Of the 611 procedures studied (399 on men and 212 on women), 576 were performed under spinal and 35 under general anesthesia. Patient ages ranged from 15 to 80 (average 43) years. One third were followed for more than 2 years and 55% for over 6 months. A myelogram preceded 77% of the operations. Average hospital stay was 7 days.

General anesthesia was employed in the following situations: (1) a near complete or total myelographic block; (2) inability to accomplish a subarachnoid tap; (3) myelographic demonstration of arachnoiditis; (4) inadvertent production of a "high spinal;" and (5) patient refusal of spinal anesthesia.

Approximately 93% of the operations under spinal were at the lowest 2 interspaces (table 1); only 81% of those done under general anesthesia were at the same spaces (table 2). In 58 operations, 2 herniated discs were removed. Each operated

level was counted separately.

More than 17% of the operations under spinal anesthesia were for recurrent disc herniation (table 3); 12 patients underwent 3 operations under spinal, 3 underwent 4, and 1 underwent 5.

Neurologic complications were carefully evaluated in an effort to separate surgical trauma from anesthetic damage. Motor or sensory deficit at a level different from that operated on, contralateral pain, or contralateral deficit was classified as a residual probably attributable to anesthesia.

TECHNIC OF ANESTHESIA

Anesthetic trays containing glass syringes, spinal needles, and small disposable needles which had been cleaned ultrasonically were wrapped and autoclaved in a central location. Single-dose vials of procaine, tetracaine, and ephedrine were packaged on the tray in a separate envelope marked on the outside with a sterilization indicator.

After the anesthesiologist inserted an IV catheter and checked vital signs, the patient was turned to the lateral position with the affected side down. The anesthesiologist scrubbed briefly, gloved, and painted the back with povidone-iodine solution. After local infiltration with procaine, a 22 or 25 spinal needle was introduced into the subarachnoid space in the midline at a level above the affected disc. A mixture of 10% procaine and 1% tetracaine (usually 8 to 10 mg tetracaine and 40 to 50 mg procaine), diluted to 2.5 to 3 ml with clear cerebrospinal fluid (CSF) was injected over 8 to 10 seconds. After injection, 0.1 to 0.2 ml of CSF was aspirated and reinjected to assure needle position. The patient was placed supine for 5 to 10 minutes, and the progression of anesthetic level carefully monitored. The operation was performed in the lateral position with the affected side up, after further skin infiltration with 1% lidocaine with epinephrine.

RESULTS

Under spinal anesthesia, 91.6% of patients achieved good-to-excellent results (table 4). All but 1 of the 8.4% fair and unsatisfactory results were so classified because of residual back pain. One patient, whose preoperative myelogram showed a large defect at L4-L5, had a moderate postoperative paresis of ankle flexors and extensors after unilateral exploration at the appropriate level. Reexploration 5 days later under general anesthesia revealed a large centrally herniated lumbosacral disc. The patient recovered to a "fair" status.

TABLE 5
Results of Surgery Under General Anesthesia

	Number	Percentage
Excellent*	17	48.6
Good†	7	20.0
Fair‡	4	11.4
Unsatisfactory§	7	20.0
Total	35	100.0

*Totally asymptomatic.

†Mild back pain, unlimited activity.

‡Some limitation of activity, or change of job required.

§Persistent pain, severely limited activity, worsening of symptoms.

Patients operated on under general anesthesia achieved 68.6% good-to-excellent results (table 5).

Of 11 patients graded fair or unsatisfactory, 7 had persistent pain and 4 had severe neurologic deficit. Two patients made unsatisfactory recoveries from preoperative paraparesis resulting from central disc herniation. Another sustained a bilateral footdrop after operation and the fourth, a unilaterial footdrop which partially recovered. The patients operated on under spinal anesthesia cannot be compared with those done under general anesthesia since those undergoing general anesthesia were clearly neurologically worse preoperatively.

Early complications following operations under spinal anesthesia (table 6) included 11 cases of increased neurologic deficit. Of the 5 patients with motor and sensory deficits, 3 had footdrop following L-5 root retraction, 1 had temporary saddle anesthesia after removal of a large central disc, and 1 suffered weakness of plantar flexion with associated calf dysesthesias after disc removal at the lumbosacral level. In the group with sensory changes only, 3 complained of persistent dysesthesias in a distribution consistent with the dermatome of the manipulated root and there were 2 cases of numbness of the contralateral thigh, probably from compression of the lateral femoral cutaneous nerve in the lateral operative position. A case of early contralateral postoperative pain was reoperated 2 months later with removal of an extruded fragment on the opposite side at the same level.

Other complications were infrequent (table 3). Only 1% of the spinals resulted in spinal headache. There were no wound infections. One CSF fistula, following a dural tear, was repaired at reexploration by reclosure of the lumbodorsal fascia. Trochanteric bursitis, found in 1%, likely resulted from pressure on the bursa in the lateral position.

TABLE 6
Early Postoperative Complications

Complications	Spinal (576 cases)	General (35 cases)
Increased neurologic deficit		
Motor and sensory change	5	3
Sensory change only	5	1
Contralateral pain	1	0
Urinary retention		
< 2 days	17	2
> 2 days	1	5
Pneumonitis or atelectasis	6	0
Phlebitis	4	0
Spinal headache	6	0
Aseptic meningitis	1	0
Discitis	1	0
Ileus	4	3
Wound problems		
Hematoma	2	0
Infection	0	0
CSF fistula	1	0
Trochanteric bursitis	5	0

The early neurologic complications associated with general anesthesia included 1 bilateral and 2 unilateral footdrops, and an instance of temporary dysesthesia in the distribution of a retracted S-1 root.

DISCUSSION

Operations on the herniated lumbar disc under spinal anesthesia produced results similar to those reported in other series. Several authors claim 90 to 95% good-to-excellent results in cases of typical radicular compression.[8-10]

Minor neurologic sequelae of spinal anesthesia have been estimated to occur in 0.5 to 0.8% of patients.[11,12] Since the majority of these relate to the lumbar and sacral dermatomes,[11] it is usually impossible to separate the complications produced by anesthesia from those related to surgical manipulation. Our 1 case of contralateral paresthesia was relieved upon removal of a contralateral recurrent disc.

The major reluctance to administer spinal anesthesia for lumbar disc surgery stems from fear of paralysis due to transverse myelitis or chronic progressive adhesive arachnoiditis. These entities are rare serious complications of spinal anesthesia,[12-14] occurring in less than 0.01% of cases. Progressive adhesive arachnoiditis may represent a nonspecific response to an intrathecal irritant.[11,13]

The patients surveyed in this study were, on average, older and had a higher percentage of herniated upper discs than has been found in a summary of 9082 cases from 30 reports in the literature.[7] Nearly 15% underwent 2 myelograms, and 17% had 2 or more disc operations under spinal anesthesia. Despite significant exposure to possible insult, chronic progressive adhesive arachnoiditis was not found. Indeed, 1 patient with known arachnoiditis had lysis of adhesions under spinal anesthesia, with clinical improvement. While this procedure is not recommended, our experience is in accord with that of Ditzler and associates,[5] who reported 10 patients with arachnoiditis to whom spinal anesthesia was administered without harmful effect. Our total experience of 9000 cases has led us to conclude that this feared complication of spinal anesthesia has not appeared more commonly in operations on the laterally herniated disc.

Five cases of significant neurologic residual were found in 3168 previously reported lumbar disc operations under spinal anesthesia (table 7). In Ditzler's series,[5] residual deficit related to application of concentrated nupercaine to the cauda equina. In Rosenberg's case,[6] progressive weakness developed in association with a deep wound infection and resolved with treatment of the infection. Spangfort's report[7] gave no information about the origin of the deficit.

Temporary urinary retention, as noted in table 3, was uncommon. Rosenberg and Berner[6] found urinary retention was more common after disc surgery under general anesthesia than under spinal. This observation has not been confirmed in a large randomly selected sample.

Our 1% incidence of postoperative headache was about 10% of that usually associated with spinal anesthesia. We hypothesize that epidural blood serves as a "patch," and reduces the dural leak.

One advantage of spinal anesthesia for the herniated disc may be decreased mortality. In the 4 series (table 7) employing spinal anesthesia for disc surgery, the 3 deaths represent a mortality rate of 0.08 percent. This is one-half that found in 15 recent reports of results of nearly 8300 cases of disc surgery.[7] In Hartford Hospital's 9000 cases of disc surgery under spinal anesthesia, there has been 1 postoperative death, from myocardial infarction, a mortality rate of 0.01 percent.

We conclude that proper administration of spinal anesthesia for the herniated lumbar disc is a safe procedure. Serious neurologic complications attributable to the anesthetic method have not been observed more frequently than when using spinal anesthesia for other operations. Low mortality and morbidity coupled with a short average hospital stay indicate to us that this is the anesthesia method of choice for such surgical operations.

ACKNOWLEDGMENT

The authors wish to thank Drs. James C. Collias, Norman H. Gahm, William B. Scoville and Benjamin B. Whitcomb for making available their records of the patients included in this study.

BICARBONATE DURING RESUSCITATION. Arterial pH, PCO_2 and osmolality were measured during cardiopulmonary resuscitation in dogs with or without intravenous sodium bicarbonate (1 mEq/kg). In the first 15 minutes of resuscitation pH did not fall below 7.35 and serum osmolality increased significantly when sodium bicarbonate was not administered to dogs. When bicarbonate was added to the regimen pH increased transiently, $PaCO_2$ increased and remained above awake levels and serum osmolality was elevated. These data confirm that adequate ventilation during resuscitation is sufficient to prevent the development of acidosis in the absence of pre-existing acidosis. $PaCO_2$ increased after bicarbonate despite adequate ventilation. These studies suggest that bicarbonate should not be used during cardiopulmonary resuscitation in the absence of (1) inadequate alveolar ventilation, (2) when cardiac arrest is brief and preexisting acidosis is unlikely or (3) in repeated doses without pH confirmation. Current recommendations of the National Conference on Cardiopulmonary Resuscitation are to administer bicarbonate 1 mEq/kg twice during the early minutes of resuscitation and repeat 0.5 mEq/kg at 10 minute intervals. *(Bishop RL, Weisfeldt ML: Sodium bicarbonate administration during cardiac arrest. Effect on arterial pH, PCO_2 and osmolality. JAMA 235:506-509, 1976)*

Hypoxemia and Hypocarbia Following Intermittent Positive-Pressure Breathing

FRED G. WRIGHT, JR., CAPTAIN, USAF (MC)*
MARY F. FOLEY, LT COL, (NC)†
JOHN B. DOWNS, MD‡
MICHAEL R. HODGES§

The authors determined the effects of short-term, vigorous intermittent positive-pressure breathing (IPPB) on arterial blood O_2 tension (Pa_{O_2}) in 10 unmedicated preoperative adult patients (ASA class I). Arterial blood was analyzed before and 0.5, 5, 15, and 40 minutes after 12 minutes of IPPB with nebulized 0.9% NaCl and room air. Pa_{O_2} increased from 89.1 ± 11 torr (mean ± SD) to 102.1 ± 13.9 torr, and arterial CO_2 tension decreased from 29.5 ± 4 torr to 18.4 ± 3 torr, causing significant respiratory alkalosis (pHa 7.62 ± 0.05). Five minutes after IPPB, Pa_{O_2} decreased to 69.2 ± 8 torr; alveolar-arterial P_{O_2} difference, breathing 21% O_2, increased significantly; and serum K^+ concentration decreased significantly. All these values returned to baseline levels within 40 minutes. The authors, acknowledging the value of IPPB when specifically indicated, counsel caution in patients with borderline pulmonary reserve and arterial oxygenation.

INTERMITTENT positive-pressure breathing (IPPB) is used widely as pulmonary therapy for postoperative patients and for patients with chronic lung diseases. Such therapy is thought to be beneficial, or at least to do no harm.[1] However, mechanically assisted, large tidal-volume breathing initiated in cooperative patients may cause alkalosis. Hypocarbia and alkalosis may decrease arterial blood O_2 tension (Pa_{O_2}).[2,3] Recently, hypoxemia has been described in patients with obstructive lung disease following IPPB.[4]

We initiated our study to determine the effects of short-term, vigorous IPPB in healthy preoperative adult patients with no evidence of preexisting pulmonary dysfunction.

METHODS

Ten unmedicated ASA class I patients, ranging in age from 20 to 35 (mean 28) years, were placed in semi-Fowler's position. A radial artery cannula was inserted percutaneously to facilitate blood sampling. Each patient received IPPB with room air for 12 minutes from a volume-preset ventilator (bird Mark 9-6) with an inspiratory pressure plateau of 0.8 seconds and a tidal volume of 12 ml/kg. Normal saline solution (5 ml) was added to the nebulizer. Patients

were instructed to inhale, pause, then exhale at a comfortable respiratory rate (usually 14 to 18 breaths per minute). Pao_2, arterial CO_2 tension ($Paco_2$), and arterial pH (pHa) were measured with standard electrode technics* before and 0.5, 5, 15, and 40 minutes after IPPB. Alveolar-to-arterial O_2 tension difference breathing 21% O_2 ($A\text{-}aDo_2^{0.21}$) was calculated from the equation:[5]

$$A\text{-}aDo_2^{0.21} = FIO_2\ (PB - 47) - PACO_2\ (FIO_2 + \frac{1\text{-}FIO_2}{R}) - Pao_2$$

assuming a respiratory quotient (R) of 0.8 and alveolar CO_2 tension ($PACO_2$) = $Paco_2$. Barometric pressure (PB) was recorded prior to study and subjects received an inspired O_2 concentration (FIO_2) of 0.21 at all times. Serum K^+ concentrations were measured with a flame photometer,† hemoglobin by the cyanmethemoglobin method, and hematocrit by centrifugation at the times mentioned. At least 2 investigators were present during each study period. Data were analyzed by analysis of variance, a 2-tailed Student's *t*-test for paired data being used to determine significant differences from control values where indicated.

RESULTS

IPPB increased Pao_2 from 89.1 ± 11 (mean ± SD) torr to 102.1 ± 13.9 torr ($p<0.01$). $Paco_2$ decreased from 29.5 ± 4 torr to 18.4 ± 3 torr ($p<0.01$) and pHa increased from 7.44 ± 0.02 to 7.62 ± 0.05 ($p<0.01$) immediately after IPPB. Five minutes after discontinuing IPPB, Pao_2 values decreased to 69.2 ± 8 torr ($p<0.01$) and remained lower in every subject than pre-therapy values until the 40-minute sampling. $Paco_2$ and pHa were not statistically different from pre-IPPB values 5 minutes after therapy in any patient (fig 1, table).

$A\text{-}aDo_2$ was initially unchanged by IPPB, but increased significantly 5 minutes post-therapy from 19.5 ± 13.3 to 42.9 ± 7.3 ($p<0.01$) (table, fig 2). Serum K^+ was unaffected initially by IPPB and alkalosis, but fell from 3.6 ± 0.3 to 3.1 ± 0.3 mEq/L ($p<0.01$) 5 minutes after IPPB and gradually increased toward, but did not reach, pretherapy levels until the 40-minute sampling (table, fig 2). There were no significant changes in hematocrit, serum Na^+, or hemoglobin concentrations during the study.

Following IPPB, volunteers said that they felt slightly light-headed, but were otherwise comfortable. All patients appeared at all times to breathe without obvious hypoventilation or apnea.

DISCUSSION

Most patients were apprehensive before the study, which may explain why control pHa and $Paco_2$ values reflected respiratory alkalosis. Prior studies[6] have questioned the

efficacy of postoperative IPPB therapy because of the inability of pressure-limited devices to deliver adequate tidal volumes. Therefore, we elected to use an IPPB volume approximately double the patient's normal spontaneous tidal volume. An inspiratory pressure plateau has been shown to produce increased alveolar distribution of inhaled gas,[7] and prior studies not using an inspiratory pressure plateau have been criticized.* Although we selected the tidal volume and inspiratory flow pattern, patients determined the respiratory rate and degree of hyperventilation. We assumed $PACO_2$ = $Paco_2$ and R = 0.8 in calculating A-aDo_2. If $PACO_2$ were actually less than $Paco_2$, changes in A-aDo_2 following IPPB would have been greater. Similarly, were R actually greater than 0.8, the post-IPPB increase in A-aDo_2 would have been greater. By these assumptions, we minimized calculated change in A-aDo_2 following IPPB.

There are numerous possible explanations for the observed fall in Pao_2 after IPPB.

*Bird F: Personal communication.

According to the Fick equation, [cardiac output = O_2 consumption ($\dot{V}O_2$)/arterio-mixed venous blood O_2 content difference ($Ca\text{-}\bar{v}O_2$)], $Ca\text{-}\bar{v}O_2$ is directly proportional to $\dot{V}O_2$ and inversely proportional to cardiac output. Pao_2 is inversely related to $Ca\text{-}\bar{v}O_2$ when Pao_2 is less than the PAO_2,[5] due to the transit of the mixed venous blood through a right-to-left shunt. Therefore, decreased cardiac output or increased $\dot{V}O_2$ may elevate $Ca\text{-}\bar{v}O_2$ and depress Pao_2.[8] Cherniack and associates[9] found that most cardiac output depression resulting from hyperventilation of anesthetized dogs occurred within the 1st minute. However, we observed no change in $A\text{-}aDo_2$ during hyperventilation (table, fig 2). If decreased cardiac output caused Pao_2 to fall in our patients, we would expect the effect to have occurred during hyperventilation, not 5 minutes later. An increase in $\dot{V}O_2$ also may have decreased Pao_2 without changing cardiac output.

Khambatta and Sullivan[10] found that respiratory alkalosis after 2 hours of hyperventilation caused $\dot{V}O_2$ to increase significantly but to return to normal within a 2-hour recovery period. Increased $\dot{V}O_2$ associated with alkalosis occurs both clinically[11] and experimentally.[12,13] It is unlikely that 12 minutes of hyperventilation was sufficient to increase O_2 consumption enough to account for the marked fall in Pao_2, but we cannot rule out the possibility. Both acute alkalosis and hypocarbia will cause a leftward shift in the oxyhemoglobin-dissociation curve and decreased Pao_2.[5] Since Pao_2 increased during the period of severe respiratory alkalosis and decreased during the recovery period, a shift in the oxyhemoglobin-dissociation curve probably played no significant role in changing Pao_2 in our patients.

Most investigators[2,3,9] have postulated that apnea or hypoventilation following prolonged hyperventilation is a potential source of hypoxemia. Our studies may show that hyperventilation partially depletes total body CO_2 content, but subsequent hypoventilation allows reaccumulation of these CO_2 stores. According to the alveolar-air equation, an increased $PACO_2$ will decrease PAO_2 and, therefore decrease Pao_2. In contrast, we found $Paco_2$ and, therefore, presumably $PACO_2$, less than baseline values when Pao_2 was lowest. Since $Paco_2$ did not increase in any patient after IPPB, calculated PAO_2 was not decreased and hypoventilation alone could not account for the decrease in Pao_2.

Mismatching of alveolar ventilation and perfusion ($\dot{V}A/Q$) may cause hypoxemia during inhalation of room air.[5] A decreased exchange of CO_2 in the presence of normal or slightly increased O_2 uptake at the alveolar level (marked decrease in respiratory quotient) may cause acute loss of alveolar volume and functional residual capacity (FRC) until normal CO_2-O_2 exchange is reestablished. Forrest[14] demonstrated in guinea pigs that the decrease in total alveolar volume following hyperventilation was related to the duration of hyperventilation but was maximal during the first 5 minutes. His findings complement those of McClenahan,[15] who reported that hyperventilation of adult rat lungs reduced the amount of effective pulmonary surfactant, thus promoting alveolar atelectasis, decreased FRC, and decreased lung compliance.

Nisbet and associates[16] compared the Pao_2 of 2 groups of dogs mechanically ventilated for 1 to 2 hours. One group was maintained at a normal $Paco_2$ and the other at a low $Paco_2$. The Pao_2 fell and the $A\text{-}aDo_2$ increased in the hypocarbic dogs, but these changes were not observed in the dogs with normal $Paco_2$. They attributed the difference in arterial oxygenation to decreased cardiac output, $\dot{V}A/Q$ inequality, or both. Hyperventilation-induced $\dot{V}A/Q$ mismatching probably explains the observed decrease in Pao_2 and increased $A\text{-}aDo_2$ in our patients.

Decreased serum K^+ during respiratory alkalosis has been reported previously.[17] Respiratory alkalosis will decrease cellular H^+ concentration, extracellular K^+ will enter cells to maintain cation balance, and serum K^+ will decrease. In our patients, the extravascular shift of K^+ lagged behind the pHa change, and serum K^+ remained below baseline values for up to 40 minutes, suggesting that a more complex relationship may exist between serum K^+ and pHa than previously reported. An acute fall in serum K^+ might have significant clinical implications in some patients with preexisting pathology (eg cardiac arrhythmias) or in those receiving medications such as diuretics and digitalis.

The purpose of this study was not to determine the efficacy of IPPB in patients with respiratory insufficiency. Our subjects were young, healthy, anxious, and unmedicated preoperative patients. Initial pHa and $Paco_2$ values indicated a state of acute hyperventilation, which may have exaggerated our findings. In this setting, IPPB resulted

in further hyperventilation, hypocarbia, and alkalosis, leading to significant arterial hypoxemia.

Patients with decreased pulmonary reserve and initially low Pao_2 may not respond in identical fashion. However, IPPB-induced acute alkalosis, hypoxemia, and hypokalemia in a previously compromised patient might be detrimental. For these reasons, we recommend IPPB be administered only when specific indications warrant its use. Furthermore, precautions should be taken to prevent hyperventilation, and to minimize the risk of hypoxemia, supplemental O_2 should be administered following therapy, especially in patients with borderline pulmonary reserve and arterial oxygenation.

ACKNOWLEDGMENT

We express our gratitude to the blood-gas technicians for aid in conducting the study, to Robert Fuchs for statistical assistance, Ms Cindy Bunt for secretarial assistance, Ms Dianna Kosman for editorial advice, and to J. H. Modell, MD, for his support.

Quantitation of peripheral vascular versus direct cardiac effects of isoproterenol (0.002 mg/kg) was attempted in a new pharmacologic animal model, the unanesthetized calf, before and after replacement of its natural heart with a pneumatically driven artificial heart (AH). Isoproterenol significantly increased ($p<0.01$) cardiac output and pulmonary shunt and decreased aortic blood pressure before and after AH replacement. Elevation of cardiac output and pulmonary shunt was greater ($p<0.05$) and depression of aortic pressure less ($p<0.05$) before AH replacement than after. Isoproterenol did not change pulmonary artery (PA) or right atrial (RA) blood pressures before AH implantation but did reduce ($p<0.05$) PA diastolic and mean pressures and increase mean RA pressures after. Systemic vascular resistance was significantly ($p<0.01$) reduced by isoproterenol before and after AH implantation. Heart rate, O_2 uptake, respiratory rate, tidal volume, and minute volume were all markedly increased before AH implantation but unchanged after. These findings demonstrate that approximately half the increase in output and pulmonary shunt and all changes in O_2 uptake and respiratory dynamics after administration of isoproterenol are related to cardiac effects of the drug. Our data also suggest that the unanesthetized bovine before and after AH replacement is a unique model for study of the differential pharmacology of drugs with respiratory, cardiac, and peripheral vascular effects.

RECENT advances in the development of an artificial heart (AH) to replace the natural heart of patients with uncorrectable or untreatable heart disease have made available a unique model for study of the differential cardiovascular and pulmonary effects of drugs with respiratory and cardiovascular actions.[1-4] This model, the unanesthetized calf before and after its natural heart is removed and replaced with a pneumatically powered, pulsatile artificial one, allows the direct cardiac effects of a drug to be differentiated from its actions on peripheral vasculature. Using the bovine AH model, we undertook the present study of the myocardial and peripheral vascular

effects of a single IV 0.002 mg/kg dose of isoproterenol. In addition, the effects of isoproterenol on respiratory frequency, tidal volume, minute volume, O_2 uptake, and pulmonary shunt were also evaluated before and after AH implantation.

METHODS

The experimental subjects were 20 unanesthetized 80 to 104 kg bull calves. After induction of each animal with 3 to 5 mg/kg of IV sodium methohexital, intubation, and maintenance of anesthesia with 1 to 2% halothane, a 10-gauge needle was placed percutaneously into the right external jugular vein. With continuous pressure recording, a 7-Fr Swan-Ganz triple-lumen catheter was threaded through the needle, through the right ventricle, and into the proximal pulmonary artery. Another catheter (14 Fr) was placed percutaneously into the opposite external jugular vein and threaded into the right atrium. Following this, a small neck or groin incision was made and a third catheter (17 Fr) threaded into the central aorta through either the left carotid or left femoral arteries. Catheter position was documented by fluoroscopy and catheter patency maintained with a dilute heparinized (2 units/ml) solution of lactated Ringer's solution, administered at a rate of 1 to 2 ml/hr via a constant-infusion pump. Anesthesia was then terminated and the animals extubated and allowed to recover for 24 to 48 hours.

Pre-Artificial Heart Implantation Study Procedures.—Standing in a metal calf cage, the calf was allowed to breathe 100% O_2 through a specially designed airtight calf face mask. Inspiratory and expiratory J-valves (3 cm ID)* were attached to the mask portals and connected to an O_2 source. Pulmonary artery (PA) and aortic blood samples were obtained (for O_2 content analysis) after 20 minutes of O_2 breathing, and heart rate and systolic, diastolic, and mean PA and aortic and mean right atrial (RA) pressures were recorded. Oxygen uptake ($\dot{V}O_2$), respiratory rate (f), tidal volume (V_T) and minute volume ($\dot{V}$) were then measured over a 3-minute period by removing both J-valves from the mask portals; attaching one of the portals to a standard 9-liter, O_2-filled closed-circuit spirometer equipped with water and CO_2 absorbers; and plugging the other portal of the face mask.

*Warren E. Collins, model P-304.

$\dot{Q}_T$ was calculated using the Fick equation:

$$\dot{Q}_T = \frac{\dot{V}O_2}{Cao_2 - C\bar{v}o_2}$$

$\dot{Q}_S/\dot{Q}_T$ was determined from the modified shunt equation:

$$\dot{Q}_S/\dot{Q}_T = \frac{(PAo_2 - Pao_2) \times 0.0031}{(Cao_2 - C\bar{v}o_2) + (PAo_2 - Pao_2) \times 0.0031}$$

where $PAO_2 = PB - PH_2O - PaCO_2$

Blood Pco_2 was measured with a Severinghaus electrode, pH with a Radiometer glass electrode, and Po_2 with a modified Clark electrode. All electrodes were maintained at 39° C and frequently recalibrated with standard solutions and gases of known concentration and tension. Temperature corrections were made when necessary, using standard blood-gas correction factors. Oxygen saturation was determined on an AOC* oximeter and hgb on a Fisher hemophotometer. Rectal temperature was monitored with a Yellow Springs temperature probe and recording module. It was assumed that 1 gm of fully oxygenated calf blood combined with 1.39 ml of O_2.† Blood O_2 content in

*American Optical Company.

†It has been shown (Kosochi T and Stanley T, unpublished data) that freshly drawn, heparinized 12 to 16-week-old calves' blood will bind 1.38 to 1.41 ml of O_2/gm hgb when fully oxygenated.

ABBREVIATIONS AND SYMBOLS

AH = artificial heart
Cao_2 = O_2 content (ml) in 100 ml of arterial blood
$C\bar{v}o_2$ = O_2 content (ml) in 100 ml of mixed venous pulmonary artery blood
f = respiratory rate
Hgb = hemoglobin
LA = left atrial
PA = pulmonary artery
PAo_2 = partial pressure of O_2 in alveolar air
Pao_2 = partial pressure of O_2 in arterial blood
$PA\text{-}ao_2$ = alveolar-arterial O_2 tension difference
$PaCO_2$ = partial pressure of CO_2 in arterial blood
PB = barometric pressure
PH_2O = partial pressure of water in respiratory alveoli (47 torr)
PVR = pulmonary vascular resistance
$\dot{Q}_S/\dot{Q}_T$ = pulmonary shunt
$\dot{Q}_T$ = cardiac output
RA = right atrial
SVR = systemic vascular resistance
$\dot{V}$ = minute ventilatory volume
V_D/V_T = dead space/tidal volume
$\dot{V}O_2$ = O_2 uptake
V_T = tidal volume

volumes percent were calculated from the hgb capacity, O_2 saturation, and dissolved O_2, according to the equation:

O_2 content = (1.39 × gm hgb/100 ml blood) + 0.0031 × Pao_2.

SVR was calculated from the equation:

$$SVR = \frac{\text{mean aortic blood pressure} - \text{mean RA pressure}}{\dot{Q}_T}$$

Following control measurements and with the calves breathing into the spirometer, 0.002 mg/kg of isoproterenol was rapidly given IV and after 1 minute, PA and aortic blood samples recollected; $\dot{V}O_2$, f, V_T, $\dot{V}$, heart rate and PA, aortic and RA blood pressures remeasured; and $\dot{Q}_T$ and $\dot{Q}_S/\dot{Q}_T$ recalculated. Two days later, each calf had his natural heart replaced with a pneumatically driven artificial heart.

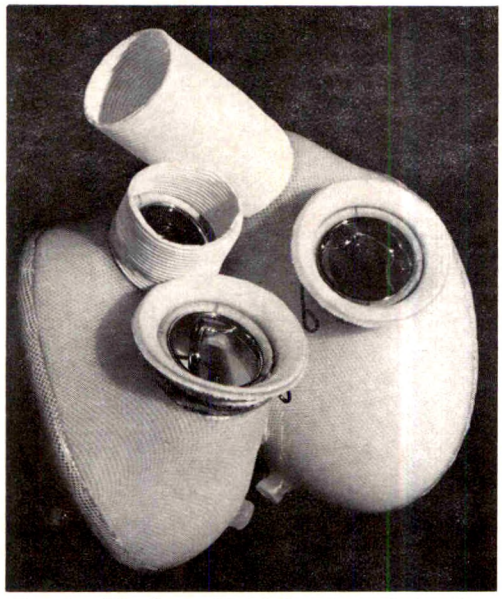

FIG 1. Silastic artificial heart used in these experiments.

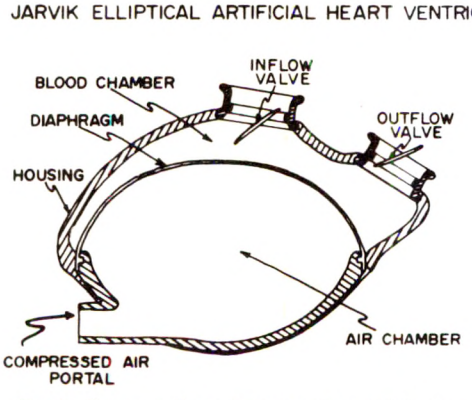

FIG 2. Cross-section of pneumatic artificial heart.

Design of Artificial Heart and AH Driving System.—A silicone rubber* or polyurethane elliptical type of AH (fig 1), previously described,[1-4] was used. Composed of 4 chambers (2 artificial atria and 2 artificial ventricles), it contains 4 Bjork-Shiley pyrolytic-carbon disc valves and weighs approximately 300 gm. Each ventricle (fig 2) consists of a rigid outer casing and a pliable inner blood-containing chamber, between which compressed air is applied for compression and ejection of blood.

An intrinsic AH control system (also previously described[1-4]) is based on the maintenance of relatively normal atrial pressures. This system basically consists of 2 direct-acting, 3-way solenoid valves in the control module, which apply compressed air through the 2 air-drive lines during systole and, during diastole, exhaust air to the atmosphere. With this system, the rate of filling and, therefore, the volume of blood entering each ventricle during diastole increases with an increase in atrial pressure. This volume is expelled during the next ventricular systole. As filling of the ventricle diminishes, so does stroke volume. There is, thus, an inherent balance between the pulmonic and systemic circulatory systems, as with the natural heart, and extremes of high and low atrial and venous pressures are avoided.

Artificial Heart Implantation Procedures.—All calves were anesthetized with 350 to 500 mg of sodium methohexital, intubated, and ventilated with O_2 at volumes of 1500 to 2000 ml/breath and rates of 10 to 14/min with a volume-limited respirator. Anesthesia was maintained with intermittent 2 mg/kg doses of ketamine and 0.5 mg/kg doses of succinylcholine IV. After a right lateral thoracotomy, removal of the Swan-Ganz and RA catheters, and placement of cardiopulmonary bypass catheters in the right carotid artery and inferior and superior jugular veins, cardiopulmonary bypass was initiated.

The natural heart was then excised, leaving the right lateral portion of the right atrium with both vena caval orifices and the bases of both atria. Silastic artificial left and right atria were sutured to the remnants of the natural atria. The artificial heart was then attached to the natural PA and aorta by standard woven Dacron arterial grafts and to the artificial atria by a quick-connect cinch mechanism. The PA

*Silastic®, silicone rubber of the Dow-Corning Company, Midland, Michigan.

and aortic grafts and artificial RA and left atrium (LA) contained Silastic taps, to which pieces of high-pressure IV tubing were connected and brought outside the chest for blood sampling and pressure monitoring.

Post-Artificial Heart Implantation Protocol and Study Procedures.—The calves were extubated 12 to 16 hours after AH implantation and all were eating, drinking, and behaving normally 24 to 36 hours later. They received no medications except gentamicin and/or penicillin thereafter. Post-implantation studies were initiated 4 to 36 days after AH implantation when V_T was >400 ml, $Paco_2$ <45 torr and Pao_2 >70 torr for 6 or more hours while breathing room air. Additional criteria for acceptance in the study included a $\dot{Q}_S/\dot{Q}_T$, and mean PA, aortic, and RA pressures within 20% of pre-AH levels when AH cardiac output was adjusted (via AH rate changes) to approximate preimplantation values.

When these requirements were met, each animal was allowed to breathe 100% O_2 through the calf face mask and the pre-AH implantation study procedures repeated. An additional parameter available for measurement post-AH implantation was mean LA pressure. The latter was obtained, as was RA, PA, and aortic pressures and blood samples, from high-pressure tubing connected to taps on the artificial atria and vascular grafts attaching the artificial ventricles to the natural PA and aorta. With mean LA pressure, it was possible to calculate pulmonary vascular resistance (PVR) after AH implantation, using the equation:

$$PVR = \frac{\text{mean PA pressure} - \text{mean LA pressure}}{\dot{Q}_T}$$

RESULTS

There was no significant difference in any parameter measured during control conditions (before administration of isoproterenol) prior to and after AH implantation (tables 1 and 2). Isoproterenol significantly ($p<0.01$) increased $\dot{Q}_T$ and $\dot{Q}_S/\dot{Q}_T$ and decreased systolic, diastolic, and mean aortic blood pressure before and after AH replacement. Elevation of $\dot{Q}$ and $\dot{Q}_S/\dot{Q}_T$ was markedly greater ($p<0.05$), and depression of aortic blood pressure significantly less ($p<0.05$), before AH replacement than after. Correlation of changes in $\dot{Q}_S/\dot{Q}_T$ with those in $\dot{Q}_T$ was good both before ($r=0.79$) and after ($r=0.84$) implantation. Isoproterenol did not significantly change systolic, diastolic, and mean PA or mean RA pressures before AH implantation. After implantation, systolic PA pressure was also unchanged by isoproterenol; however, diastolic and mean PA pressures were significantly ($p<0.05$) decreased and mean RA pressure significantly ($p<0.05$) increased.

SVR was reduced 48% by isoproterenol before AH implantation and 42% after. Both reductions were significant ($p<0.01$) but the difference between them was not ($p>0.2$). After AH implantation, PVR was reduced 31% by isoproterenol. PVR could not be calculated before implantation because LA pressure was not measured. Isoproterenol produced marked increases in heart rate (+119%), $\dot{V}O_2$ (+15%), f (+28%), V_T (+16%), and $\dot{V}$ (+48%) before AH implantation but made no significant change in any of these parameters after AH implantation. Arterial pH and $Paco_2$ were not significantly changed by isoproterenol either before or after AH implantation.

DISCUSSION

The mode of action and in particular the cardiovascular effects of the catecholamines have been extensively investigated for over 70 years.[5-7] These studies have demonstrated that isoproterenol, epinephrine, and norepinephrine have significant peripheral vascular effects, and that the first two also have profound direct positive inotropic and chronotropic actions on the myocardium. Additional studies[8-12] have shown that all 3 agents significantly increase respiratory rate, tidal volume, minute ventilation, and total body O_2 consumption; however, the influence of peripheral vascular versus direct cardiac effects of these drugs on cardiac output and respiratory dynamics has not been quantitated. The most important reason for this is that until now there has not been an intact experimental animal model that would permit such investigations. We believe that recent advances in the design and development of a pneumatically driven, pulsatile, artificial heart, which can be implanted into the chest cavity of 12 to 18-week-old calves, has made such studies feasible.

In this study, a single IV dose of 0.002 mg/kg of isoproterenol caused a 63% increase in $\dot{Q}_T$ before AH replacement and a 29% increase after. These findings indicate that 46%, or approximately half, of the increase in $\dot{Q}_T$ after this dose of isoproterenol in the calf with his natural heart intact is

achieved through peripheral vascular mechanisms, a decrease in arterial resistance and/or an increase in venous return. The profound arterial-dilating effects of isoproterenol secondary to beta-adrenergic stimulation are well known.[5-7] Less known, but possibly equally or more important, are the effects of this agent on capacitance vessels. Some have suggested that isoproterenol increases venous return by constricting capacitance vessels,[13] others that isoproterenol causes a dilation of such vessels.[14]

Green[15] has recently demonstrated that the immediate (within 1 min) effect of isoproterenol is to dilate the splanchnic outflow vessels, releasing trapped blood from the splanchnic bed. After 3 minutes, most of this increased blood volume is then redistributed via a reduction in peripheral arterial resistance from splanchnic to peripheral (muscular) compartments. Our protocol did not allow us to differentiate immediate (<1-min) changes in $\dot{Q}_T$ from those occurring at 3 minutes. Furthermore, the bovine AH animal model does not permit separation and quantitation, with any degree of accuracy, of changes in arterial resistance from changes in venous capacitance. However, it is clear from the large decrease in calculated SVR before and after AH implantation, and the significant increase in RA pressure after implantation but not before, that isoproterenol has a marked effect on both SVR and venous return.

Perhaps more important than differentiation between the direct cardiac effect of isoproterenol and its peripheral vascular effects is investigation of the influence of the drug on respiratory dynamics, particularly f, V_T, $\dot{V}$ and $\dot{V}O_2$. In this study, the latter were increased 28, 16, 48, and 15%, respectively, before AH implantation but not significantly changed after implantation. A number of other investigators[8-12,16-19] have had results similar to our pre-AH implantation findings in unanesthetized man and other animals. Cobbold and coworkers[8] found that 0.1 μg/kg of isoproterenol administered as a continuous infusion over a period of 30 minutes increased f a maximum of 30% and V_T 30 to 45% in man. Pulmonary $\dot{V}$ increased 66% within 5 minutes and subsequently fell to a level 30% above resting ventilation, a level maintained through the period of infusion. The changes in ventilation corresponded to increases in O_2 consumption and averaged 30% above control levels for the whole study. Similar, though less profound, respiratory changes have been found with infusions of epinephrine and norepinephrine.[9-12]

Although there have been many attempts to investigate catecholamine-induced hyperpnea, the mechanism is still unknown. Our findings in this study, while not demonstrating the exact cause of isoproterenol hyperpnea, do suggest that the mechanism is related to myocardial inotropic and/or chronotropic stimulation. Furthermore, they indicate that increases in $\dot{V}O_2$ after isoproterenol are not related to peripheral vascular effects of the drug or apparently to anything other than cardiorespiratory changes. Our data do not differentiate the percent of $\dot{V}O_2$ increase due to increased myocardial activity from that due to increased respiratory activity. However, it appears that $\dot{V}O_2$ changes after isoproterenol are not primarily due to $\dot{Q}_T$ alterations, since output increased an average of 29% after AH implantation but $\dot{V}O_2$ remained unchanged.

$\dot{Q}_S/\dot{Q}_T$ was markedly increased (+48%) before AH implantation and also significantly increased (+20%) after implantation. A number of investigators[16-19] have found significant increases in $\dot{Q}_S/\dot{Q}_T$ and $P_{A\text{-}a}O_2$ gradients after isoproterenol. Although the precise etiology remains uncertain, alveolar collapse and interference with hypoxic pressor responses have been attributed as mechanisms.[18] Palmer and Diament[20] have suggested that the primary cause of these changes is a decrease in airway resistance and an increase in physiologic dead space. It is difficult to conceive, in view of the significant difference in $\dot{Q}_S/\dot{Q}_T$ changes following isoproterenol before and after AH replacement, how the same dose of drug could cause less alveolar collapse, a greater hypoxic pulmonary pressor response, or a smaller decrease in airway resistance after AH implantation than before. It appears more reasonable, since correlation of changes in $\dot{Q}_S/\dot{Q}_T$ with those in $\dot{Q}_T$ were very high both before and after AH replacement, that $\dot{Q}_S/\dot{Q}_T$ changes after isoproterenol are more directly related to $\dot{Q}_T$ or pulmonary blood volume alterations and disturbances of ventilation and perfusion matching secondary to these changes.

Kreuzer[19] came to the same conclusion after showing that norepinephrine always produced significant decreases while epinephrine either decreased, increased, or yielded a biphasic $A\text{-}aDo_2$ response, depending on the dose of the amine used and presumably whether alpha or beta-adrenergic

stimulation predominated in his anesthetized dog preparations. He also suggested that a redistribution of blood from the pulmonary to the systemic circulations (as would probably occur after isoproterenol) or from the systemic to the pulmonary circulation (as would probably occur after norepinephrine) depended on the strength and duration of systemic and bronchial versus pulmonary vasoconstriction or vasodilation.

Absence of LA pressure measurements prevented calculation of PVR and comparison of changes in it with that of SVR during the pre-AH replacement periods of our study. However, comparison of these parameters post-AH replacement indicates that SVR was reduced to a greater degree than PVR, suggesting that pulmonary blood volume may have been decreased by isoproterenol after AH implantation despite an increased $\dot{Q}_T$. Whether pulmonary blood volume was also decreased by isoproterenol before AH replacement and, if so, whether it was decreased to a greater extent than after AH replacement, are questions that cannot be answered at this time. Likewise, it is impossible to determine from our data whether pulmonary blood volume changes (if they do indeed occur and are related to alterations in $\dot{Q}_S/\dot{Q}_T$) are important factors in the development of isoproterenol hyperpnea.

Perhaps, in spite of the absence of changes after AH implantation, alteration in $\dot{Q}_T$ is the principal determinant of isoproterenol hyperpnea. It is possible that significant changes in f, V_T and $\dot{V}$ occur only after a large change in $\dot{Q}_T$, and that 0.002 mg/kg of isoproterenol did not produce enough of an increase in AH output after AH implantation to alter any of these parameters. If this were the case, large changes in $\dot{Q}_T$, as produced by any mechanism, should induce hyperpnea.

Recent experiments in our laboratories have demonstrated that this is true.[4] Using the unanesthetized calf with an artificial heart and electively and nonpharmacologically changing heart rate (via a knob on the AH control module), we[4] found an ideal range of $\dot{Q}_T$ that minimized f, $\dot{V}$, $\dot{V}O_2$, $\dot{Q}_S/\dot{Q}_T$, and V_D/V_T and maximized V_T in each animal studied. The ideal range varied in width (from 1.2 to 2.6 L/min, or up to 37% of $\dot{Q}_T$) and in absolute numbers from animal to animal and in the same animal with change in position and metabolic state. Changes within the ideal range of $\dot{Q}_T$ did not produce significant changes in any of the above parameters. On the other hand, increases or decreases in $\dot{Q}_T$ out of the ideal range were almost always associated with increases in f, $\dot{V}$, $\dot{V}O_2$, $\dot{Q}_S/\dot{Q}_T$, V_D/V_T and decreases in V_T that were directly related to the magnitude of the $\dot{Q}_T$ alteration. It was suggested on the basis of these observations that there is an ideal range of $\dot{Q}_T$ which optimizes respiratory dynamics and minimizes $\dot{V}O_2$ for any given metabolic state.

These data and the results of this experiment raise a number of interesting questions. Can other noncatecholamines that produce profound effects in $\dot{Q}_T$ result in similar respiratory and $\dot{V}O_2$ changes? Is the hyperpnea of hypovolemic and cardiogenic shock related to $\dot{Q}_T$ changes? Does the hyperpnea of these entities differ from that resulting from isoproterenol? If $\dot{Q}_T$ alterations are the primary mechanism of catecholamine hyperpnea, is the pathway through the CNS or is it a direct effect on the lung?

These questions are unanswered at present but will have to be answered in the future if the mechanism of catecholamine-induced hyperpnea is to be finally understood. The AH-implanted bovine animal model may help in the solution of these problems, as well as in differentiation of the respiratory, cardiac, and peripheral vascular effects of any drug with cardiorespiratory actions.

ASTHMA. An attempt was made to define criteria that would identify patients with acute asthma who should be managed as in-patients rather than outpatients. Asthma attacks not successfully treated in the emergency room were characterized by severe airway obstruction (peak flow rate less than 16% of the predicted) and a poor response to the initial epinephrine injection (0.3 ml subcutaneously) as evidenced by a peak flow rate improving less than 16% or remaining below 60 l/min. Accurate assessment of the degree of airway obstruction and subsequent responsiveness to bronchodilators (epinephrine and aminophylline) was not possible by clinical impression or physical examination. In the patients requiring hospitalization hypoxemia was modest and hypercarbia was not present. *(Banner AS, Shah RS, Addington WW: Rapid prediction of need for hospitalization in acute asthma. The Local Anesthetic Activity of Tetrodotoxin Alone and in Combination With Vasoconstrictors and Local Anesthetics

H. JACK ADAMS, PhD*
MURRAY REID BLAIR, JR., PhD†
BERTIL H. TAKMAN, PhD‡
Framingham, Massachusetts§

Tetrodotoxin (TTX), alone and in combination with various vasoconstrictors and local anesthetics, was evaluated for its ability to produce peripheral nerve blocks in the rat and central neural blocks in the cat and dog. High frequency and long duration of block can be attained if sufficiently high concentrations of TTX are used, although latency is long and high dosage may produce systemic toxicity. Frequency and mean duration of block can be increased and systemic toxicity reduced if TTX is administered with a vasoconstrictive agent. Conventional local anesthetics also enhance the nerve-blocking activity of TTX. When appropriate concentrations of TTX and local anesthetics are used, a high frequency of blocks characterized by short latency and long duration can be demonstrated. The studies present some indirect evidence that local anesthetics enhance TTX activity by reversibly increasing the permeability of various neural barriers to TTX.

Most published studies on tetrodotoxin‖ (TTX) have been concerned with its site and mechanism of action, its effects on such structures as the neuromuscular junction, and its pharmacologic effects on isolated tissues and in whole animals.[1-4] Only a few have evaluated its remarkable local-anesthetic properties.[5-9]

Exploratory studies in our laboratory having indicated that conventional local anesthetics enhance the nerve-blocking activity of TTX, especially at those anatomic sites in which there are barriers to penetration, such as the dura mater and the neural sheath, we conducted studies to examine this phenomenon more fully.

METHODS

Isolated Frog Sciatic Nerve. — Sciatic nerve trunks of *Rana pipiens* were prepared (after the Camougis-Takman method[10]) by dissecting the nerve trunk from its roots in the spinal cord to the ankle and placing it on silver-silver chloride electrodes for stimulation of the nerve trunks and recording of the compound action potential at intervals throughout the blocking and recovery periods. Tasaki-Ringer solution (pH 7) was used both as a control medium and as a solvent for the test agents, and the nerve trunks were stimulated at 30 Hz. Based on exploratory studies, concentrations of lidocaine and of TTX were selected that produced a 5 to 15% block of the compound action potential after 30 minutes of exposure. Data were obtained on 7 nerve trunks exposed to 0.625 mM lidocaine, 8 exposed to 1 x 10^{-7} M of TTX, and 14 to a solution containing both lidocaine and TTX.

Rat Sciatic Nerve Blocks.—Precisely 0.2 ml of local anesthetic solution was injected

‖A toxin originally extracted, in 1950, from the ovaries of the globe fish (*Spheroides rubripes*) in Japan; LD_{50} in mice 10 μg/kg IP. *Ed.*

into the midthigh region of 1 hind limb around the sciatic nerve trunk. After injection, each animal was examined at intervals to ascertain frequency, onset, depth, and duration of block, as manifested by loss and recovery of motor function in the injected limb.

Frequency represents the number of successful blocks out of the total number of trials; *onset* is the time interval between the injection and the maximum degree of block obtained; and *duration* is the time interval between attainment of the maximum degree of block and either recovery of the ability to grasp or complete return of normal motor function. Frequencies, onsets, and durations given in the text and tables are for complete blocks resulting in total paralysis of the injected limb.

Five specific studies of rat nerve were conducted.*

1. TTX alone and with epinephrine.
2. TTX alone and with lidocaine.
3. TTX with lidocaine and with vasoconstrictors (phenylephrine, epinephrine, levonordefrin).
4. TTX and procaine.
5. TTX with local anesthetics.

Epidural Anesthesia in the Cat.—One male and 3 female cats, weighing 2.8 to 4 kg, were surgically prepared (by the method of Duce[11]) under anesthesia, by implantation of a polyvinyl catheter into a lumbar vertebra, for introduction of local-anesthetic solutions into the epidural space. Animals were allowed a minimum of 24 hours for recovery before tests. Each animal then received, on each of 3 consecutive days and in a randomized order, 1.5 ml of (1) 2% lidocaine; (2) TTX 1 μg/ml; or (3) 2% lidocaine with TTX, 1 μg/ml. All solutions contained 1:100,000 epinephrine.

Epidural Anesthesia in the Dog.—Adult male dogs, weighing an average of 10 kg, were surgically prepared (by the Lebeaux method[12]) under anesthesia, by implantation of a polyvinyl catheter into L-6 vertebra, for introduction of local-anesthetic solutions into the epidural space. All animals were allowed to recover for at least 24 hours before tests. Test solutions (5 ml) were administered at the rate of 1 ml/min, and animals were examined at frequent intervals for signs of onset of sensory analgesia and motor blockade. Examinations were continued at intervals until recovery from sensory and motor block was complete. The 2 hind limbs were evaluated independently for onset and duration of sensory analgesia and motor blockade. Each of 3 pairs of animals received 1 of the following 3 solutions: 2% lidocaine; TTX, 4 μg/ml; 2% lidocaine with TTX, 4 μg/ml. All solutions contained 1:100,000 epinephrine.

Solutions.—Stock solutions of TTX† (pH adjusted to 4-5) were prepared in distilled water and kept refrigerated. Dilute solutions for the studies were freshly prepared on the day of use, as were HCl solutions of the local anesthetics. Epinephrine, when employed, was added to the solutions immediately before use.

RESULTS

Isolated Frog Sciatic Nerve.—Lidocaine produced a mean block of 16% and TTX a mean block of 6%. The solution containing 0.625 mM lidocaine and 1×10^{-7} M of TTX produced a mean block of 47%, which is significantly greater ($p<0.01$) than that caused by either agent alone.

Rat Sciatic Nerve Blocks.

1. TTX Alone and With Epinephrine.—Epinephrine improved the frequency and increased duration of block at concentrations below 10 μg/ml. The toxicity of TTX was also reduced by the vasoconstrictor. No fatalities occurred at 10 μg/ml, and although all the animals given the 20 μg/ml solution died, the mean time to death in this group was 52 ± 12 minutes compared with 13 ± 2 minutes for the group given this concentration of TTX without epinephrine.

2. TTX Alone and With Lidocaine.—Neither TTX, 1 μg/ml, nor 0.1% lidocaine produced any blocks. However, a solution containing TTX and 0.1% lidocaine produced sciatic nerve block of 1 hour's duration in 66% of the animals. At 0.2%, lidocaine produced sciatic nerve block with a mean duration of 1 hour in only 50% of the animals, but a solution containing TTX and 0.2% lidocaine produced sciatic nerve block, with a mean duration of 79 minutes, in all the animals.

3. TTX With Lidocaine, Plain and With Vasoconstrictors.—The plain solution of TTX and lidocaine produced a block of

*Additional details available from senior author on request.

†Sankyo Company, Ltd.

about 3 hours duration in 1/5 of the animals injected. With the vasoconstrictors, frequency of block was 100% and mean duration about 6 hours. Unpaired *t*-tests showed that the onset time with levonordefrin was significantly longer than with phenylephrine ($0.02>p>0.01$) and epinephrine ($p<0.01$) but did not differ significantly between phenylephrine and epinephrine.

4. Temporal Relationship Between the Synergistic Effects of TTX and Procaine.—Procaine (2%) produced sciatic nerve block with a mean duration of 99 minutes. This duration was not affected by a subsequent injection of distilled water at 30 minutes. TTX, 1.5 μg/ml, produced no blocks in this experiment. The longest duration occurred when procaine and TTX were administered simultaneously. The mean duration of blocks became progressively shorter as the interval between the procaine and TTX injections was increased. TTX at 120 minutes had no effect; the mean duration of the procaine block was essentially the same as when procaine alone was given and when procaine was followed by distilled water.

5. TTX Administered Simultaneously With Various Local Anesthetics (table 1).—With TTX alone, frequency of block was only about 10% and the mean onset time was long. Frequency of block was 100% with all solutions containing both TTX and a local anesthetic, and mean onset times were virtually identical to those of the corresponding local anesthetics alone. However, mean durations of the solutions containing the 2 agents were 2½ to 5 times greater than with the corresponding local anesthetics.

6. Epidural Anesthesia in the Cat (table 2).—In general, frequency and duration of block were greater with the mixture of lidocaine and TTX than with either agent by itself.

TABLE 1
Rat Sciatic Nerve Blocks with TTX and Local Anesthetics

Agent	Concentration	Frequency of block	Onset* of block	Duration of block
Tetrodotoxin	2 μg/ml	2/20	13	151
Procaine	2%	5/5	2	60 ± 7
TTX:procaine	2 μg/ml:2%	5/5	2	314 ± 58

Tetrodotoxin	1 μg/ml	0/8	—	—	0/8	—	—
TTX:lidocaine	1μg/ml:2%	7/8	7	109 ± 8	8/8	<1	188 ± 9

*All solutions contained 1:100,000 epinephrine.
†Four animals, each hind limb evaluated separately.
‡Mean onset in minutes.
§Mean duration in minutes ± SD.

7. Epidural Anesthesia in the Dog (table 3).—Mean durations were essentially the same for TTX alone and TTX with lidocaine; they were, however, 2 to 2½ times longer than with lidocaine alone. Mean onset times for TTX were in general 2 to 4 times longer than with lidocaine. Of special interest is the observation that perception of noxious stimuli in the pudendal region, which was blocked in only one dog for about 2 hours with TTX, was blocked in both animals for a mean duration of about 5 hours with TTX and lidocaine.

DISCUSSION

TTX is an extremely potent agent capable, in microgram concentrations, of producing reversible blocks of long duration *in vitro* and *in situ*. Because of its low lipid solubility, it apparently penetrates with difficulty such barriers as the dura mater and the neural sheath around peripheral nerves. Evans,[9] for example, reported that TTX was ineffective when applied to peripheral nerves unless they were first desheathed, but that topical application of very low concentrations of TTX to the intradural portion of spinal roots produced conduction block, presumably because those roots lack a sheath. The studies reported here demonstrate that reversible nerve blocks of long duration can indeed be produced in peripheral nerves if sufficiently high concentrations of TTX are used.

As we observed in the rat sciatic nerve blocks, however, concentrations that produce a high frequency of successful blocks may also cause systemic toxicity and death. Vasoconstrictors in appropriate concentrations increase the frequency of successful blocks and reduce systemic toxicity and fatalities. The concomitant administration of classic local anesthetics also enhances the conduction blocking activity of TTX, as demonstrated in the studies of peripheral nerve blocks in rats and epidural anesthesia in cats and dogs. If suitable concentrations of TTX and local anesthetic agents are combined, these exhibit the short latency and high frequency of successful blocks characteristic of the local anesthetic and the remarkably long blocks characteristic of TTX.

It is possible to demonstrate what appears to be a true potentiation if the TTX or the local anesthetic, or both, are used at concentrations that are marginally effective or even ineffective. For example, neither TTX at 1 μg/ml nor 0.1% lidocaine effected any blocks when injected around the rat sciatic

TABLE 3

Epidural Anesthesia in the Dog

*Onset and duration in minutes as means ± SD.

†Block in 1 of 2 animals only.

nerve trunk; when both were administered simultaneously, however, a better than 50% frequency of blocks was obtained with a mean duration of about an hour. It was also possible to demonstrate in the cat that a concentration of TTX that by itself produced no overt signs of epidural anesthesia doubled the duration of block produced by 2% lidocaine.

A further example can be singled out of the studies of epidural anesthesia in dogs. Analgesia in the pudendal area lasted for about 2 hours in the 2 animals tested with 2% lidocaine; TTX at 4 μg/ml effected block of this area for about 2 hours in only one dog. The solution containing both agents, however, produced sensory block in the pudendal area in both animals with a mean duration of 5 hours.

Lebeaux[12] has pointed out that, if the catheter is surgically implanted at L-6, the nerve roots mediating pain in this area are several spinal segments removed from the site of administration of the drug solution. The concentrations of TTX and lidocaine are, after diffusion from the site of administration and penetration through the barriers interposed between the epidural space and the spinal roots, lower than at the site of administration. Consequently, the synergistic effects of an adequate concentration of local anesthetic and a concentration of TTX that, on the basis of poor frequency, long onset, and relatively short duration, can be regarded as considerably less than maximally effective, are manifested as a block that is 2½ times longer than that produced by either agent alone.

The mode of action of the vasoconstrictors in enhancing the nerve-blocking effects of TTX seems clear. They decrease blood flow through the area, reduce systemic absorption, and thus maintain a higher concentration of TTX at the site of administration for a longer time. The mode of action of local anesthetics, on the other hand, is less obvious.

Staiman and colleagues[13] demonstrated a potentiation of TTX by lidocaine on frog nerve *in vitro*. In our studies with intact isolated frog sciatic nerve trunks we, too, have observed that blocks obtained with a mixture of lidocaine and TTX were significantly greater than with either agent alone and also greater than the sums of the blocks produced by these agents separately. Our studies also showed that local anesthetics enhanced the activity of TTX when injected around the sciatic nerve trunk in the rat and when administered epidurally in the cat and dog.

Therefore, the enhancement of the blocking activity of TTX in the presence of barriers such as the dura mater and the neural sheath suggests that, in addition to acting at different sites on the nerve membrane, as postulated by Staiman's group, TTX and lipid-soluble anesthetic agents may interact at another site: the neural barrier. The enhanced activity of the TTX may be due to an increase in permeability of the barrier to TTX brought about by the anesthetic agent. This would certainly explain the results obtained in our studies, but further studies are required to ascertain whether local anesthetics do indeed facilitate the movement of TTX across such barriers at the dura mater and the neural sheath.

The aim of the studies reported here was to examine the interaction of TTX and local anesthetics in various animal models and not to ascertain the potential clinical usefulness of these mixtures. However, the results do suggest the possibility that, with appropriate mixtures of TTX, a local anesthetic, and, for certain types of block, a vasoconstrictor, reversible blocks of long duration may be obtained with no more risk to the patient than with current blocking agents. Such a formulation would be highly desirable in those types of regional block in which prolonged relief of pain is the primary requisite.

ACKNOWLEDGMENT

The authors thank Mrs. Donna Charron and Miss Georgette Kilpatrick for their excellent technical assistance in conducting these studies.

DYSAUTONOMIA. Plasma norepinephrine concentrations and dopamine-beta-hydroxylase activity were measured in 10 normal patients and 10 patients with familial dysautonomia. After lying recumbent for 20 minutes plasma norepinephrine was similar in both groups. Normal subjects more than doubled their plasma norepinephrine after standing 5 minutes while dysautonomic patients did not increase their plasma norepinephrine. In dysautonomic patients blood pressure supine was similar to normals but fell nearly 50% with standing. Heart rate increased in controls but not dysautonomic patients during standing or isometric exercise. Blood pressure correlated with plasma catecholamine levels in dysautonomic but not normal patients. Dopamine-beta hydroxylase activity was reduced in dysautonomic patients. These data suggest that the spontaneous low activity of the sympathetic nerves is adequate to maintain normal plasma norepinephrine levels in dysautonomic patients. However, these patients do not release sufficient norepinephrine to provide circulatory adaptation to standing or exercise. *(Ziegler MG, Lake CR, Kopin IJ: Deficient sympathetic nervous response in familial dysautonomia. CARL L. NELSON, MD‡
JOAN W. FLACKE, MD§
ASTRIDE B. SEIFEN, MD‖
Little Rock, Arkansas**

Sodium nitroprusside (SNP) was used to produce deliberate hypotension in 30 selected patients, 9 to 78 years of age, for total hip replacement under halothane-N_2O-O_2 anesthesia. Hypotension was induced in the first 13 patients by infusing a 0.01% (100 μg/ml) solution of nitroprusside (NP) in 5% dextrose. Blood pressure was diminished to a level just producing a dry surgical field. Preliminary data demonstrated that the mean arterial blood pressure (MAP) achieving this condition was 65 torr ($p<0.01$) and that the minute dosage of NP (μg/min) required to consistently reduce MAP to 65 torr could not be predicted on the basis of body weight.

However, the age/weight ratio (yr/kg) of each patient, plotted against the known minute dosage of NP given during anesthesia, produced a highly significant dose-response curve ($p<0.001$, $r = -0.8226$).

The preliminary dose-response curve was examined in a double-blind study on an additional 17 patients. The curve derived from the prospective study did not differ from that of the preliminary study. In addition, the combined data from the retrospective and prospective studies (30 patients) gave a better statistical fit than did those from the preliminary study alone ($p<0.001$, $r = -0.8939$).

The nomogram provides an additional margin of safety in the use of this potent, fast-acting drug. SNP has been found predictable and effective in reducing surgical blood loss in selected patients undergoing total hip replacement.

SODIUM NITROPRUSSIDE (SNP) is a potent, rapid-acting, antihypertensive drug which produces arteriolar vasodilation by direct action independent of the autonomic nervous system.[1] Its short duration of action necessitates a continuous infusion to maintain a constant effect. These properties have made the drug useful in a variety of clinical situations.[2-4] In some centers, nitroprusside (NP) has been used to produce deliberate hypotension since 1962.[5] Other recent reports[6-9] indicate that this agent produces controlled hypotension which, in contrast to other methods, enhances tissue perfusion while effectively reducing surgical blood loss.

Our group has recently described a study[10] in which cardiac output and other circulatory parameters were measured in 13 patients undergoing total hip replacement, using halothane-N_2O-O_2 anesthesia and SNP-induced hypotension. Patient ages

Paper received: 3/22/76
Accepted for publication: 4/1/76

ranged from 9 to 78 years. Our results, confirming those of others,[6-9] indicated that NP produces a physiologically superior hypotensive state. Cardiac output rose toward normal during the hypotensive period. The increase was 20% above that of control patients undergoing the same procedure but kept normotensive. Urine output was not compromised and no arterial or venous acidosis was noted. Surgical blood loss was significantly reduced as a result of arterial hypotension, with a MAP of 64 ± 4 torr (± SE) resulting in a dry surgical field.

We noted, as have others,[7] that the NP dosage required to produce comparable levels of hypotension in a group of patients was not predictable on the basis of body weight. A better relationship existed between age and dose, although this correlation was not statistically significant either. However, analysis of the data revealed a highly significant correlation between a patient's age/weight ratio (yrs/kg) and NP minute dosage (μg/min) required to maintain levels of hypotension comparable to those attained in other patients. When the age/weight ratio for each patient in the earlier study was plotted against the minute dosage given, a highly significant ($p<0.001$, $r = -0.8226$) dose response resulted. This suggested that an appropriate dosage of NP could, in fact, be predicted (fig 1).

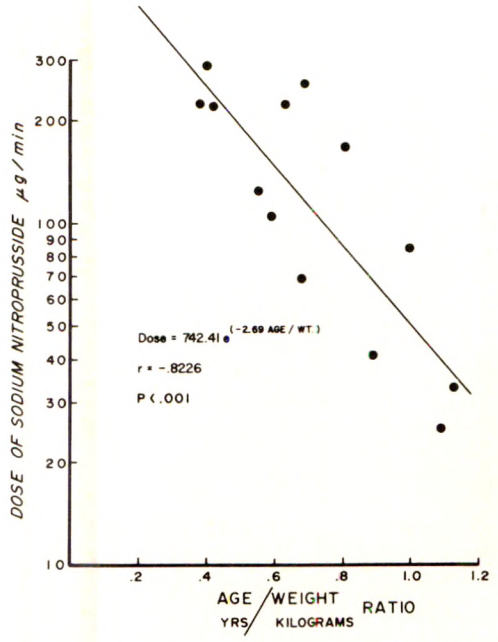

FIG 1. Highly significant dose-response curve resulting from retrospective analysis of age/weight ratios (yr/kg) plotted against the minute dosage of NP needed to maintain comparable levels of hypotension in earlier study.[10]

METHODS

Seventeen patients admitted for total hip replacement were studied. None of the subjects had evidence of cerebrovascular disease, clinical or electrocardiographic evidence of ischemic heart disease, anemia, renal hypertension, serious peripheral vascular disease, or severe obstructive lung disease. Advanced age was not considered a contraindication to deliberate hypotension during anesthesia.

Premedication consisted of appropriate doses of morphine, diazepam, and scopolamine, except in patients over 60, in whom morphine was omitted. Anesthesia was induced with 2% IV thiamylal and maintained with halothane (0.5 to 0.75%) in N_2O-O_2 (50:50). Patients were intubated after an appropriate dose of succinylcholine. A radial arterial cannula was inserted before the induction of anesthesia and the arterial blood pressure displayed continuously, along with the pulse rate and a lead II ECG, on a Tektronix® model 412 oscilloscope. In addition, the urine output, central venous pressure, and tympanic temperature were monitored. Arterial blood gases were sampled at 30-minute intervals throughout the procedure. A warming blanket was used to minimize heat loss.

Five percent dextrose in lactated Ringer's solution was given at a rate of 12 to 15 ml/kg during the 1st hour and at 6 to 10 ml/kg/hr thereafter. Homologous blood was administered only when a surgical blood loss of more than 500 ml was anticipated.

Continuous positive-pressure ventilation was not used as an aid in producing hypotension; instead, ventilation was assisted in order to maintain the $Paco_2$ between 37 and 41 torr. Nondepolarizing muscle relaxants were omitted, to avoid their possible hemodynamic effects. Patients remained supine during operation, with slight elevation of the hip. Blood loss was estimated from the content of the suction bottles and by weighing sponges. Irrigation fluid was collected in a separate suction system.

Three concentrations of SNP, 0.01% (100 μg/ml), 0.005% (50 μg/ml), or 0.0025% (25 μg/ml) in 5% dextrose, were used. One of these concentrations was assigned at random to consecutive patients, this variation being intended to prevent the study team from becoming familiar with the response

to only a single concentration. One anesthesiologist was assigned the responsibility for the induction and maintenance of hypotension in each case.

The person administering the NP had no knowledge of the concentration used or of the age/weight ratio of the patient. However, as a safety precaution, a starting volume (ml/min) was assigned. This volume was determined by the study leader, who knew the drug concentration being delivered, the age/weight ratio of the patient, and the NP dosage anticipated from the described dose-response curve. The study leader did not participate in the administration of the anesthetic or the NP after the initial order had been given.

Hypotension was induced just before skin incision. The NP solution was given through a peripheral IV catheter at an infusion rate controlled by an infusion pump,* allowing accurate control of the delivered volumes. Starting at the assigned volume, the rate of infusion was adjusted empirically to lower and maintain a mean arterial pressure (MAP) of ± 65 torr. This pressure was chosen, on the basis of our preliminary study, as being safe and effective in reducing surgical blood loss.

The infusion was discontinued and the blood pressure allowed to return to normal before wound closure in order to permit hemostasis. The duration of hypotension was measured from the time the desired level of pressure had been reached until the infusion was stopped. The total dose of NP administered over that time period was also recorded. The average minute dosage (μg/min) required to maintain each patient's MAP at 65 torr was calculated. This dosage was plotted on semilog paper against age/weight ratios and compared to that predicted from the preliminary dose-response curve.

RESULTS

In the 17 patients, 15 to 75 years of age, studied, the desired level of hypotension was attained and maintained without difficulty. The MAP during hypotension in the study group was 65 ± 4 torr.† Once the desired level of blood pressure was reached, only minor changes in the rate of infusion were required to maintain constant levels of hypotension. As a result, the calculated average minute dose of NP (μg/min) differed little from the actual minute-to-minute dose resulting from minor fluctuations in pressure.

The action of NP began within 60 to 90 seconds after starting the infusion and the duration of action was short when the infusion was stopped. Blood pressure began to rise toward normal within 120 seconds after infusion ended. Blood pressure decreased in proportion to the amount of NP infused; however, no correlation was found between the minute dosage of NP required to lower the blood pressure of a given patient to comparable levels in a group of patients of similar weight. This finding confirms the results noted in our earlier study (fig 2).

An inverse relationship between patient age and minute dosage was again noted, but the correlation was not statistically significant (fig 3). When the required dose of NP was plotted against the age/weight ratio of each study patient, a highly significant relationship could be seen. The curve derived from this study did not differ significantly from that of the previous study. The combined data from the 30 patients in the 2 studies (fig 4) gave a better statistical fit ($p<0.001$, $r = -0.8939$) than that found in the preliminary study alone.

The duration of deliberate hypotension for the 17 patients averaged 90 (± 15) minutes. Acid-base balance remained normal and no tendency toward acidosis was noted. Actual operating time averaged 110 ± 15 minutes. The average blood loss in the study patients was 450 ml (± 100) compared with 1480 ml (± 200) in 10 patients receiving total hip replacement under normotensive anesthesia by the same surgical team.

Transfusion was required in only 2 of the 30 study patients, each receiving 2 units. Both patients had had multiple operations on the involved hip, and the transfusion was required as a result of posthypotensive blood loss. In comparison, a total of 23 units of homologous blood was given to the 10 control patients, who were kept normotensive. When no blood was given during or after operation, the hemoglobin count declined slowly until the 3rd postoperative day. The lowest postoperative hemoglobin noted in the study was 8.8 gm/100 ml in a Jehovah's Witness patient. No adverse effects were seen as a result of SNP-induced hypotension.

*Harvard Apparatus Company, Millis, Massachusetts.

†Mean value refers to the arithmetic mean.

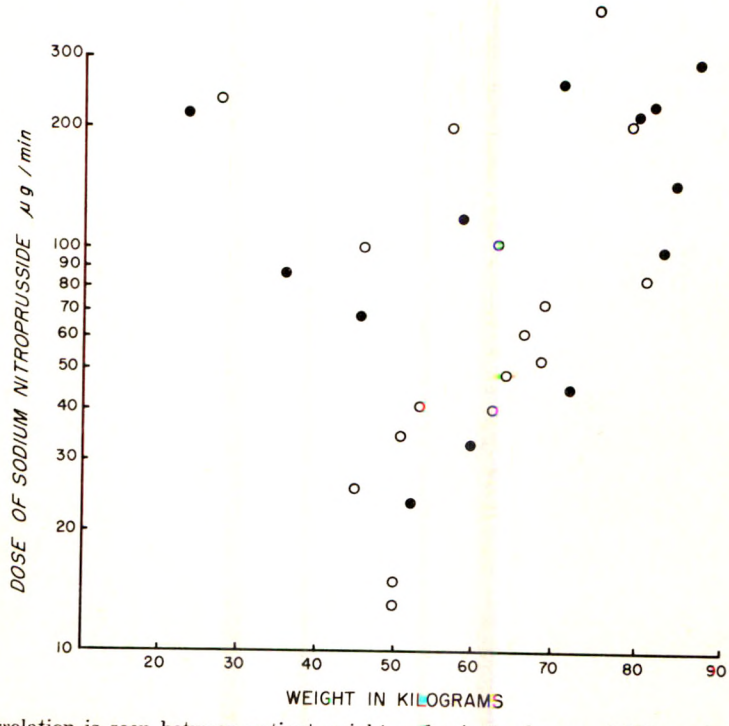

FIG 2. No correlation is seen between patient weight and minute dosage of NP needed for comparable levels of hypotension. Preliminary study[10] data (solid circles) are compared with present study data (open circles).

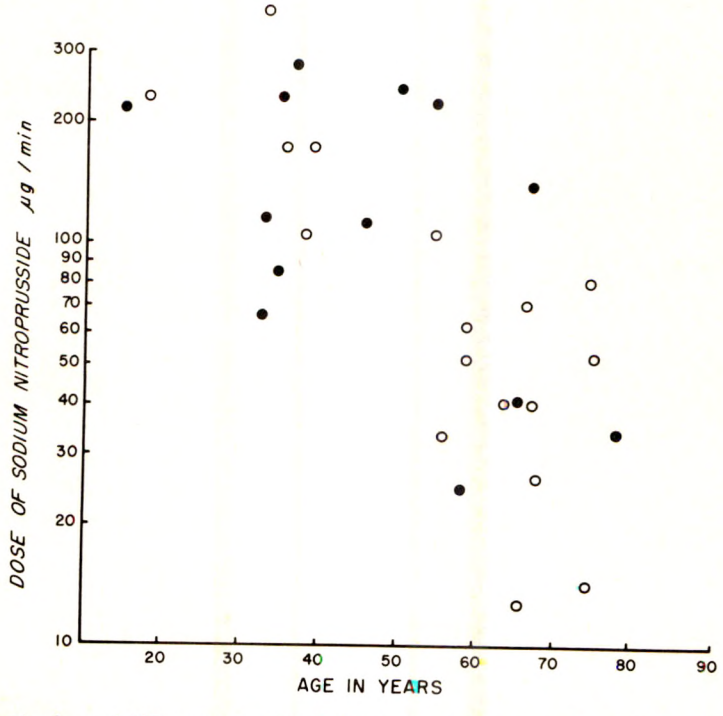

FIG 3. The minute dose of NP appears related inversely to the age of the patients but the relationship was not statistically significant. Preliminary study[10] data (solid circles are compared with present study data (open circles).

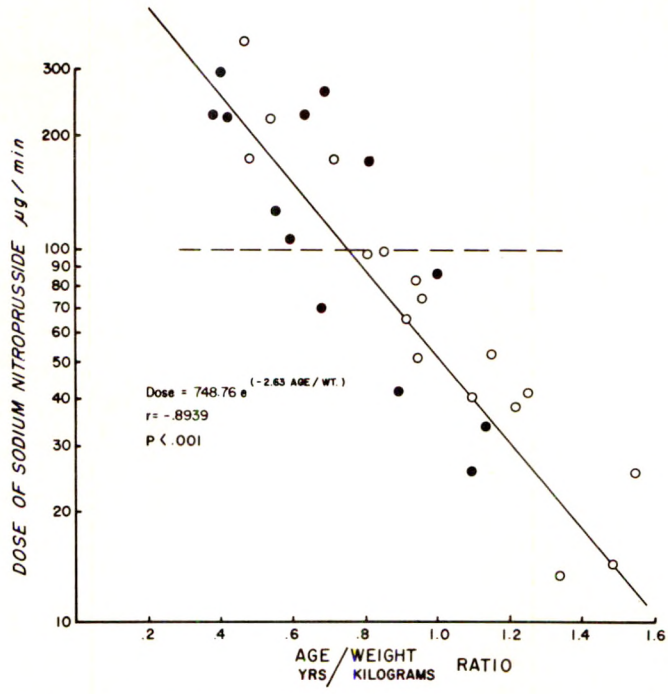

FIG 4. Age/weight ratios (yr/kg) produce a highly significant dose-response curve relating the minute doses of NP needed to produce comparable levels of hypotension in a given patient population. The combined data of the preliminary study[10] (solid circles) and the present study (open circles) produce a better statistical fit than does the original curve (fig 1). A concentrated solution (100 µg/ml) is used when predicted dosage is above 100 µg/min.

DISCUSSION

The safety of NP has been ascribed[6-9] not only to its improvement of tissue perfusion during hypotension but also to the evanescence of its action. The speed of onset and duration of action of NP is between 60 to 120 seconds, necessitating a continuous infusion to maintain constant levels of hypotension. The magnitude of the blood pressure response is dose dependent, and pressure levels can be changed within seconds, if needed, by altering the infusion rate. In the past, this speed of action, coupled with an apparent variation of potency and dose in a given patient population of similar body weights, has constituted one of the main difficulties in NP administration.

Previously, NP dosage had to be adjusted empirically according to response, recommended dosage ranging from 0.5 to 30 µg/kg/min.[7] Our experience with 30 patients has confirmed this wide range of doses based on weight. The dosage of NP required to produce comparable levels of hypotension within a group of patients of similar body weight is entirely unpredictable (fig 2). An inverse relationship between age and required dose was more apparent, but this correlation was not statistically significant either (fig 3). However, when both age *and* weight were considered (age/weight ratios), a highly significant dose-response relationship resulted (fig 4).

A nomogram relating the age/weight ratio to infusion rate has proven to be of considerable practical value in our hands. It has eliminated the time-consuming and often dangerous empirical search for the NP dose required to produce consistently safe levels of hypotension in a given patient. Thus, the nomogram represents an additional margin of safety in the use of this potent and fast-acting drug.

Taylor's group[9] and Davies and coworkers[11] have noted that young patients require larger doses of NP than do adults to produce the same degree of hypotension. A review of the nomogram confirms that observation. The age/weight ratio of a normally developing child from age 2 years until maturity remains relatively constant at between 0.3 and 0.5. Ratios in this range on the curve would indicate that the required NP dosage under halothane anesthesia would be in the range of 200 to 300 µg/min throughout

childhood and adolescence. However, the relationship between age, weight, and dosage remains constant over a wide range of ages. For example, a 38-year-old patient from the current study weighed 98 kg, for an age/weight ratio of 0.35. He required 275 μg/min of NP to produce and maintain a MAP of 65 torr. Likewise, a 9-year-old patient in the previous study, weighing 24 kg (age/weight ratio = 0.38) required 230 μg/min to produce a comparable level of hypotension. On a weight basis, the 9-year-old received 9.6 μg/kg/min as compared to 2.3 μg/kg/min for the 38-year-old.

Doubts have been expressed about the safety of NP, particularly in children,[11,12] because its immediate metabolic products are cyanide and thiocyanate. Vesey's group[13] reported a significant rise in plasma cyanide following the infusion of NP for hypotensive anesthesia. They concluded, however, that those levels encountered did not produce toxic effects. Recently, several anesthetic deaths[12,14,15] have been reported in which NP was implicated, but most of these occurred under extraordinary circumstances in which the evidence against NP may be spurious. Only Davies and colleagues[12] clearly documented a death due to NP overdose. Johnson[4] described the therapeutic index of NP to be around 10:1, but McDowell's group,[16] working with primates, suggested that the ratio might be closer to 6:1. Also, the concentration of accumulated toxic byproducts is related obviously not only to the total dose given but also to the time over which it is administered.[17] Certainly, NP has been safely used for extended periods in treating hypertensive crises without a dangerous build-up of toxicity.[3] The fatality reported by Davies involved 120 μg/kg/min (4800 μg/min) of NP given over 80 minutes. This patient's age/weight ratio was 0.35 and he thus received 20 times the dose the nomogram would have predicted. Davies attributed this large dose to tachyphylaxis, a phenomenon not observed in our series, even in the young.

The question of tachyphylaxis requires comment. Autonomic nervous system responses, especially sympathetic, during anesthesia and operation, are a function of the depth of anesthesia, as well as of body temperature, hypoxia, respiration, and acid-base balance. In these circumstances, an increase in sympathetic vasoconstrictor activity or heart rate may result. To overcome this active sympathetic effect, an increasing infusion rate of NP will be needed to maintain constant levels of hypotension against the efforts of the homeostatic system.

In our experience, the so-called tachyphylaxis to the drug during anesthesia, requiring doses greater than that predicted, has served as a warning of unattended sympathetic compensation secondary to physiologic alterations, rather than true tachyphylaxis. Correction of a temperature deficit, inadequate anesthesia, hypoxia, or acidosis has always reduced the NP requirement. The fatal case reported by Davies[12] exhibited a marked but compensated metabolic acidosis (base deficit = −9) before the NP was administered. The possibility of a metabolic defect was not excluded. Equally, the other fatal reports in which NP has been implicated included severe physiologic alterations such as hypothermia[14] (31° C body temperature), airway obstruction, hypoxia,[15] and/or acidosis.

We have found SNP to be safe, effective, and predictable in reducing blood pressure and surgical blood loss in selected patients undergoing total hip replacement in the supine position. The effects of drugs or anesthetic technics, other than those described, on the slope or position of the NP dose-response curve remain to be explored.

Guest Discussion

ROBERT K. STOELTING, MD
Department of Anesthesia
Indiana University Medical School
Indianapolis, Indiana

Dr. Lawson and coworkers have demonstrated that the age/weight ratio correlates with the minute dose of sodium nitroprusside (SNP) necessary to reduce the blood pressure to about 65 torr. Accordingly, my discussion will deal with those characteristics that may influence SNP dose requirements.

Factors that should be considered in determining the dose of any drug include body weight, patient age and physical condition, route of drug administration, hepatic and renal function. Unique to the SNP dose requirements one should also consider the blood pressure prior to drug administration, the desired magnitude of blood pressure reduction, and the influence of any concomitantly administered drugs, such as anesthetics.

Body weight (and body surface area) reflect the volume of drug distribution, which may be different in thin versus obese or in dehydrated versus edematous patients. The relative volume of body fluid compartments may vary with age and be influenced by serum protein concentrations. Recently, Koltz and associates[1] reported that the elimination, or beta half-life, of diazepam increased in direct proportion to patient age, due to increased drug distribution volume.

The maintenance of a constant drug concentration during steady-state infusion, as with SNP, is determined by the rate of biotransformation as reflected by the drug half-life and the volume of drug distribution in the body.[2] The hypotensive effect of SNP is due to the nitroso portion of the free drug.[3] The evanescent response reflects the drug's rapid breakdown to products lacking vasodilating properties.[4] This breakdown occurs in 2 steps: First, there is a nonenzymatic reaction of the iron atom with sulfhydral groups (primarily in the erythrocytes) to form cyanide. Second, cyanide is converted to thiocyanate by the hepatic enzyme, rhodanase.

Whether underlying hepatic disease or enzyme induction would influence the rate of SNP biotransformation is not established. Conceivably, altered rates of biotransformation might result in different blood-pressure effects from the same minute dose of SNP, since more or less drug would remain in the active form. However, liver function is probably unimportant in determining the SNP dose, since the initial drug breakdown is not enzyme dependent. Likewise, the initial nonenzymatic biotransformation would suggest that decreased drug delivery to the liver, secondary to anesthetic-produced reductions in hepatic blood flow, would not influence the SNP dose necessary to reduce blood pressure.

Little is known about protein binding or tissue and blood solubility of SNP and how these factors might influence the distribution volume of the drug. Even were these known, the adjustment of dosage on the basis of pharmacokinetic principles is only an approximation, with the final maintenance dose determined by patient response.

I would like to ask Dr. Lawson the following questions:

1. Why did the age/weight ratio correlate with the minute dose of SNP when neither variable alone produced a similar correlation?

2. How does one adjust the dosage nomogram at the extremes of body weight or fluid balance?

3. Would the dosage nomogram be similar in hypertensive versus normotensive patients or with similar control blood pressures but different anesthetic maintenance drugs (halothane-N_2O versus fentanyl-N_2O)?

Addendum

ANSWERS TO DR. STOELTING'S QUESTIONS:

1. Why did the age/weight ratio correlate with the minute dose of SNP when neither variable alone produced a similar correlation?

Examination of the graphs relating dose to age *or* weight suggests that the minute dose of SNP required to produce comparable levels of hypotension in a group of patients is inversely related to age but directly proportional to weight. However, neither factor alone correlated sufficiently to be clinically useful in predicting dose-response. Age and weight appeared to have counteracting effects in dose-response, each modifying the other, but to different degrees. We examined weight/age ratios, age/weight ratios, and body surface area in relation to the dose requirements. Weight/age ratios did not produce a mirror image of the age/weight ratio response but *was* statistically significant ($p<0.01$). Age/weight ratios produced a more significant response ($p<0.001$). Thus age, when used as the numerator in the ratio, appeared to be the more important factor in determining dose, although the relationship is inverse. Weight (mass) modifies the age dose-response by determining the volume to which the drug was distributed. Statistically, body surface area fared no better than weight alone in predicting dose-response.

Clinically, age is perhaps an indirect assessment of metabolic rate (biotransformation) which also varies inversely with age. Too, age might relate indirectly to changes of vessel compliance with age. I feel that the use of age and weight to determine the dose response of SNP is a useful clinical tool. One might produce a more accurate dose-response curve if it were clinically feasible to determine metabolic rate and body surface area in the everyday practice of anesthesia.

2. How does one adjust the dosage nomogram at the extremes of body weight or fluid balance?

Our study was performed on carefully selected patients who were otherwise healthy except for their hip disease. Criteria for hip replacement ruled out the selection of obese patients. We have administered SNP to several obese patients for other procedures. The minute dose for these patients, in retrospect, was predictable on the proposed nomogram when their weight, used in the age/weight ratio, was corrected to their ideal weight according to life insurance tables. They took less than predicted if their actual weight were used in determining dosage. Thus, adipose tissue remains a "slow space" for nitroprusside as well as other agents used in anesthesia.

We have not had any experience with nitroprusside in patients at the extremes of fluid balance. Patients, under these conditions, thus far, are not candidates for hypotensive anesthesia.

3. Would the dosage nomogram be similar in hypertensive versus normotensive patients or with similar control blood pressure but different anesthetic maintenance drugs (halothane-N_2O versus fentanyl-N_2O)?

Patients with renal hypertension are not candidates for deliberate hypotension during anesthesia but nitroprusside may be used to control hypertension during surgery on these patients. We have administered nitroprusside to 7 patients with controlled essential hypertension for hypotensive anesthesia exclusive of the present report. The dose-response fell within the statistical range predicted by our nomogram. However, there have not been enough patients of this type to determine if their dose-response curve might be shifted from the norm for their particular condition. Schlant and coworkers[1] noted in 1962 that patients with hypertension appeared more sensitive to the effects of nitroprusside. However, we have since recognized that uncontrolled hypertensive patients also have a reduced plasma volume. Volume depletion might accentuate the effects of vasodilatation rather than be representative of a true hypersensitivity to SNP. We have not explored the effects of other anesthetic agents on the slope or position of the SNP dose response curve.

A CLASSIC drug of antiquity,[1] cocaine, the active alkaloid of the shrub *erythroxylon coca,* is perhaps the most exquisitely euphorogenic as well as the most monumentally illegal drug of all time.[2] In the drug-using counterculture, a remarkable upsurge in popular illicit use of cocaine was witnessed in mid-1970, reaching a plateau by mid-1972.‖[3] It is our purpose to offer a practical clinical review of the treatment of acute and chronic cocaine overdose (OD), along with some of the rich background history of this drug.

"The Dreadful Andes plac'd twixt Winter's Store of the Winds, Rains, Snow, and that more humble Earth, That gives the small, but valiant, Coca birth."
Abraham Cowley (1721)[1]

The coca leaf was believed to be a gift to the Inca people from Manco Ccapac, son of the Sun God, bestowed as a token of esteem and sympathy for their suffering labor. The leaves were initially to achieve a rather narrow usage among the religious and political aristocracies of the Inca society; a much broader and perhaps more sinister pattern was noted following the destruction of the Incan civilization in the 16th century by Francisco Pizzaro and the invading conquistadores, as the lower classes and slaves were "paid off" in coca leaves as an effective method of increasing and and prolonging low-cost, high-output labor. In practice, coca leaves, bound into a ball (or *cocada*) with guano or cornstarch, were chewed with lime (as alkaline ash) to release the active alkaloid.

Thus coca served as a stimulating tonic to those working in the thin air of the Andes. Further, anthropologic documentation indicates that the highly sophisticated surgical procedure of trephination was repeatedly successful in this era, as the operating surgeon allowed coca-drenched saliva to drip from his mouth onto the surgical wound, thus providing adequate (and very real) local anesthesia, and permitting the operation to proceed in relative quiet.*

Little was heard of coca as a medical entity until 1859, when the Italian physician, Paolo Mantegazza, declared coca leaves to be a "new and exciting weapon against disease;" his narrative, however, cannot be regarded as objective scientific observation, as he wrote:

‖Greater than 50% of a recent random sample of clients at the Haight-Asbury Free Medical Clinics reported use of the agent "at least once during the past 2 months."

*Such surgically incised skulls, along with pottery shards depicting faces with cheeks stuffed with coca leaves, have been dated back some 1200 years.

"Borne on the wings of two Coca leaves, I flew about in the spaces of 77,438 worlds, one more splendid than another. . . . It seemed to me that I was separated from the whole world, and I beheld the strangest images most beautiful in color and in form than can be imagined."

In England, meanwhile, coca leaves were being viewed as a pharmacologic curiosity, while American physicians echoed Mantegazza, heralding the drug as a cure-all for almost every recognized malady, including alcoholism, tuberculosis, opiate addiction, and heart failure.

Alfred Neimann isolated the coca alkaloid in 1860 and named it "cocaine." By 1865, preparations of coca leaves and wine were introduced onto the open market, the classic example being "Vin Mariani." A true advertising genius, Angelo Mariani received public testimonials to his tonic from such dignitaries as Queen Victoria, Pope Leo XIII, Sarah Bernhardt, and Thomas Edison (Mariani's company published these in a series of 12 volumes), and he may have come closer to "turning on the world" than any man in history.[4]

The coca boom was soon to follow in Europe, when in 1884, a cocaine "kit" from Eli Merck was delivered to Dr. Sigmund Freud in Vienna. Ever the visionary experimenter, Freud was shortly using coca in the treatment of various medical and psychologic disorders. Between 1884 and 1887, he wrote five papers ("Über Coca") extolling coca as a wonder drug, but his "coca euphoria" subsided abruptly and he subsequently deleted these laudatory writings from the collected papers of his autobiography.

Simultaneous with Freud's enthusiastic pronouncements, his own colleague. Dr. Karl Koller, delivered a formal paper before a prestigious group of ophthalmologists on the potent local anesthetic effects of cocaine upon the corneal nerve endings, and was subsequently praised by Freud as the "true discoverer" of anesthesia.

The introduction of cocaine as a local anesthetic created enormous new opportunities for surgical anesthesia, and Dr. William Halsted, of Johns Hopkins in Baltimore, performed the first "nerve blocks" in 1885.[5] (By 1886, Halsted was to write no further about cocaine as he battled his own 2 gm/day habit.) Coca Cola®, the first of the popular proprietary cocaine-containing "soft drinks," was introduced by Asa G. Candler in 1888, and in the ensuing years countless cocainized over-the-counter nostrums flourished. In the surgical amphitheater circa 1899, cocaine had been employed as a successful "spinal anesthetic" by Drs. Tait and Cagliari of San Francisco and Dr. Rudolph Matas of New Orleans.

In 1906, the Pure Food and Drug Act was passed, legislating the mandatory labelling of all proprietary medications. This marked the end of the cocaine-Coca-Cola alliance, but it was not until the Harrison Tax Act of 1914 that cocaine was legally (although pharmacologically inaccurately) defined as a "narcotic;" and, with all semblance of quality control removed, its use disappeared underground.

Except for a small (and diminishing) recognized use of cocaine in strictly medical settings, it has existed since that time as a black-market commodity. Over the ensuing 62 years its presence has been noted among suppressed inner-city populations, various enclaves of American music culture, the affluent, and the artistic "bohemian" culture.

Take a Whiff on Me

Blacker de berry, de sweeter de juice,
Takes a brown-skin woman for my partickler use
An' ho, ho, baby, take a whiff on me.
Chew my 'baccer, spit my juice,
Gonna love my baby, 'till it ain't no use
An' ho, ho, baby, take a whiff on me.
Whiffaree an' a whiffarye,
Gonna keep on a-whiffin' until I die,
An' ho, ho, baby, take a whiff on me.
Cocaine for horses an' not for men,
Doctors say it'll kill you but they don't say when
An' ho, ho, baby, take a whiff on me.
Leadbelly (1933)

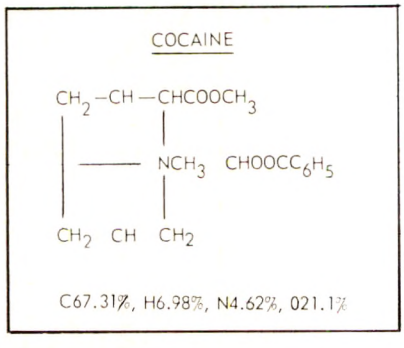
An aura of mystic romanticism has enshrouded cocaine throughout its history. Robert Louis Stevenson is said to have composed the 1st draft of "Dr. Jekyll and Mr. Hyde" in 3 days while undergoing treatment of tuberculosis with cocaine. Arthur Conan Doyle, the literary genius who created the sleuth who was to become the epitome of cold, crystalline logic, opened his novel, *The Sign of Four*:

"Sherlock Holmes took his bottle from the corner of the mantelpiece, and his hypodermic syringe from its neat morocco case. . . . 'It is cocaine,' he said, 'a seven-percent solution. Would you care to try it?' "

Presently the coca leaf is cultivated legally in only 2 countries, Peru and Bolivia, where is produced the majority of the world's supply. After each harvest in March, June, and November, a complex exportation process ensues, the product being smuggled across various borders either in leaf form or as a raw paste extracted by kerosene, with varying degrees of sophisticated refining carried out en route.* From coastal debarkation ports, cocaine eventually finds its way to a broad world market, with North America and Europe serving as its major consumers.

In recognized street jargon, the feminine gender ("Her," "Lady," "La Dama Blanca," "Girl") is used synonymously for cocaine; other popular nicknames ("Happy Trails," "Nose Candy," "The Star Spangled Powder," "Snow," "Flake," "Heaven Leaf," "The Rich Man's Drug," "The Pimp's Drug") describe aspects of the agent's appearance and hint at some of cocaine's fascinating sociologic facets.

The Chemistry and Pharmacology of Cocaine.—Chemically, cocaine is benzoylmethylecgonine with the empiric formula $C_{17}H_{21}NO_4$.



Cocaine, the only naturally occurring local anesthetic, is an ester of benzoic acid and the nitrogen-containing base, ecgonine. On hydrolysis, it yields benzoic acid, methyl alcohol, and the tropine derivative, ecgonine.[6] It exists as a fairly stable, white crystalline compound; its hydrochloride salt dissolves in ½ its own weight in water.

Pharmacologically, cocaine exhibits a distinct duality of action: it is a local anesthetic of high efficacy (and also high toxicity), and a potent systemic CNS stimulator. This latter effect is noted from above downward, the first recognizable effects being cortical.

As for the autonomic nervous system, cocaine potentiates adrenergic receptor site organs and slows the uptake of both endogenous and exogenous catecholamines. Cocaine markedly contributes to systemic heat production and retention through a greatly increased somatic activity despite concurrent vasoconstriction. In legitimate medical use, cocaine continues to enjoy a popularity as the topical anesthetic nonpareil, although its high toxicity, "bad press," and DEA red-tape have led many physicians to turn to the less efficacious but much more readily available alternative of lidocaine.

"Lady of the Street."—In the current drug subculture, cocaine remains the "champagne of drugs." The experienced "cokehead" considers himself to represent the aristocracy of drug-users. Enormously inflated on the illicit market, an ounce of "coke" may be purchased for from $500 to over $1500, $50 to $100 a gram, or $10 a "line" or "snort" of up to 200 mg of "material." (Ask, but don't buy from, any cab driver in Mexico City.) All of this for what may have been "stepped-on" by various intermediary entrepreneurs, and may represent 25 to 80% quinine (for a better taste), lidocaine crystals (for the "freeze"), plus a little amphetamine (for the "rush"). Pure wholesale cocaine sells to medical institutions, on the other hand, for about $20 an ounce.

As coke has entered the drug-using consciousness of white middle-America, the earlier historical pattern of IV injection has now been largely supplanted (in a righteously needle-fearing society) by the inhalation route, in which a "line" of coke is "horned," "snarfed," or "snorted," often through a Federal Reserve note of high denomination (to denote affluence) or through a red, white, and blue sipping straw.

A complication from this method of administration is septal perforation, due to intense and repeated vasoconstriction. Snorters are also prone to infection of the nasal mucosa and upper respiratory tract, due to chronic local irritation. This may further lead to several days to a week of sneezing and (pseudo) coryza-like symptoms following an evening with "La Dama Blanca." In addition, reactive hyperemia following a coke-spree leads to boggy mucosa and a chronic stuffy nose (Afrin® is a favorite relief). Thus the coke-head's dyad is seen, of

*One hundred kg of coca leaves yields approximately 1 kg of refined cocaine.

(a) the paraphernalia (silver spoon or straw on a necklace, or a snuffbox) and (b) the ever-present nasal spray. The cocaine user is truly protected by the limitations of his own pocketbook and of his nasal mucosa.

Cocaine must be recognized as *the* ultimate euphorogenic (and in high doses, hallucinatory) drug available on the street today. Its preference by the drug connoisseur is undisputed. Cocaine tends to enlarge and glorify the entire world of the user. It also further continues to enjoy the reputation as the "primo" enhancer of sexual activity. Coke is used in sexual situations, not only via the inhalation and IV routes but also by being rubbed directly onto the genitalia, thereby producing partial anesthetization and a tingling sensation.[7] In the physically/pharmacologically exhaused individual, however, cocaine may have definite inhibitory effects on sexual performance, particularly in regard to male potency.

Caveat emptor! A practical street method of bioassay of coke is to (1) fill a dark glass receptacle with Clorox® (sodium hypochlorite) and (2) drop a pinch of the alleged substance ("neat," ie, uncut) into the middle of the Clorox pool. If the buyer has not been "burned" by a bogus product, he will note the initial white color turning to a greenish blue halo with the pinch plummeting to the bottom. (Many other chromophores will give a similar reaction.) The classic street test remains the "straight snort;" if the front incisors and canine teeth are numb after a "test line," it is presumptive positive evidence of "The Real Thing."[3]

Cocaine Overdose and Treatment.—Even with small doses of cocaine, an increase in blood pressure and pulse rate is initially seen.[8] If OD occurs, the victim may first report mental depression, dry throat, and dizziness. He/she may express a sudden overwhelming desire to defecate or micturate, in a spasm of smooth-muscle tonus. Sweating, confusion, and vomiting are noted as the central sympathetic onslaught continues.

An unhappy effect of a few milligrams too many is a paradoxic respiratory depression following an initial increase in rate and depth. A rapid, shallow pattern may ensue, Cheyne-Stokes may appear, and death may occur due to central respiratory collapse. Further, intense vasoconstriction combined with hypermetabolism may lead to hyperpyrexia; hyperreflexia, CNS anoxia, and tonic-clonic convulsions may supervene. A CNS "bleed" may occur. Ventricular fibrillation or direct cardiac standstill, even with doses as low as 30 mg, has been reported. Individual variability, and possible anaphylactoid sensitivity to cocaine, further narrow the discernable safety margins.

The standard fatal dose of coke is considered to be 1.2 gm (in a 70-kg man), with the LD_{50} being 500 mg. This may prove misleading, as these figures were derived from oral dosage; it must be recalled that cocaine is rapidly hydrolyzed in the stomach and thus largely inactivated. It has been estimated that the liver can detoxify 1 minimal lethal dose of coke per hour. An extrapolation from the larger doses given above would translate to 10 gm/day, if taken in incremental doses! (Neither true physical dependence nor tolerance — either to its pleasurable or toxic effects—occurs, and fortunately for the casual user, the 10 gm/day figure translates in street economy to a staggering $500 to $1000.)

Prolonged or chronic use of cocaine may lead to an irrational affect not unlike paranoid schizophrenia. Plagued with the dark shadows of increasing nervousness, inability to concentrate, and disturbed sleep patterns, the chronic user is increasingly prone to violence.[9] Due to these paranoia-producing qualities, and coupled with the very real heavy legal sanctions involved in the possession/use of cocaine, the user will seldom be seen in your office or in emergency rooms of traditional medical facilities. More often, in an attempt to "come down," he will self-medicate with a combination of alcohol, barbiturates, "Soapers," heroin, and/or other sedative-hypnotics (which further muddies the water, when— and if— you are called to treat him). If, however, panic or the true acute crisis of cardiac or respiratory collapse following cocaine use brings such an individual to your door—in *all* cases, acute or chronic—the treatment is symptomatic, and should remain flexible and dynamic.

In cases of acute toxicity, death most often occurs within 2 to 3 minutes, but may occur up to 30 minutes following ingestion/injection. If the acute OD victim survives the first 3 hours, his chances of recovery are almost certain.

Remember the biphasic nature of the "caine reaction," with initial sympathetic stimulation, followed by abrupt generalized CNS depression (at all levels). It thus follows that he who would administer first aid must first determine just which phase of

A CHRONOLOGY OF COCAINE

9th Century AD	Pre-Incan period. Coca leaves found in graves in the Central Amazon.
1200-1553	Inca Empire. Coca declared gift of Sun God; a divine plant.
10th-12th Century	Tombs, Andes region, containing trephined skulls. Juice from coca leaves believed used for local anesthesia.
1553	Francisco Pizarro and followers "paid off" workers in coca leaves, hastening destruction of Incan civilization.
1569	Increase in coca leaf chewing by lower classes of Andean Indians reported by Nicholas Monardes.
1580	Monardes brings coca leaves to Europe.
1853	Dr. Alexander Wood of Edinburgh invented the hypodermic syringe.
1853	Charles-Gabriel Pravaz, of Lyon, France, added an improved needle to the syringe.
1855	Gaedicke, of Germany, isolated an alkaloid of the leaves of the coca plant, naming it "erythroxylon."
1859	Dr. Paolo Mantegazza, of Italy, declared coca leaves a great new weapon against disease.
1860	Alfred Niemann purified the coca alkaloid and named it "cocaine," also noting its numbing effect on the tongue.
1865	"Vin Mariani," a preparation of wine and coca leaves, introduced to open market.
1873	Alexander Bennett demonstrated the anesthetic properties of cocaine.
1878	Vasili Konstantinovich von Anrep thoroughly studied the pharmacologic properties of cocaine, partly by injecting the skin of his own arm. He suggested the use of cocaine as an anesthetic agent.
1884	Karl Koller (an associate of Freud), at Vienna General Hospital, introduced cocaine into medical practice as a local anesthetic for eye operations.
1884-1887	"Ueber Coca:" Sigmund Freud wrote 5 enthusiastic papers extolling the virtues of coca and cocaine.
1884-1885	"The Great Cocaine Explosion:" Cocaine a fad overnight. Merck and Company and Parke-Davis and Company entered commercial field.
1884	Dr. William Halsted, of Johns Hopkins, injected cocaine into nerve trunks, obtaining "nerve block" or "conduction" anesthesia.
1885	Dr. James Leonard Corning, of New York, suggested use of cocaine for spinal anesthesia.
1888	Asa G. Candler introduced Coca-Cola as a "tonic for elderly people who were easily tired." First (and most successful) or proprietary cocaine-containing "colas." The soda fountain becomes a part of Americana.
1897	Dr. George W. Crile, of Cleveland, used direct infiltration of nerve trunks with cocaine for amputation. Dr. Harvey Cushing, of Johns Hopkins, performed a herniorrhaphy using a similar technic.
1898	August Bier, of Griefswald, Germany, obtained true spinal anesthesia—injecting animals, an assistant, and *himself* with cocaine (a paraplegic circus).
1898-1899	Drs. Tait and Cagliari, of San Francisco, and Dr. Rudolph Matas, of New Orleans, used cocaine for spinal anesthesia in surgical procedures.
1902	Richard Willstätter synthesized cocaine.
1902	Survey by Crothers showed only 3 to 8% of the cocaine sold in New York, Boston, and other metropolitan areas went into the practice of medicine or dentistry.
1906	Pure Food and Drug Act: Required accurate labelling on all over-the-counter preparations.
1914	Harrison ("Narcotics") Tax Act: Persons authorized to handle or manufacture drugs required to register, pay a fee, and keep a record of all "narcotics" (including cocaine) in their possession.
1914-1970	Cocaine underground. Used by "bohemians," "go-go girls," "gypsies" (chorus boys and girls), "jazz," "beat," "country and western," and "rock" music cultures. Also, highly esteemed in prisons and depressed ghettos for its euphoric properties.
1970-present	Reemergence in white "middle-America" of cocaine as illicit drug of preference.
1975	Cocaine named by "Rolling Stone" magazine as "Drug of the Year . . . Again!"

the cycle he is witnessing. The present authors have noted in a series of over 50 cases the beneficial response to use of the beta blocker, propranolol, in reversing the immediate sympathomimetic effects of cocaine.* In the presence of frank convulsions, incremental doses of the ultrashort-acting barbiturates (thiopental), given IV in doses of 25 to 50 mg, have proven beneficial (but always beware of potentiating CNS anoxia; don't "dose a dose").

In the presence of the chronic user who is restless, sleepless, and paranoid, the benzodiazepines (almost *never* the phenothiazines) in 1.5 normal dosage, either PO, IM, or IV, have proven of great efficacy. In *every* case, consider the patient as one large, raw nerve endplate. Approach with the science of "ART" (Acceptance; Rest and Reassurance; Talkdown Technic).

Keep cool; keep the patient cool (ice for hyperpyrexia is good). If you can convince this patient that you are a physician and not a policeman, then the both of you may survive.

*Propranolol is given in 1-mg increments IV at 1-minute intervals, up to 8 mg total. Heart rate and general metabolic status will return to normal limits within 1 to 3 minutes. The centrally acting emetic effect of cocaine will not be obtunded, however.

Case History Number 91: Sustained High Inspired P_{O_2} Without Toxic Sequelae

PHILIP S. GIBBS, MD*
S. S. MOORTHY, MD†
ALVIN M. LoSASSO, MD‡
Indianapolis, Indiana§

PULMONARY disorders such as infection, atelectasis, barotrauma, and pulmonary O_2 toxicity may occur during treatment of patients with respiratory failure. The development of O_2 toxicity, a well-documented hazard,[1] depends on the duration and dosage of O_2 administration[2] and a high P_{IO_2}.[3] However, when O_2 is needed, it must be given.

We describe a case of a child with respiratory failure who was exposed to high inspired partial pressures of O_2 for nearly 3 weeks without developing overt O_2 toxicity.

CASE REPORT

A 2-year-old girl was admitted with acute respiratory failure after aspirating a liquid hydrocarbon (paint thinner). Soon after the aspiration, the patient was given first aid at her home and transported to the hospital with mouth-to-mouth resuscitation. She was oxygenated and intubated upon arrival in the emergency room.

The admittance examination revealed an obtunded, cyanotic, well-developed child in respiratory distress. Her rectal temperature was 37.8° C, pulse rate was 160/min, and respiratory rate was 60/minute. Ascultation of the lungs revealed bilateral coarse rales. Other systems were normal. A chest x-ray at this time demonstrated bilateral alveolar infiltrates (fig 1).

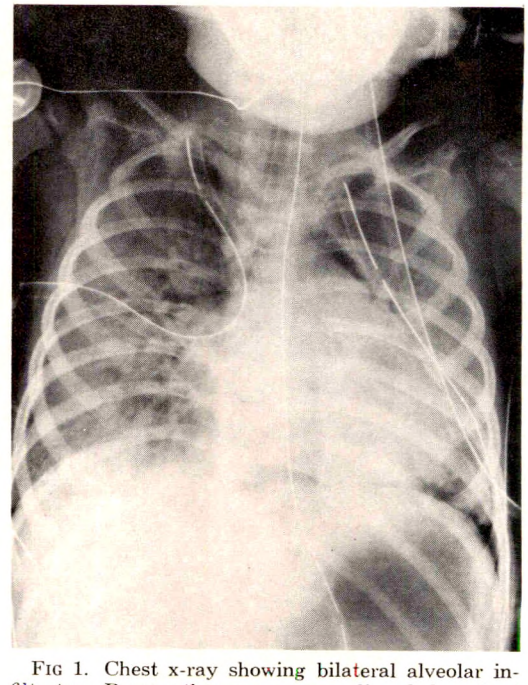

FIG 1. Chest x-ray showing bilateral alveolar infiltrates. Pneumothoraces were relieved by chest tubes.

The patient had a convulsive episode, during which she was accidentally extubated. She was subsequently maintained on 80 to 90% inspired O_2 for 2 days by mask, when she showed further deterioration. She was

*Assistant Professor.
†Assistant Professor.

is followed by proliferation of cuboidal granular pneumatocytes (type II) to regenerate the epithelial lining.[2] As a result of these studies, the hypothesis that factors supplied by the blood are necessary for O_2 to become toxic has been proposed.[3] The mechanisms involved in this complex process remain to be identified conclusively.

Several human experiments have confirmed that 50% O_2 can be inhaled by normal subjects for extended periods without clinical evidence of pulmonary irritation.[4,5] There is increasing evidence that critically ill patients cannot be compared with normal subjects to predict the development of pulmonary O_2 injuries, but no conclusive evidence is currently available that those with preexisting pulmonary disease are *more* sensitive to the toxic effects than are normal volunteers.[6] Although some investigators feel that wide alveolar-arterial O_2 tension differences, as observed in this paper, somehow protect against pulmonary O_2 damage,[7] this observation has not been substantiated in animals given normobaric O_2 levels.[8]

The treatment of significant hypoxemia, as indicated by the authors, is essential and should supersede but not eliminate our concerns about the effects of hyperoxia. Prolonged respiratory insufficiency is a situation where O_2 toxicity becomes an increasing problem. Technics aimed at reducing the shunt fraction, such as carefully selected and monitored ventilatory patterns and the addition of positive end-expiratory pressure (PEEP), may reduce significantly the ambient O_2 requirement and/or the duration of exposure. In conditions where there is evidence of air-block, PEEP must be used with caution, since it can aggravate emphysematous changes and increase CO_2 retention.

The possible predisposing effect of intermittent positive-pressure ventilation (IPPV) on pulmonary O_2 toxicity remains controversial. Animal studies suggest that mechanical overventilation leads to a loss of pulmonary surfactant, with augmentation of terminal atelectasis, but IPPV with normal tidal volumes does not impair pulmonary function.[9] Such studies, if applicable to the human, reinforce the need for precision in ventilator care.

The remark in the present report that "there is no radiographic evidence of permanent damage to the lungs" should not be misinterpreted to indicate that no impairment exists. Major abnormalities in vital capacity and other measures of pulmonary function may be present for weeks despite a "normal" Pao_2 and chest film.[10] If these patients have another pulmonary insult, such as pneumonia or bronchitis, before full recovery, they experience what seems to those unaware of the persistent underlying disease to be a disproportionate increase in O_2 and pulmonary-support requirements.

This clinical report corroborates the contention that maintaining Pao_2 at levels which provide for the aerobic metabolism of vital organs does not invariably result in serious pulmonary O_2 damage, even though high inspired O_2 concentrations are required. This may reflect the effects of some as yet poorly understood protective factors. In any event early recognition and rapid correction of complications, meticulous ventilator management, and appropriate respiratory physiotherapy are mandatory in order to achieve such a successful outcome.

PROBLEMS of intraoperative temperature control in the neonate are well documented. Use of warming blankets, overhead warming lights, humidified warm gases, heated IV fluids, and warm fluid-filled gloves have facilitated better temperature control. However, such modalities are not always adequate.[1] The following report presents an additional method of temperature control during neonate cystoscopy, during which irrigation of the bladder may result in hazardous hypothermia.

REPORT OF A CASE

A 10-week-old, 2.8 kg Caucasian infant was admitted with anemia and *E. coli* sepsis secondary to obstructive uropathy. As diagnostic workup revealed posterior urethral valves, he was scheduled for cystoscopy and fulguration. Preoperatively, the patient was given 0.1 mg of atropine IV and brought to the cystoscopy suite. Following an uneventful awake tracheal intubation, halothane, N_2O, and O_2 were administered with a nonrebreathing system. Despite the use of a warming blanket, overhead warming lights, and warm humidified gases, tympanic membrane temperature showed a precipitous fall at the beginning of cystoscopy, using continuous bladder irrigation with sterile, 23.5° C, water. At a temperature of below 35° C, the procedure was abandoned and he was returned to the recovery room, with a temperature of 34.5° C.

Seven days later, the infant was again taken to the cystoscopy suite for cystoscopy and perineal urethroplasty. After awake tracheal intubation, anesthesia was induced with halothane-N_2O-O_2 via a nonrebreathing system. Temperature was controlled with radiant heat lights and a warming blanket and mattress, but the lithotomy position made possible only minimal contact

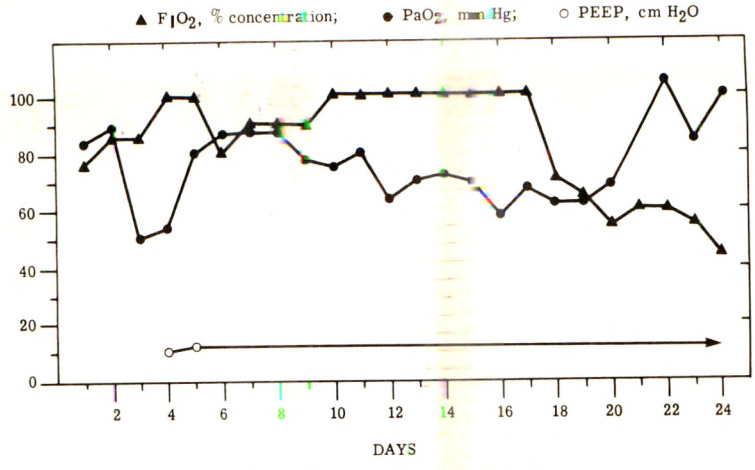

FIG 2. Course of ventilation and O_2 exchange.

reintubated and put on CPAP with 10 cm H_2O pressure and then on controlled ventilation on the Engström ventilator with PEEP. Subsequently, the ventilator was changed to a MA-I to provide an assist-control mode of ventilation.

The patient developed a right pneumothorax on the 4th day after admission and on the left side on the 5th day, both of which were treated by insertion of chest tubes with underwater seal and negative pressure suction. A tracheostomy was performed on the 8th day because of no improvement in her clinical status. She continued to require mechanical ventilatory assistance with high levels of inspired O_2.

Very high peak inspiratory pressures, approaching 100 cm H_2O were necessary to achieve adequate ventilation. To achieve these pressures, we had to change the type of volume ventilator from the MA-I to the Engström, and finally to the Emerson due to the mechanical limitations of the two former ventilators.

The patient began to show improvement in oxygenation from the 20th day after admission, at which time she required an F_{IO_2} of 0.55 to give a Pa_{O_2} of 76 torr (fig 2). Later, her course was one of progressive improvement. She was finally weaned from ventilatory assistance and supplemental O_2, and was discharged from the hospital 50 days after admission.

DISCUSSION

This case illustrates both the difficulties in the management of a child with respiratory failure and an absence of significant reversible manifestations of O_2 toxicity [illegible] high inspired P_{IO_2}, needed to maintain an acceptable Pa_{O_2}, although the high ventilatory pressures required produced barotrauma.

In our patient, radiologic delineation of pulmonary O_2 toxicity was difficult because of the underlying primary disease process. If there were changes, these did not persist when the patient improved. It has been reported that some patients in respiratory failure are more resistant to pulmonary O_2 toxicity than normal volunteers.

Prolonged exposure to high P_{IO_2} of both adult and pediatric patients with respiratory failure without developing toxicity, has

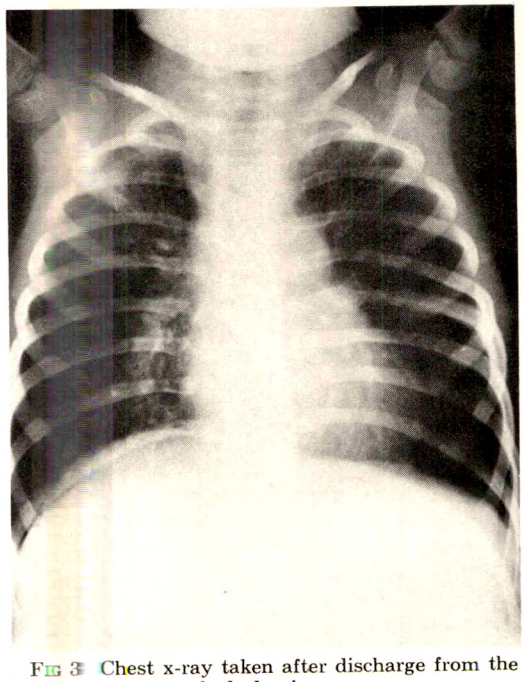

FIG 3. Chest x-ray taken after discharge from the hospital shows marked clearing.

been reported.[4] Why some individuals develop such toxicity while others do not is difficult to explain. High levels of such enzymes as superoxide dismutase may give protection.

Patients with respiratory failure should be closely monitored, and all effective methods should be used to reduce P_{IO_2} while maintaining an optimal P_{aO_2}.[5] However, a calculated risk must sometimes, as in our case, be taken. After subsequent complete clearance of the disease process, there was no noticeable radiologic evidence of permanent damage to the lungs (fig 3).

Comment

ROBERT K. STOELTING, MD

Pulmonary O_2 toxicity is a function of the inspired O_2 partial pressure and the duration of administration. The use of PEEP may permit the physician to achieve acceptable arterial oxygenation with inspired O_2 concentrations unlikely to introduce the hazard of pulmonary O_2 toxicity. Nevertheless, occasional patients, like the one described in this report, still require high O_2 partial pressures to prevent the permanent organ damage resulting from arterial hypoxemia.

It is fortunate that pulmonary O_2 toxicity does not always occur, as the physician has no choice but to use whatever O_2 dose is necessary. Indeed, the critically ill patient may respond differently than the normal volunteer. For example, patients with large right-to-left intrapulmonary shunts survive high O_2 concentrations for over a month.[1] Thus, reduced arterial oxygenation may in some way protect against adverse pulmonary effects of the high inspired O_2 concentrations used to treat the hypoxemia.

Discussion

EDWIN L. GRESHAM, MD
Associate Professor of Pediatrics and
Obstetrics and Gynecology
Section of Fetal-Neonatal Medicine
Department of Pediatrics
Indiana University School of Medicine
Indianapolis, Indiana

This paper describes one example of the complex pulmonary problems encountered with increasing frequency by specialists in pulmonary disease. It alludes to the ever-present dilemma of the pulmonologist, who must decide how much supplemental O_2 is required and what other mechanical and/or surgical methods are necessary to prevent the devastating effects of hypoxemia, while avoiding complicating barotrauma and O_2 poisoning.

Shortly after the discovery of O_2 in the atmosphere, Lavoisier[1] found that the pure gas produced inflammatory reactions in the lungs. Since those early studies, many investigators have added to our knowledge, but even now the mechanism(s) by which O_2 damages tissue and the nature of cellular resistance to its toxic action are not completely understood.

Observations in animals have indicated that high inspired O_2 concentrations lead to primary destruction of alveolar capillary endothelial cells. Squamous epithelial c (type I) are damaged secondarily, ar

with the warming mattress. Tympanic temperature, which was 38° C during the induction of anesthesia, once again began to fall at the beginning of continuous bladder irrigation. After 30 minutes, the temperature had decreased to 35° C. At this point, a standard blood-warming coil was interposed between the bladder irrigation system and the cystoscope and immersed in a water bath maintained at 40° C. The cystoscopy with urethroplasty continued for an additional 20 minutes. Anesthesia was completed without incidence, and in the recovery room, the infant's temperature was 35.8° C.

DISCUSSION

The critical temperature of the newborn undergoing cystoscopy in the lithotomy position is often compromised by the use of a relatively cool solution (at room temperature) for the continuous irrigation of a core compartment. The body mass of the neonate is approximately 5% that of the adult, while body surface area is only 15%. Therefore, there is a threefold greater capacity for heat dissipation. The neonate also lacks the subcutaneous fat and tissue of the adult, which normally provide insulation against heat loss.[2] Core conductance to the periphery also is greater in the neonate, facilitating greater heat loss over a shorter period of time.[3,4]

Most anesthetic agents contribute to hypothermia by reducing afferent stimuli, preventing shivering and muscular activity, inhibiting metabolism, and causing cutaneous vasodilation. Inadvertent hypothermia is one cause of neonatal morbidity and mortality.[5] Continuous irrigation of a highly vascular core compartment with a warm aqueous solution may facilitate maintenance of a normal body temperature when used from the start of neonate cystoscopy.

Estimation of Anesthetic Solubility in Blood

ALFRED FEINGOLD, MS MD*

PHARMACOKINETICS of inhalation anesthetics classically describe the blood/gas partition coefficient (B/G) as an important determinant of the speed of induction of and emergence from inhalation anesthesia. For this reason, the solubility in blood has been determined for virtually all anesthetics.

This blood solubility may be divided into 3 major components: solubility in lipids, water, and plasma proteins.[1-4] Featherstone's group[1] and Lowe† have reasoned that B/G may be estimated by addition of 0.8 times the water/gas partition coefficient (W/G) and 0.005 times the fat/gas partition coefficient (F/G). These coefficients correspond to the water and lipid content of normal blood and result in the equation:

$$B/G = 0.8\ W/G + 0.005\ F/G \qquad (I)$$

The application of this formula, however,

*From Steward.[5] ( ) values from Lowe when they differ more than ±10% from those reported by Steward.

†B/G = 0.88 W/G + 0.012 F/G (for Steward's data). ( ) B/G = 0.89 W/G + 0.01 F/G (for Lowe's data).

‡Percent difference = $100\left(1 - \frac{\text{calculated B/G}}{\text{reported B/G}}\right)$.

fails to explain large amounts of blood solubility, attributed to protein solubility or to protein binding.

It seemed worthwhile to examine a large number of anesthetic agents and to determine by numerical analysis the best coefficients of equation I. In addition to producing a simple formula for approximating B/G, this might further identify those inhalation anesthetics whose blood solubility is strongly influenced by plasma proteins.

METHODS

Using the summarized data of Lowe and of Steward and associates[5] for B/G, W/G, and F/G in man (at 37° C), 13 anesthetics were studied. Since the values recommended by these authors differ, an arbitrary tolerance of ±10% was chosen. When Steward's values were within ±10% of those from Lowe, Steward's values were used; when Lowe's values were outside this range, they were treated separately and appear separately in the table.

These data resulted in an overconditioned matrix of 13 equations with 2 unknown coefficients, x and y:

$$B/G = x\ W/G + y\ F/G \qquad (II)$$

A digital computer program minimized the root-mean-square difference between B/G calculated from equation II and those values reported. A separate estimate of x and y was obtained for the data which included Lowe's values. For both estimates of x and y, the percent difference between the reported and the calculated B/G was determined.

RESULTS

The best coefficients for the 13 anesthetics studied are x equals 0.88 and 0.89 and y equals 0.012 and 0.01 for Steward's and Lowe's data, respectively. The table lists the anesthetics in order of the mean absolute percent difference. The mean percent differences for diethyl ether, trichloroethylene, halothane, isoflurane, nitrous oxide, and methoxyflurane are within the ±10% tolerance selected for this study. Enflurane, cyclopropane, fluroxene, divinyl ether, chloroform, ethylene, and xenon all have more anesthetic dissolved in blood than can be accounted for by this simple equation. The greatest discrepancy between the calculated and reported B/G occurs for cyclopropane (+40 to +49%), ethylene (+40%), xenon (+29 to +35%), divinyl ether (+16 to +34%), and enflurane (+19 to +27%).

DISCUSSION

The accuracy of any equation for predicting B/G from W/G and F/G depends in

part on the accuracy of the values used. For this reason, 2 sources of summarized partition coefficients were used. The 2 sets of W/Gs and B/Gs differ in an unsystematic way. However, the F/Gs from Lowe are consistently higher than those from Steward, reflecting different methodologies.

The order of the anesthetics in the table is little affected by choosing the values of 1 author rather than the other. The coefficients calculated for both sets of partition coefficients are sufficiently close to suggest the following equation as the best estimate of B/G:

$$B/G + 0.89\ W/G + 0.011\ F/G \quad (III)$$

Several inhalation anesthetics have been shown to bind to proteins. Featherstone[1] showed that 53% of the cyclopropane dissolved in whole blood resulted from protein binding. Schoenborn demonstrated the binding of xenon to hemoglobin[6] and cyclopropane to myoglobin.[7] Cowles and colleagues[8] reported that the B/G of cyclopropane and ethylene increase at low concentrations, which is consistent with protein binding.

Normal blood is reported to contain 81% water and 0.6% lipid.[9] These values are slightly larger than those used in previous estimates; however, the estimation of B/G within ±10% for 6 of the anesthetics requires coefficients which represent even greater water and lipid content. This suggests that all of these 6 anesthetics have significant solubility in plasma proteins, as shown for halothane by Lassberg and Hedley-Whyte.[2]

Even with these larger coefficients, there remains a large discrepancy between the calculated and reported B/G for 7 anesthetics. Four of these (fluroxene, chloroform, enflurane, and divinyl ether) have not been previously reported to have significant solubility in plasma proteins or to undergo significant protein binding.

Significance of Pco_2 Within Low-Pressure Endotracheal Tube Cuffs

PAUL R. LEVESQUE, MD*

STANLEY and coworkers[1,2] recently demonstrated that the pressure within air-filled endotracheal tube cuffs increases during N_2O inhalation. Since this phenomenon is the result of transfer of N_2O into the cuff gas space, it is also likely that the CO_2

*Associate Professor of Anesthesia, Tufts University School of Medicine; Anesthesiologist, New England Medical Center Hospital, Boston, Massachusetts 02111.

Paper received: 7/8/75

Accepted for publication: 12/8/75

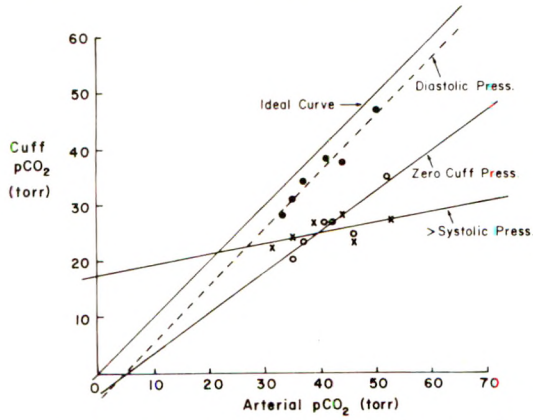

FIGURE. Regression lines illustrating the close correlation between cuff Pco_2 when cuff pressure approximates arterial diastolic pressure (dotted line).

partial pressure within the cuff might reflect the $Paco_2$ of the tracheal mucosa.

METHODS

Measurements were made on 6 anesthetized, intubated adult patients (following informed consent) undergoing surgical procedures lasting 4 hours or more. A radial artery cannula was inserted preoperatively for blood pressure monitoring and arterial blood sampling. Anesthesia was maintained by 40 to 60% N_2O with O_2 and enflurane.

Following induction of anesthesia, an NCC 8 mm ID polyvinyl endotracheal tube, equipped with a thin-wall, high-residual-volume, low-pressure flabby cuff, was inserted and inflated with sufficient air (12 to 15 ml) to raise the cuff pressure 10 to 20 torr above arterial systolic pressure (120 to 200 torr). Intracuff pressure was monitored by an aneroid manometer connected to the pilot tube. Forty-five minutes later, arterial blood and cuff gas were sampled. To avoid contamination of the gas sample by air from the pilot tube, the first 2 ml portion was discarded and a 3-ml sample taken for Pco_2 measurement.

Cuff pressure was then adjusted to equal arterial diastolic pressure (60 to 80 torr), and 45 minutes later the same sampling procedure was carried out. Finally, cuff pressure was lowered to zero but tracheal seal preserved by residual air remaining in the flabby cuff. Sampling was done 45 minutes later, as above, and results were analyzed electronically.

RESULTS AND COMMENTS

Close correlation is demonstrated (figure) between cuff Pco_2 and $Paco_2$ when the intracuff pressure approximates patient's diastolic pressure: regression equation is $Y = 1.03x - 5.28$ and $r = 0.9076$. These results show that diffusion from the tracheal mucosa through cuff membrane occurs. Indeed, when intracuff pressure is allowed to exceed arterial systolic pressure, no correlation exists between cuff Pco_2 and $Paco_2$: regression equation is $Y = 0.187x + 17.614$ and $r + 0.619$. When cuff pressure is zero but tracheal seal is preserved, the regression equation is $Y = 0.715x - 3.819$ with $r = 0.897$. This indicates either that equilibrium was taking place between cuff Pco_2 and mean airway $Paco_2$, or that the surface area of contact of the cuff with tracheal mucosa was too small to achieve rapid equilibrium with $Paco_2$. (Airway tension was not measured.)

Clinical Applications.—1. When tracheal seal cannot be achieved with low cuff pressure (20 torr), at least cuff pressure should not exceed the patient's arterial diastolic pressure. This should prevent impairment of mucosal blood supply and avoid tracheal damage.

2. Whenever arterial cannulation is contraindicated (for instance, in patients with hemophilia, peripheral vasculitis, etc) a close approximation of $Paco_2$ can be achieved by sampling gas from the endotracheal tube cuff after 1 hour of cuff inflation at approximately patient diastolic pressure. Whether cuff Pco_2 equilibrates with arterial or venous Pco_2 is unknown, but (arterialized) venous Pco_2 has been demonstrated to approach $Paco_2$ during anesthesia.[3]

Shearing Hazard of Intra-Arterial Teflon Catheters

EDWARD A. TALMAGE, MD*

Sayre, Pennsylvania †

Downs and associates,[1] evaluating several "needle-through-catheter" intravascular devices for percutaneous radial artery cannulation, found the 20-gauge Longdwel® Teflon catheter‡ to be accompanied by significantly fewer vascular complications than the 18-gauge Longdwel or the 18 or 20-gauge Argyle Medicut®.§ The 20-gauge is also recommended by others[2] for dorsalis pedis artery cannulation.

In evaluating the 20-gauge Vicra Quik-Cath®‖ Teflon needle-catheter combination, we often detected a grating sensation as the needle and catheter were advanced into the artery. Examination upon withdrawal revealed a frayed and crimped catheter tip, with distorted, irregular edges and sharp, tentacle-like projections (figure). It was first thought that calcified vessel walls might be producing this effect, but the grating sensation could be detected immediately after passage through the skin before the vessel wall was contacted, and the same deformity was produced after a single passage through the skin. Advancement of such "sheared" or frayed catheters into the artery after puncture of the vessel was either difficult, accompanied by the grating sensation, or impossible, due to resistance to catheter entry into the vessel. The inner cannula tip might be in the vessel lumen, with a pulsating blood return, yet catheter advancement would be impeded through impingement of its distorted edges on the vessel wall. As passage of such rough-edged catheters partly or completely into the vessel increases the incidence of hematoma formation, the grating sensation is a clear indication to withdraw and discard such cannulas, to avoid any possible damage to the intima and media of the vessel wall. The grating sensation, possibly accompanied by resistance to the entrance of the catheter into the vessel, is best appreciated when the operator grasps the cannula directly in his fingers, as use of a syringe or a Longdwel outer guard as a handle may dampen the sensation so much that it escapes detection.

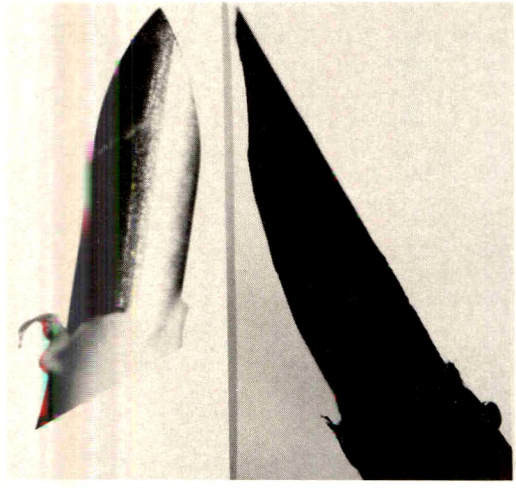

FIGURE. Enlarged view of representative catheter and cannula showing sharp edges and projections (approx. x 25).

The tip of the 20-gauge Longdwel catheter has revealed similar structural alterations and deformities of its leading edge. Some catheters, regardless of brand, appear more subject to shearing than others. Inner cannulas just larger than optimum may cause excessive stretching of the catheter edge, rendering it more subject to shearing upon passage through skin and/or vessel wall.

One of the goals in the development of

these catheters has been to make the junction between the needle and the catheter as smooth as possible, to facilitate passage through the skin, entrance into the vessel, and slipping the catheter off the needle into the vessel once the vessel wall has been punctured and a good flow obtained. This has generally been accomplished by tapering the distal tip of the catheter, reducing the outside diameter to the minimum compatible with structural integrity of the catheter, in most cases a knife edge. Theoretically, such a knife-edged taper might be easily crimped or roughened if the catheter material were not sufficiently strong to resist the shearing forces to which the edge is subjected in its passage through the skin, subcutaneous tissues, and vessel wall.

Perhaps the knife edge on the catheter tip could be modified to a somewhat rounded tip of just sufficient radius to resist the above-described shearing forces, care being taken to avoid oversize inner cannulas. Such rounded tips should present little or no impediment to passage through normally elastic skin or vessel walls. Alternatively, one could pre-puncture the skin with a slightly larger needle, but the vessel wall might still distort the catheter edge. It would seem prudent to avoid intra-arterial or intravenous advancement of catheters whose passage has been accompanied by the grating sensation described.

Evaluation of Larynx and Trachea by Xeroradiography

S. S. MOORTHY, MB, BS, MD*
ALVIN M. LoSASSO, MD†
HAROLD KING, MD‡
EDMUND FRANKEN, MD§
Indianapolis, Indiana‖

PATHOLOGIC changes in the larynx and the trachea may result from tracheal intubation.[1] Xeroradiography, which involves exposing a highly charged selenium plate to x-rays,[2,3] gives excellent images of the larynx and trachea for evaluation both before and after intubation.

In xeroradiography, the surface of the plate becomes conductive to the exposed areas and acquires a charged image depicting radiation intensities. This plate is exposed to a cloud of blue powder which is attracted to the plate according to the intensity of charge. The final image can be

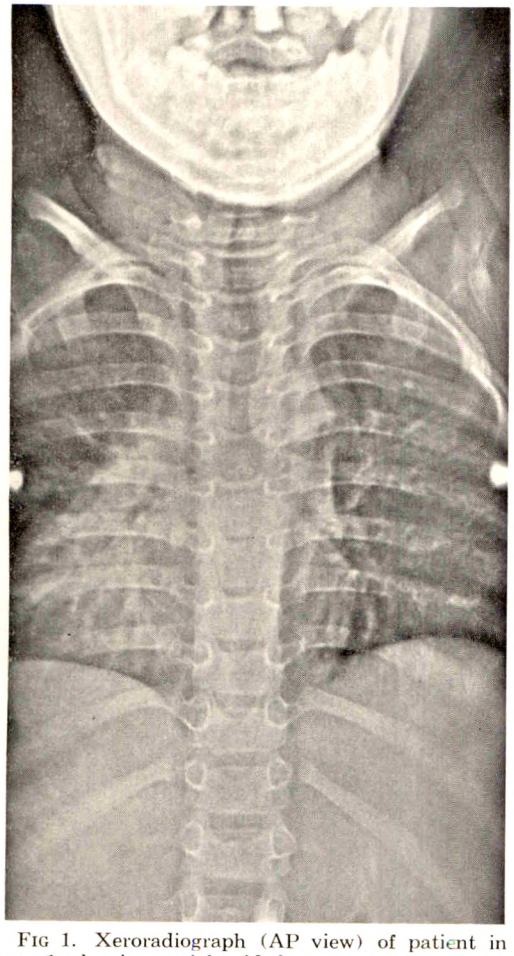

FIG 1. Xeroradiograph (AP view) of patient in case 1, showing a right-sided aorta pressing on the trachea. (The image is reversed.)

viewed directly or transferred to a plastic-coverec paper. When printed, the sides of the image are reversed.

We report 2 cases and a prospective study, to aler the anesthesiologist to the use of xeroradiography as a noninvasive approach to detect abnormalities of the larynx and trachea and for evaluation of the airway after intubation.

CASE REPORTS

Case 1. Detection of changes in the trachea before operation.—A 3-year-old boy was admitted for repair of tetralogy of Fallot. He was in no preoperative respiratory distress. However, preoperative xeroradiography revealed a right-sided aortic arch pressing on the trachea (fig 1), alerting the physicians to the danger of postoperative airway obstruction from tracheal compression. This patient had an uneventful postoperative course.

Case 2. Subglottic stenosis and web following prolonged intubation.—A 10-year-old girl was admitted for repair of cardiac defects and takedown of pulmonary artery banding under cardiopulmonary bypass. Postoperatively, the patient required mechanical ventilatory support for 7 days by indwelling uncuffed endotracheal tube. Following tracheal extubation on the 7th day, only hoarseness was present. She was discharged on the 17th postoperative day. On the 25th postoperative day, she was readmitted with acute upper-airway obstruction.

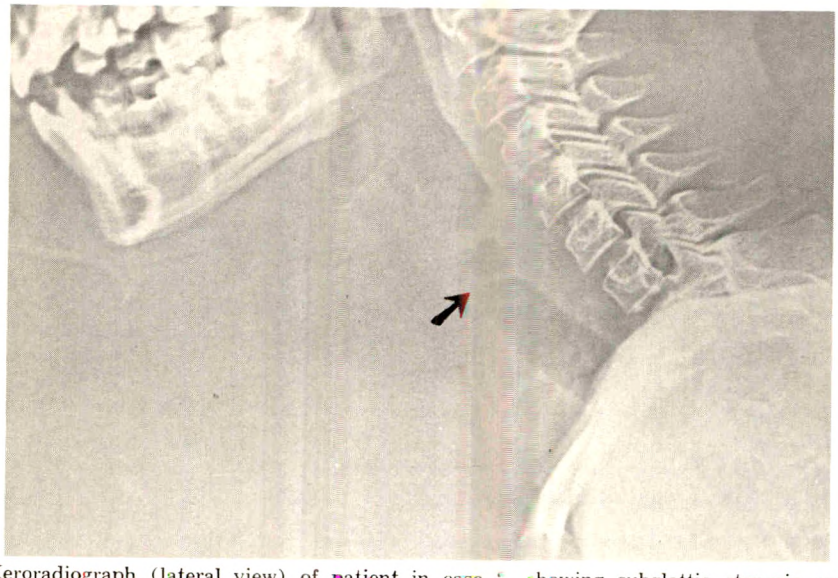

FIG 2. Xeroradiograph (lateral view) of patient in case 2, showing subglottic stenosis and (arrow) laryngeal web.

Xeroradiography of the larynx and trachea showed subglottic stenosis and a laryngeal web (fig 2). The patient underwent tracheostomy followed by repeated tracheal dilations.

PROSPECTIVE STUDY

To determine the incidence of laryngotracheal abnormalities as revealed by xeroradiography, we studied 16 pediatric patients (4 to 14 years) scheduled for elective open-heart operations. All were endotracheally intubated with polyvinyl-chloride tubes whose size (French) was determined by the formula "age + 17," modified as indicated by clinical judgment. In only 1 patient was a cuffed tube used. Fourteen of the patients were intubated for 28 hours, one for 8 hours, and one for 72 hours.

Of the 16 patients, 14 showed no laryngeal or tracheal changes on xeroradiography at 24 to 72 hours after extubation. Narrowing of the trachea by 1 mm was seen in 2 patients after intubation (uncuffed) for 28 and 72 hours, respectively.

DISCUSSION

While only minimal changes were observed by xeroradiography in 2/14 patients studied, more prolonged intubation, use of low-volume, high-pressure cuffs, or xeroradiography several days after extubation might have shown different results. Indeed, the 1 patient who developed a laryngeal web after 7 days of intubation did not manifest symptoms until several days postextubation. Perhaps xeroradiography during the asymptomatic period would have revealed this lesion to be forming. The boy examined by xeroradiography before intubation, who then showed tracheal compression, was asymptomatic.

ACKNOWLEDGMENT

The authors thank Dr. Eugene Klatte, Professor and Chairman, and Dr. Huen Yune, Department of Radiology, for their help, and Miss Linda Hicks for secretarial assistance. The authors thank Dr. Robert K. Stoelting for his helpful suggestions.

Pneumatocele of the Larynx: A Complication of Percutaneous Transtracheal Ventilation

EDWARD CARDEN, MA, MB, BChir, FRCP(C)*
THOMAS C. CALCATERRA, MD†
ALLEN LECHTMAN, MD‡
Los Angeles, California§

REPORT OF A CASE

A 27-YEAR-OLD Hawaiian suffered neck trauma in an automobile accident, requiring emergency tracheostomy through the 2nd and 3rd tracheal rings. His larynx was explored, and extensive damage to the right thyroid lamina and right vocal cord was repaired by mucosal approximation and

Paper received: 12/15/75

Accepted for publication: 2/25/76

a laryngeal stent, removed 3 weeks after repair. Because of glottic insufficiency, Teflon was injected into the right vocal cord area without appreciable augmentation of the posterior third of the cord. The cord was therefore nonmobile and laterally displaced, especially posteriorly. Since he had difficulty talking and coughing, he was scheduled for removal of a Teflon granuloma of the anterior aspect of the cord and Teflon injection to its posterior part.

The patient received 100 mg of meperidine and 0.5 mg of atropine IM, 1 hour before operation. On his arrival in the operating room, a 16-gauge IV cannula was placed in the left arm and infusion was started. When the blood pressure cuff and ECG leads had been attached, the patient was preoxygenated for 4 minutes with 100% O_2, using a circle system with an inflow rate of 16 L/min. He was given IV fentanyl (0.2 mg) until drowsy; then, thiopental (375 mg), and 80 mg of succinylcholine IV. A 0.2% solution of succinylcholine was infused at about 10 mgms/min. A 14-gauge, 3.8 cm Deseret Radio Opaque Teflon catheter was then inserted through the cricothyroid membrane into the trachea. (This catheter has side holes near the tip, designed originally for venous lines in patients on dialysis.) A 10-ml syringe was attached and air aspirated from the trachea to confirm position. The catheter was connected to a high-pressure jetting system consisting of a Bird high-flow N_2O-O_2 blender, pressure-reducing valve, and a flow-interrupting device.[1] Anesthesia was maintained by intermittent jetting from this catheter with a mixture of N_2O-O_2 (60:40) at a pressure of 30 psi, producing adequate chest expansion with an estimated tidal volume of 800 ml.

As the patient had a relatively short neck, the surgeon extended the patient's head to insert the laryngoscope; in the process, the tip of the cannula was pulled back from its position in the trachea to a position between the cricothyroid membrane and the skin, with resultant expansion of the neck during jetting. Jetting was immediately stopped, while the needle was removed and replaced through the same puncture site with a 5-cm, 14-gauge needle of the same type, and the jetting system was then reattached. Ventilation of the patient was now easily maintained but the neck was still slightly swollen and the characteristic crepitus of subcutaneous emphysema could be felt. On insertion of an operating laryngoscope blade, the surgeon observed a large pneumatocele distending the right aryepiglottic space. This gas was aspirated easily with a 17-gauge needle on a laryngeal syringe. The proposed operation was then completed.

DISCUSSION

This method of management during laryngeal operations has been advocated by various authors.[2-5] However, it is not without complications among which is pneumothorax due to excessive pressure in the lung if jetting is continued with the vocal cords closed or the upper airway obstructed.[6] Air has been injected through the posterior side of the tracheal wall by inadvertently placing a long needle through the other side of the trachea.* This could proceed to mediastinal emphysema and bilateral pneumothoraces.

It is interesting that the gas was able to track through the fascial planes to the area of the vocal cords. The air may have spread cephalad because of fibrosis in the tissues below the site of needle puncture following healing of the tracheostomy. Also the needle puncture was at the cricothyroid membrane rather than between the tracheal rings, which is the more common site.[2-5] The surgeon, however, was easily able to deal with the problem by letting out the air from the swollen area, enabling the patient to regain his normal anatomy.

Since the pressure developed in the lungs is dependent upon the flow of gas from the needle and the resistance to flow is inversely proportional to the length (Hagen-Poiseuille law), a short needle will deliver better ventilation than a long one. We now routinely use 5-cm needles for this technic.

Acute Ethanol Intoxication and Its Prolonged Effect on a Full-Term Neonate

S. S. KIM, MD*
ROBERT HODGKINSON, MD†
Bronx, New York‡

DURING a double-blind trial of neurobehavioral assessment of neonates, we observed a baby whose depressed performance was subsequently explained by the inadvertent administration of IV ethanol to the mother during labor. This report is presented to: (1) emphasize the need of care in routine IV therapy and (2) review the pharmacologic significance of alcohol with respect to the neonate.

CASE REPORT

A 36-year-old multipara weighing 72.6 kg was admitted in early labor. Her previous medical, surgical, and obstetric history was unremarkable. After 5 hours, her membranes ruptured at 4 cm dilation of the cervix and an IV infusion was started. When, 3 hours later, there was no progress and pelvimetry confirmed cephalopelvic disproportion, cesarean section was decided on. Meperidine (50 mg) and promethazine (25 mg) had been given twice, 8 and 5 hours previously.

On arrival in the operating room, the anesthesiologist noted the extreme drowsiness, disorientation, and nystagmus of the mother. Checking the IV bottle, it was found that almost 700 ml (40 gm) of 5% alcohol had been given in error for lactated Ringer's solution, most of it probably in the previous hour. The patient was induced with 250 mg of thiopental (less than the 4 mg/kg usually given for a crash induction) and 100 mg of succinylcholine, and maintained on a 6-L flow of O_2 until the baby was delivered 5 minutes later. There was no meconium, and fetal heart sounds were stable. As the 1-minute Apgar score was 3 (1=color, tone, and heart rate), the baby's trachea was intubated and 100% O_2 administered with intermittent positive pressure. The 5-minute Apgar was 7 (respiration, response, and color were each 1). The heart rate and tone responded rapidly and the baby was described as vigorous at 10 minutes. The heart rate was 120 and the blood pressure 80/60 2 hours later. The baby's weight was 3000 gm, length 49 cm, and head circumference 34¼ cm. There was no evidence of hypothermia, hypoglycemia, or dehydration at any time.

The Scanlon[1] group of neurobehavioral tests were administered 1 hour before a feed on days 1 through 10 by an investigator (SSK) with no knowledge of the anesthetic management, the method of delivery, or the perinatal risk factors (the fact that alcohol had been administered was not known to the investigators until 48 hours later). The scores were compared with those of 35 other babies delivered by cesarean section and receiving the same amount of thiopental. Fifteen of the mothers had received the same amount or more of meperidine. This baby had a lower score for the overall score (based on the evaluator's assessment performance of all neurobehavioral tests) than any of the other 35 neonates on each of the first 3 days of life.

The subject baby's score for tone, rooting, and alertness were also the lowest in the series for the first 3 days. Eight babies had an equally low sucking score, 5 an equally low Moro reflex score, and 4 an equally low response to sound score for the first 3 days. After the 3rd day, all the baby's scores were normal except for tone, which was intermittently found to be low until the 7th day. The mother and baby were both well and were discharged on the 10th day.

DISCUSSION

The IV administration of alcohol was introduced in 1967 to inhibit premature labor,[2]

Paper received: 11/10/75
Accepted for publication: 1/22/76

although a recent trial has shown it to be no more effective than a placebo.[3] Use of alcohol to delay labor can be dangerous to both mother and baby. The acidity and volume of maternal gastric secretions are proportionate to the amount of alcohol administered, and subsequent anesthesia has been associated with aspiration of the highly acid secretion, followed by pneumonitis.[4]

Alcohol freely passes through the placenta; an acute withdrawal syndrome[5] has been described, as well as fetal alcohol syndrome[6] (microcephaly, growth retardation, and multiple congenital abnormalities) following chronic alcoholism.

The alcohol dehydrogenase activity in the fetus is only 25% that of the adult,[7] and the rate of disappearance of alcohol from the neonate is probably slower than the mean 7 gm/hr shown by a normal 68-kg adult.[8] In addition to its effect on neurobehavior, alcohol is a potent depressant of hypocapnic and hypoxic drive in man.[9]

In view of its doubtful efficacy in suppressing premature labor, its potent cerebral-depressant effect on the fetus already handicapped by prematurity, and its propensity to produce a highly acid, high-volume gastric secretion in the mother, it is time that the use of IV alcohol be reevaluated. If its use is to be continued, the anesthesiologist should ascertain that alcohol bottles resembling bottles of lactated Ringer's solution are segregated from other infusional fluids, should recognize the increased risk of maternal acid aspiration, and should be prepared to resuscitate a possibly very inebriated neonate.

* * *

Editor's note: A reviewer comments: "Our gastroenterologists are doing clinical research on IV alcohol in normal volunteers and are impressed with the marked increase in gastric secretion and the high incidence of hemorrhagic gastritis."

We Salute . . . .

Edmond I. Eger, II, M.D.

FEW individuals have made the impact on clinical anesthesia that has Edmond I. Eger, II. His bibliography of more than 150 publications reads like the index of a textbook: anesthetic systems, uptake, elimination, MAC, theories of anesthesia, factors which affect anesthetic requirement, mechanism of action, metabolism, toxicity, and cardiorespiratory effects of anesthesia. Dr. Eger recently compiled his research into an excellent book, *Anesthetic Uptake and Action.**

Ted Eger was born in Chicago September 3, 1930. He attended high school there, graduated from the University of Illinois in 1951, and received his MD degree from Northwestern University Medical School in 1955. He completed an internship at St. Luke's Hospital in Chicago and served his residency in anesthesia with Dr. Stuart C. Cullen at the State University of Iowa. From 1958-1960, Dr. Eger acted as Chief of the Anesthesia and Operative Section, US Army Hospital, Ft. Leavenworth, Kansas. During this period, one of his first studies, "The Factors Affecting the Alteration of Nitrous Oxide in the Circle System," was completed.

In 1960, Dr. Eger joined the Department of Anesthesia at the University of California San Francisco Medical Center, where over the next 8 years he attained the rank of Professor. He currently serves as Vice Chairman for Anesthesia Research at the University of California and maintains an active research program of his own.

Dr. Eger was recipient of an NIH Research Career Development Award from 1961 to 1965. He is active in numerous professional societies, including the ASA and AUA, and is a Diplomate of the American Board of Anesthesiology. He currently is a member of the ASA Committee on Research and also serves as consultant to the US Naval Hospital in Oakland and the VA Hospitals in San Francisco and San Diego.

Ted is a kind and generous man, giving freely of his time, his energy, and his counsel. He has the extraordinary ability to excite young physicians as to the fun and usefulness of research, as evidenced by the fact

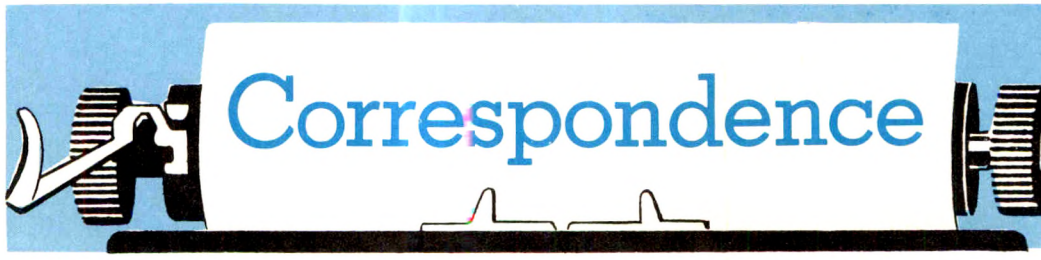
*The Williams and Wilkins Company, Baltimore, Maryland.

that the majority of the 25 research trainees he has supervised have chosen full-time academic careers. He helps young people to "do their own thing." Although he constantly assists them in solving problems and suggests alternative routes, he does not actively compete but rather enables the trainees to mature into satisfied, independent investigators.

Though best known as an investigator, his abilities as a teacher and clinician are also highly regarded. He has made the complex subject of uptake and distribution both understandable and clinically useful. His work on anesthetic systems has been instrumental in teaching us all why we do what we do in the operating room. As a clinician, he possesses the superb attribute of being able to take knowledge from the laboratory and rationally apply it to patient care.

But perhaps that characteristic for which Ted is best loved by those with whom he has worked is his attitude toward people and his approach toward life. He attacks life with the same vigor as he does his work. His interests are widespread, ranging from the love of music and ballet to backpacking and cross-country skiing. Ted, his wife, Dollie, and their four children spend many vacations together traveling, camping, and walking the John Muir Trail.

It is with pleasure and pride that the Editors of *Anesthesia and Analgesia* salute Edmond I. Eger, II, for his many contributions to our specialty.



To the Editor:

In reference to the Questions and Answers section of volume #54, page 211, I wonder if you could be more specific concerning "Nonflammable germicides or detergents . . . to be used when the use of electrosurgery is contemplated," as stated by Paul F. Leonard, M.D., Department of Anesthesiology, Mayo Clinic, Rochester, Minnesota.

A. DelPizzo, M.D., Chairman
Department of Anesthesiology
Hospital of St. Raphael
New Haven, Connecticut

* * *

To the Editor:

In response to Dr. DelPizzo's question: The National Fire Protection Association in its publication 56A "Standard for the Use of Inhalation Anesthetics 1973," states (page 40) that "Inhibited 1,1,1-trichloroethane is a suitable defatting agent." This compound is nonflammable and is biologically inert (not metabolized).

Paul F. Leonard, M.D.
Department of Anesthesiology
Mayo Clinic
Rochester, Minnesota

To the Editor:

I'm engaged in what seems at times to be a one-man crusade. As an allergist, I'm acutely aware of the life-or-death situations that can be created by insect stings. I've run into several cases where death could have been prevented if an emergency insect-sting kit had been available.

We physicians give insect-sting kits to patients who need them, and we train them in their use. Yet people in positions of responsibility—school nurses or principals, forest rangers, scoutmasters, and others who may encounter people in allergic shock—don't have the kits, nor do they know how to use them. Most state laws prohibit sales of such kits without a prescription. We physicians train our insect-allergy patients to use them, and we see that a kit is available to them. I think state laws should be changed so that persons in the kinds of key positions indicated, after receiving appropriate training, could purchase the kits without prescription. I hope others feel likewise and will be motivated to write their legislators to change the laws.

I would also appreciate hearing from other doctors who know of cases where the use of an insect-sting kit would have prevented death. Write me at: Doctors Park, Building 4-C, Asheville, North Carolina 28801.

Claude A. Frazier, M.D.
Asheville, North Carolina

In each issue of the Journal an article of particular interest and value to anesthesiologists, which has been published elsewhere, will be presented. Primarily the material will contain fundamental basic information which has been presented by anesthesiologists, physiologists, pharmacologists, and others and, on occasion, by commercial firms. In the last instance, these reprintings are not to be construed as an endorsement of the particular commercial firm or its product by Anesthesia and Analgesia—Current Researches.

Treating Acute Heroin and Methadone Toxicity

GEORGE R. GAY, MD, AACT, FAAFP*
DARRYL S. INABA, Pharm. D†

Acute heroin and methadone overdose reactions are seen with increasing frequency in E.R.s servicing middle-class white suburbia. The authors give step-by-step procedures for the management of this life-threatening medical emergency.

FOUR teen-agers carried an unconscious youth into the Haight-Ashbury Free Medical Clinics in San Francisco. He was apneic, cyanotic, and areflexic, but his pulse was strong. His friends said he'd "shot-up with smack"—heroin—just a few minutes before.

Quickly we cleared his mouth of mucus, put an oropharyngeal airway in place, and began mouth-to-mouth respiration. Simultaneously we gave him, I.V., 2 cc naloxone hydrochloride (Narcan) and 5 cc doxapram hydrochloride (Dopram).

The patient's color returned, spontaneous respirations resumed, and he regained full consciousness—all within about 20 seconds. Suddenly he spit out the airway, complaining only of "a terrific headache." We observed him for several hours and then discharged him.

Here at the Haight-Ashbury Clinics we treat well over 400 heroin and methadone addicts a week. Every day we see at least one case of acute toxicity similar to this young man's, and we've yet to lose such an overdose patient—*who had a heartbeat when he arrived.*

Opiate and opioid overdose victims classically present with pinpoint pupils (unless anoxia has caused dilation), areflexia, marked respiratory depression (from apnea to two or three shallow gasping breaths per minute), and a cyanotic, clammy pallor.[1] Always suspect that a comatose patient with questionable or nonexistent history may be such an overdose case.

Treatment, to be effective, must be prompt, and proper measures are essential. Here, in outline form, is the method of emergency therapy we've developed at Haight-Ashbury Clinics:

1. Establish an airway:[2-9]

A. Clean patient's mouth. Mucus, blood, vomitus, gum, or tobacco may be found.

B. With the patient in supine position, tip the head slightly back.[10] Grasping jaw at angles of mandible and at point of chin, draw the head back, chin high, to a "sniffing-like" position, but be careful not to hyperextend. Pull the tongue forward, making sure it isn't occluding the posterior oropharynx. If oropharyngeal reflexes are absent, insert an oropharyngeal or nasopharyngeal

*Former Director of Clinical Activities, Haight-Ashbury Free Medical Clinics, San Francisco, California. Present address: P.O. Box 1169, Mendocino, California 95460.

†Director of Pharmaceutical Services, Haight-Ashbury Free Medical Clinics, San Francisco, California.

Reprinted with permission from Medical Economics, Inc., Oradell, N.J. and the authors.

airway; if one isn't available, hold the tongue forward with your fingers.

C. Breathe for the patient if he or she is apneic—mouth-to-mouth, or mouth-to-nose,[11] or use an Ambu bag if one is handy. If room air is 20 percent oxygen, your mouth-to-mouth respiration will get at least 15 percent oxygen into the patient. Make sure air is entering the lungs—that the chest (not stomach) is expanding. Listen for breath sounds with a stethoscope. Don't stop to look or call for endotracheal equipment—you are dealing with a true emergency and hesitation can spell disaster. Endotracheal intubation should be attempted *only* by a trained anesthesiologist or surgeon—and *only* when the patient has been previously properly oxygenated. You have about two minutes to achieve intubation. If unsuccessful, resume mouth-to-mouth, oxygenating the patient well before attempting intubation again.

2. Quickly assess the cardiovascular system:

A. Check the pulse for rate and rhythm. Check precordial, femoral, temporal, or radial pulses. Don't be lulled into complacency by the strong full pulse of hypoxia, which may be premonitory to terminal arrhythmia and cardiac cessation. Remember: If the patient arrives with a heartbeat, you should be able to save him.

B. Begin external cardiac massage if heartbeat is absent, placing palms of your hands over the patient's lower sternum, depressing firmly 50 times per minute.[12-14] Determine cardiac status with ECG. Institute appropriate action—defibrillation, pacing, etc.

C. In severe cases of narcotics overdose, the patient's cardiovascular system may be so depressed that pulmonary edema develops.[15] Intubation or tracheostomy—plus continuous positive pressure respiration—may be lifesaving.[16,17]

3. Continue treatment for heroin overdose:

A. Give intravenously 2 cc (1 cc/0.4 mg) naloxone hydrochloride. This may be repeated 2 to 3 times at 2 to 3-minute intervals without fear of adverse or agonistic effect (I.V. works in seconds; I.M. administration may take 20 minutes or more to act). If the patient has "collapsed" veins, as many addicts do, try the external jugular or the femoral or inject at the base of the tongue if all else fails.

The Narcan test may be considered to be diagnostic for narcotics overdose; reversing opiate/opioid depressant effects without endangering the patient who may have other depressant drugs in his/her system.

Also, Narcan is free of narcotic agonist effect which *may* be seen with repeated doses of Lorfan or Nalline.

B. Give I.V. 3 to 5 cc (1 cc/20 mg doxapram hydrochloride).[20,21] This is an extremely safe, temporary (lasting 3 to 5 minutes), nonspecific respiratory stimulant. It usually has immediate effect, so be sure airway is open. One word of caution here . . . if prolonged apnea and pre-existing acidosis is suspected, AVOID the use of Dopram, as some hypertensive and metabolic acidotic response may be expected following its use.

C. Stay with the patient until he is fully responsive. If he used a long-acting narcotic, such as methadone hydrochloride (Dolophine), he may lapse back into coma if continuous monitoring is not provided for several hours. With the ever-expanding methadone maintenance programs in this country, providing a continuing increase in street-availability of this government approved highly potent opioid, methadone overdoses are being seen in increasing numbers.

D. If the patient fails to respond, follow established emergency procedures to secure a route for administering I.V. fluids—preferably with a large bore cannula. If moderate to severe acidosis is suspected, administer sodium bicarbonate.[22] Begin the administration of a glucose-electrolyte solution.[23] Draw blood for chemistries. Search for non-overdose etiology—evidence of trauma, blood loss, acute infectious process, and increased intracranial pressure.

E. If long-standing drug depression is suspected (for example, when a patient is discovered unattended), be on guard for atelectasis or pneumonia.[24,25] In any event, hospitalization, vigorous pulmonary therapy, and aggressive antibiotic therapy are indicated.

The typical middle-class junkie—whom you're apt to be treating in increasing numbers—is in his early 20s, white, male (although now up to 35 percent of the clients at the Haight-Ashbury Free Medical Clinics Detoxification Section are female), and an Establishment-alienated dropout from

TABLE

Symptom complex	Treatment
Pain (or expressed somatic discomfiture)	Propoxyphene napsylate (Darvon-N), 200 mg, propoxyphene hydrochloride (Darvon), 130 mg, or pentazocine (Talwin), 100 mg, q 4-6 h.
	Note: Talwin within 12 hours of a "fix" may produce narcotic antagonism creating "instant Cold Turkey" and thus reducing the medication's analgesic effect.
Sleeplessness	Flurazepam (Dalmane) 60 to 90 mg hs, Chloral hydrate, up to 2.5 gr hs.
	Note: At the Haight-Ashbury Detoxification Section we avoid use of the short-acting barbiturates, glutethimide, or methaqualone.
Nervousness	Phenobarbital, 30-60 mg, diazepam (Valium), 5-10 mg., or chlordiazepoxide (Librium), 10 to 25 mg, q 6-8 h.
Gastrointestinal distress	Belladonna leaf extract, phenobarbital (Belphen No. 1), oxyphenonium bromide and phenobarbital (Antrenyl-phenobarbital), or dicyclomine hydrochloride (Bentyl), two capsules q 4 h.
	Note: For pronounced nausea and vomiting, 5-15 mg prochlorperazine (Compazine) q 4 h orally or 10 mg by rectal suppository.

suburbia. He's been on heroin for less than 2 years, but already his habit is demanding up to 20 mg. of pure heroin a day.[26,27] That's more than enough to hide the warning pain of abscessed teeth, pelvic inflammation, or a ruptured appendix.

SHORT-TERM OUTPATIENT OPIATE/OPIOID DETOXIFICATION

Abrupt withdrawal from heroin may be discomfiting in the extreme, but life-threatening crises, such as the convulsions and hyperpyrexia occasionally seen with alcohol-tranquilizer-barbiturate withdrawal, are rare (basically only seen in the premature newborn of the addicted mother). During acute heroin withdrawal the patient may experience hypersalivation, with runny eyes and nose; fever, chills, and diaphoresis; nausea, vomiting, abdominal cramps, and diarrhea; photophobia due to dilation of the pupils; musculoskeletal pains and cramps; jitteriness and insomnia to a marked degree. These symptoms make their appearance from 6 to 8 hours after the last "fix," reaching a maximum at from 24 to 36 hours. Usually withdrawal symptoms subside after 5 days. Insomnia, general irritability, and muscular aches and pains gradually lessen over the ensuing days and weeks. At the Haight-Ashbury Free Medical Clinics, four symptom complexes are commonly treated: pain (muscle, joint, and bone aches), sleeplessness, nervousness, and gastrointestinal complaints.

DIABETES AND RESPIRATORY DISTRESS. A retrospective review determined the incidence of respiratory distress syndrome in newborns of diabetic or nondiabetic mothers. The syndrome occurred in 23.4% of the diabetic compared with 1.3% of the nondiabetic group. Therefore, the chance of this syndrome developing in an infant of a diabetic mother is about 24 times that of an infant of a nondiabetic. When all confounding factors were controlled, including the gestational age and route of delivery, the chance of the syndrome developing was still 6 times greater in the diabetic group. Thus, maternal diabetes, per se, probably predispose the infant to respiratory distress. Fetal hypersecretion of insulin may block the enzyme-inductive capability of cortisol which is necessary for lung maturation. *(Robert MF, Neff RN, Hubbell JP et al: Association between maternal diabetes and the respiratory-distress syndrome in the newborn. NEJM 294:357-360, 1976)*

The Physician & The Law

Physician Liability for Death of Heart Transplant Donor Discussed

LEGAL and moral implications of a jury verdict holding a physician not liable for the death of a heart transplant donor were discussed in an article questioning the concept of "brain death."

In the case discussed, the patient had been admitted to a hospital after suffering a massive brain injury. He sustained a later basilar skull fracture on the right side, subdural hematoma on the left, and brain stem contusion.

Emergency surgery was performed and he was placed on a respirator. The treating physician noted that prognosis for recovery was nil and that death was imminent. Shortly thereafter a neurologist obtained an EEG with the results showing "flat lines with occasional artifact."

Vital signs remained about normal for the next two hours, at which time the respirator was cut off. Five minutes later he was pronounced dead, and his heart was removed and transplanted to a recipient.

The patient's brother sued the transplant surgeon for $100,000, alleging that the transplant team engaged in a systematic and nefarious scheme to use the patient's heart and hastened his death by shutting off his mechanical support. The suit also charged that the patient's heart had been removed with only minimal attempts to notify the family and obtain permission.

No opinion was issued in connection with the jury verdict. However, the trial court gave the jury an instruction allowing it to use cessation of brain function as a possible definition of death. The jury found in favor of the transplant surgeon, determining that he had not caused the patient's death by removing him from the respirator after his brain had ceased to function.

The author of the article stated that the principals in the case and the press had treated the case as a "brain death" case. However the determination of when death occurs is a philosophical or moral question,

Reprinted with permission from THE CITATION, published by the Law Division of the American Medical Association.

not a scientific or medical one, the author said. He suggested that the decision as to when the heart may be removed for transplant be made by the patient's relatives, and argued that not consulting them was a serious infringement on the rights of the patient and his family.

He raised the issue of whether this was a "brain death" case or simply a case of stopping treatment of a terminally ill patient. To treat this as a "brain death" case, one must accept several highly questionable premises, including vesting medical professionals with authority to determine life and death. The author also questioned whether the "brain death" concept was intended to apply to death of the entire brain or only of the cortex, which controls consciousness. —*Brain Death,* by Robert M. Veatch, Hastings Center Report, November 1972, p. 10, discussion *Tucker's Administrator v. Lower* (Ct. Law & Eq., Richmond, Va., May 25, 1972).

ANTIBIOTICS. The authors reviewed the records of all surgical patients to determine the incidence of nosocomial (hospital-acquired) infections with or without prophylactic antibiotics. It is estimated that 6.3% of admissions to acute hospitals acquire nosocomial infections. The present study showed that prophylactic antibiotics had no significant effect on the incidence of hospital-acquired infections. *(Finland M, McGowan JE: Nosocomial infections in surgical patients. Observations on effects of prophylactic antibiotics. Arch Surg 111:143-145, 1976)*

Questions and Answers

We invite you to submit questions to the Editorial Office, Kahler East, Suite C, Rochester, Minnesota 55901. The names of those submitting questions will remain anonymous if so desired.

The answers will be prepared by competent authorities, and their names will or will not appear, according to their specific wishes.

QUESTION: *Is it more dangerous to run a rechargeable ECG monitor (Tektronix®) on a patient while plugged into a grounded circuit than on battery power alone (referring to the electrical hazard)?*

MD, Michigan

ANSWER #1: "Dangerous" here implies a a situation or a device fraught with a clear and present threat to life. A monitor is not "dangerous" merely because the right leg electrode is connected to the chassis and case of the device—as in early production numbers of the type 410 Tektronix (and in many other monitors and ECG machines through the early 1970s). A hazard exists only if the monitor is used on a patient in conjunction with some *other* grossly defective or incorrectly connected piece of equipment. A firm caveat to this effect is found in the excellent instruction book for the Tektronix type 410.

Operation by battery means the patient is no longer connected to ground through the grounding conductor in the power cord. With the type 410 monitor, however, the isolation from ground provided in the battery mode of operation can be defeated if the monitor case is grounded through a grounded support bracket or through an accessory grounding wire.

As a matter of principle, deliberate grounding of patients (and oneself) is to be avoided. Not long ago, though, a grounding connection to the subject was a virtual necessity—and a standard practice—in order to reduce electrical noise on monitors and recorders. Now, with improved circuitry and components, highly effective "dodges" for the noise problem are easily realized without the need to ground the subject. Monitors and ECG machines of recent design, therefore, provide a large value of resistance between every patient-connected electrode and the monitor frame and case. This is accomplished by appropriate electronic design of the "front end" (the input from the patient), and such isolation is wholly independent of whether the machine is power-line operated or in the battery mode of operation.

John M. R. Bruner, MD
Groton, Massachusetts

* * *

ANSWER #2: The simplest answer is YES. That is, in general it is safer to run all (rechargeable) battery-powered monitoring devices completely disconnected from the wall power/grounding system (regardless of whether the power system is a "grounded" circuit or an "isolated" circuit). Also, it is safer NOT to connect such an ECG monitor to another device, such as a writer which is wall powered and/or grounded.

A more complete answer would be very lengthy, since: (1) there are 2 basic types of Tektronix ECG monitors (410 and 408/412), which can be hazardous to patient or anesthetist in different ways and in differing degrees, depending on the particular electrical environment; and (2) detailed consideration of the most probable electrical faults depends on the type of wall power/grounding system (does it come from an isolation transformer or not?).

The initial answer (yes, it is more dangerous) is especially true with the type 410 (oldest model), due mainly to the relatively low resistance between the right leg lead and wall ground if the monitor is plugged in. In the type 408/412, the patient is highly isolated from the wall power/grounding system even if the monitor is plugged in; it is therefore much safer to operate the 408/412 in this way than it is the 410.

When using the type 410 with a patient who can come in contact with a high-voltage power source (a faulty cautery, defibrillator, or other line-powered device), electrical danger to the patient or anesthetist (such as a cautery burn at the right leg electrode) is minimized by the following: (1) disconnect the power cord from the monitor and the wall; (2) do not connect the case-grounding jack (on the side) to a grounded point; and (3) make sure that none of the metal surfaces of the monitor's base or mounting bracket are touching a grounded surface (such as a metal table or pole mounted on conductive wheels in contact with a conductive floor).

QUESTION: *Is the ASA classification of risk considered surgical risk or anesthetic risk?*

MD, Missouri

ANSWER #1: First, there is no ASA classification of risk; there is a classification of physical status (PS), suggested for grading or rating the preoperative condition of patients based on the amount and/or severity of disease present.

Saklad,[1] in 1941, presented a classification for physical status containing 6 categories, 4 basic, PS 1 through 4, plus 2 additional ones, PS 5 and 6, that were combinations of the basic ones to be used when a patient was to undergo an emergency procedure. At some point between 1941 and 1944, another category, PS 7, for the patient who was moribund, was added to the classification. Waters and Gillespie[2] used this classification of physical status, and then Dripps' group,[3] in 1961, modified the classification, by using PS 5 as the category for the moribund patient, eliminating PS 6 and 7 and designating emergency status by using the letter E along with the basic PS of the patient. It has remained unchanged since that time.[4,5]

The judgment as to the degree of risk to the patient from the surgical procedure or the anesthetic depends on circumstances. Some years ago it was recognized, and probably it is even more true today, that risk from operation involved many variables or intangibles that could not be precisely defined in such a way as to permit evaluation of surgical risk. Collins[6] noted that these variables fall into 3 categories: (1) those related to the patient; (2) factors related to the surgical procedure and operating conditions; and (3) anesthetic considerations. Because it was felt that only the patient, with his individual variations, was the single constant factor in the picture, the consideration was given to a classification for the patient based upon his physical condition at the time he presented for operation.

The presently published ASA classifications carry brief descriptions, considerably less detailed than in Saklad's original work, Dripp's group related the PS assigned preoperatively with aspects of postoperative mortality. Analysis of the surgical and anesthetic factors for determining the total operative risk is well presented by Saklad and by Dripps. Another variable of importance, usually neglected in such reviews, is the matter of the time taken for the procedure, which may be critical for any patient.

There does not seem to be a concise answer to the question of what is anesthesia risk and what is surgical risk. The problem really is risk for the patient that arises from the combination of surgery and anesthesia. Preoperative classification of patients according to PS is a valuable tool for the anesthesiologist but is not absolute for any patient at all times. In general, the patient who is classified as PS 1 or 2 usually will tolerate the anesthesia and operation better than those rated as PS 3 through 5, but such a determination does not guard the patient against unforeseen complications or surgical and/or anesthetic errors.

5. New Classification of Physical Status. Anesthesiology 24:111, 1963

6. Collins VJ: Principles of Anesthesiology. Philadelphia, Lea & Febiger, 1966

ANSWER #2: Neither! The ASA classification relates to the physical status (PS) of the patient and not to risk imposed by surgery or anesthesia.

In 1941, the ASA empowered a committee to devise a system for the collection and tabulation of data in anesthesia. Saklad, the chairman, stated that it was necessary to set arbitrary definitions of variables.[1] At the time, "operative risk" was one of the variables often considered, and this assessment encompassed a number of factors, including condition of the patient, operative procedure, skill of the surgeon, experience of the anesthetist, postoperative care, etc. It thus became evident that assignment of "operative risk" to a patient involved many intangible variables peculiar to the circumstances prevailing at that moment. This committee, therefore, proposed a classification of physical state of the patient, per se, with no attempt to prognosticate the influence of a surgical procedure or anesthesia. The original proposal encompassed 6 PS classes, the latter two relating to emergency procedures.

In 1962, the ASA Committee on Clinical Anesthesia Study Commissions proposed a revision of this classification to encompass 5 PS classes, each to be preceded with an "E" in the event of an emergency operation.[2] The ASA House of Delegates accepted this proposal (resolution 6) at its annual meeting in 1962. The transaction was reported[3] in 1962 and also[4] in 1963. The format has continued as the accepted model for PS classification.

QUESTION: *Would heavy exposure to anesthetic gases (halothane and methoxyflurane) over a period of about 1 month have any effect on the Breathalyzer test given by law-enforcement officers?*

MD, Connecticut

ANSWER #1: The standard Breathalyzer test for alcohol in exhaled air uses the dichromate oxidation of alcohol to acetic acid in sulfuric acid.[1] In principle, this test will respond to any oxidizable molecule in the breath. However, in practice, the rate of oxidation is too slow for any species to be detected except alcohols and aldehydes. The response of alcohols is twice the response of aldehydes, and the relevant concentration in breath is several hundred parts per million (ppm). The halogenated hydrocarbon and halogenated ether anesthetics are present in end-expired breath in concentrations below 1 ppm following routine occupational exposure.

Since the breath concentrations of these anesthetics is so low and they are less reactive than alcohol, they should have no noticeable effect on the Breathalyzer test.

REFERENCE

1. Alcohol and the Impaired Driver. Committee of Medicolegal Problems, American Medical Association, 1970

* * *

ANSWER #2: The Breathalyzer test detects the presence of ethanol vapors in the exhaled alveolar air of a suspected drunk driver. The essential reaction is an oxidation of ethanol, converting a colored dichromate solution to a nearly colorless reduced form of chromate in the presence of sulfuric acid. The color difference is quantitated by colorimetry.

The reaction is not specific for ethanol. Acetone, ether, and paraldehyde can interfere or give false-positive readings. Blood concentrations of 100 to 125 mg % of diethyl ether are required for a positive reaction in the Breathalyzer, according to a personal communication from LG Porter, Supervisor, Alcohol Testing, Approval and Permit Program, Ohio Department of

Health. Such blood concentrations of diethyl ether are anesthetic and will not be encountered in someone who is able to drive. We believe that the biotransformation of diethyl ether to ethanol contributes to the positive Breathalyzer test during ether anesthesia.

Only minute, albeit persistent, amounts of volatile anesthetics are exhaled after OR work. Methoxyflurane concentrations of less than 1 ppm have been found in the exhaled air of anesthesiologists for as long as 30 hours after giving methoxyflurane anesthesia,[1] and halothane is exhaled for at least 6 days after exposure to trace concentrations.[2]

The effect of occupational exposure to halothane and methoxyflurane on the Breathalyzer test is not known. When determining the degree of exposure from post-exposure analysis of breath, 4 variables must be considered: concentration, length of exposure, amount in breath after exposure, and period of time after exposure. Taking these factors into consideration, it is unlikely that more than 10 ppm of halothane and more than 1 ppm of methoxyflurane can be found on the breath of an anesthesiologist driving a car.

To determine whether such concentrations of halothane or methoxyflurane can give a reading on the Breathalyzer test, we prepared these samples: halothane 1 ppm and enflurane 1 ppm, halothane 10 and 100 ppm, and methoxyflurane 1 ppm, diluted in room air, injecting 30 ml of each into the Breathalyzer. In no case was a color change seen in the reagent solution.

A Guide for Authors

Anesthesia and Analgesia . . . Current Researches invites manuscripts on subjects pertinent to the specialty of Anesthesia.

Send manuscripts and illustrations in *triplicate* to:

T. H. Seldon, MD, Editor
Kahler East, Suite C
Rochester, Minnesota 55901

Four categories of reports will be considered for publication.

1. Original articles describing clinical or laboratory research.

2. Brief Reports describing new anesthetic technics, equipment, clinical, or laboratory studies.

3. Case Reports.

4. Letters-to-the-Editor.

EDITORIAL POLICIES

Peer review.—All papers submitted are reviewed by selected referees with respect to validity, pertinence, completeness, and originality. If accepted for publication, editorial revisions may be made to aid clarity and understanding. Edited copy will be submitted to authors for approval before the paper goes to the printer. Pageproofs also will be submitted to the authors for final approval. Reprint order forms will accompany pageproofs.

Cover letter.—A letter must accompany each manuscript, stating that the work has not been simultaneously submitted to another journal or previously published in part or whole. The name and address of the author to whom correspondence may be directed should be given.

Legal and ethical considerations.—Information or illustrations which might permit identification of patients must not be used.

Reports describing data from experiments performed on humans must contain a statement in the Methods section, when appropriate, that written informed consent and/or institutional approval of the investigation has been obtained, and that procedures involving the use of animals was conducted so as to minimize discomfort.

Excerpts from material published elsewhere must be accompanied by written permission from the author and publisher to reproduce the material.

JOURNAL STYLE

Format.—All portions of the manuscript should be typewritten and double-spaced, including lists of reference citations. Each component of the paper (title page, with authors' academic rank and addresses, Introduction, Methods, Results, Discussion, References, Legends) should begin on a separate page. Original articles must be preceded by an Abstract concisely describing the purpose, methods, results, and conclusions. Abstracts should not exceed 1 typewritten page in length. Brief Reports and Case Reports do not require an Abstract, but a Summary at the end may be appropriate.

Original articles should be concise (not over 3000 words) and present new information pertinent to anesthesia. Preliminary reports or fragments of material that may better be included in a single, more detailed, report should not be submitted. Brief Reports describing new equipment or technics should present new advances, with advantages over the alternatives. Descriptions of new equipment must be sufficient to permit the reader to either construct or purchase the equipment. Case Reports should emphasize important clinical conditions or variations in typical patient responses. Letters-to-the-Editor must be brief (250-500 words) and should offer constructive comments on

recently published articles or discuss areas of general interest to anesthesiologists.

Measurement units.—The metric system should be used for all such data as length, mass, volume, and temperatures. Torr should be used in place of mm Hg for partial pressures. Authors are encouraged to adopt the International System of units (moles per liter rather than mg percent) for concentrations or amounts of substances. (See Padmore GRA, Nunn JF: SI Units in relation to anaesthesia. A review of the present position. Br J Anaesth 46:236-243, 1974).

Drug names.—Generic or chemical drug names are required. Brand names may be inserted in parentheses after the generic name, if pertinent.

Abbreviations.—The first time an abbreviation appears it should be preceded by the full word it represents.

Respiratory symbols.—Symbols for respiratory physiology should be defined the first time used and should follow Pappenheimer J et al: Standardization of definitions and symbols in respiratory physiology. Fed Proc 9:602-605, 1950.

References.—References should correspond to Index Medicus style and should be listed in the same numerical order as they appear in the text. Reports that are not accessible to all readers or that have not undergone editorial review (abstracts, correspondence, or personal communications) should not be included in numerical listings but may be footnoted. They should include pertinent addresses as well as source and authors' names.

Illustrations.—Drawings and photographs (unmounted glossy prints) should be numbered in order of appearance in the manuscript and labeled on the back with the first author's name and indicate the top edge of the picture.

Tables.—These should carry a title or caption and should supplement, not duplicate, the text.

A "quick recovery" anesthetic for short surgical procedures

Ethrane® (enflurane) fulfills your anesthetic requirements for short surgical procedures.

Fast Induction, Rapid Recovery. The low blood/gas partition coefficient of ETHRANE (1.91 at 37°C) assures rapid patient induction with minimal excitation. Its mild, pleasant odor is highly acceptable and ETHRANE does not stimulate increased salivation or affect bronchomotor tone.[1] Pharyngeal and laryngeal reflexes can be quickly and easily obtunded. Following anesthesia, because of its low blood solubility, ETHRANE is promptly eliminated at the lungs permitting rapid emergence and recovery.[2]

Stable Cardiac Rhythm. Cardiac rhythm usually remains normal during ETHRANE anesthesia and is not altered even with elevations in arterial carbon dioxide.[3] Although nodal or atrial arrhythmias occasionally appear, ventricular extrasystoles are rare. Heart rate is sustained at preanesthetic levels. Bradycardia or tachycardia do not normally occur. Blood pressure tends to be reduced with induction, but this effect is reversed with surgical stimulation.[4]

Excellent Muscle Relaxation. At clinical concentrations, ETHRANE usually provides muscle relaxation sufficient for lower abdominal procedures. In addition, relaxation is often adequate for procedures of the upper abdomen. If greater relaxation is required, its potentiation of nondepolarizing relaxants reduces the dosage of such adjunctive neuromuscular blocking agents.[4]

Few Anesthetic Aftereffects. Following cessation of anesthesia with ETHRANE, recovery is rapid, uneventful, and complete. Postoperative return of adequate pulmonary ventilation is rapid.[1] Nausea, vomiting, and delirium are rare. Usually there is an early return of lucidity, desire for fluids, and generally a feeling of well-being.[1-4]

WARNING: Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia. For additional warnings, contraindications, and precautions, see following page.

Films Available for Medical Education. As a service to the anesthesia profession, Ohio Medical Products has available, without charge, motion pictures for use in continuing medical education. Topics include such areas as "Management of Ambulatory Surgical Procedures" and "The Use of ETHRANE." To arrange for a personal or group showing, contact your OHIO Anesthetic Representative, or write to our Communications Department in Madison, Wisconsin.

Ethrane® (enflurane) Versatile in concept... Versatile in performance.

CAUTION: Federal Law Prohibits Dispensing without Prescription

Description: ETHRANE (enflurane) is a nonflammable anesthetic agent. It is 2-chloro-1,1,2-trifluoroethyl difluoromethyl ether, and its structural formula is:

Some physical constants of the compound are:

Molecular weight	184.5
Boiling point 760 mm Hg.	56.5°C
Refractive index n_D^{20}	1.3026-1.3030
Specific gravity 25°/25°C	1.517
Vapor pressure in mm Hg.**	20°C 174.5 25°C 217.7 36°C 345.2

**Equation for calculation of enflurane vapor pressures:

$$\log_{10} P = A + \frac{B}{T}$$

A = 7.967
B = −1678.4
T = °C + 273.16 (Kelvin)

Partition coefficients @ 37°C	
Water-gas	0.82
Blood-gas	1.91
Oil-gas	98.5
Partition coefficients @ 25°C— rubber and plastic	
Conductive rubber	74.0
Butyl rubber	90.0
Polyvinylchloride	120.0
Polyethylene	≈2.0
Polyurethane	≈1.5
Polyolefin	≈1.2
Butyl acetate	≈3.0
Solubility of enflurane in H_2O at 22°C	0.275%
Solubility of H_2O in enflurane	0.13%
Purity by gas chromatography	>99.9%
Flammability in air	None
Flammability in oxygen (Entire concentration range to saturation at 71 and 113°F and 743 mm Hg. pressure.)	None
M.A.C. (Minimum alveolar concentration)	
Man with pure oxygen	1.68
Man with 70% nitrous oxide	0.56 (est.)

ETHRANE is a clear, colorless, stable liquid without added chemical stabilizers. ETHRANE has a mild, sweet odor. Storage of samples in indirect sunlight in clear, colorless glass for a five year period, as well as direct exposure for 30 hours to a 2 amp, 115 V., 60 cycle long wave U.V. light, produced no changes in composition detectable by gas chromatography. ETHRANE in one normal sodium methoxide-methanol solution, a strong base, for over six months consumed none of the alkali, indicative of strong base stability. ETHRANE does not decompose in contact with soda lime. ETHRANE does not attack aluminum, tin, brass, iron or copper.

Actions: ETHRANE (enflurane) is an inhalation anesthetic. Induction and recovery from anesthesia with ETHRANE are rapid. ETHRANE does not appear to stimulate excess salivation or tracheobronchial secretions, or affect bronchomotor tone. Pharyngeal and laryngeal reflexes are readily obtunded. The level of anesthesia changes rapidly with ETHRANE. ETHRANE reduces ventilation as depth of anesthesia increases. ETHRANE provokes a sigh response reminiscent of that seen with diethyl ether.

There is a decrease in blood pressure with induction of anesthesia, followed by a return to near normal with surgical stimulation. Progressive increases in depth of anesthesia produce corresponding increases in hypotension. Heart rate remains relatively constant without significant bradycardia. Electrocardiographic monitoring or recordings indicate that cardiac rhythm remains stable. Elevation of the carbon dioxide level in arterial blood does not alter cardiac rhythm. ETHRANE sensitizes the myocardial conduction system to epinephrine in dog and can produce serious arrhythmias. Comparable information in man is not available.

Muscle relaxation is adequate for intra-abdominal operation at normal levels of anesthesia. Should greater relaxation be necessary, minimal doses of muscle relaxants may be used. All commonly used muscle relaxants are compatible with ETHRANE. **The nondepolarizing muscle relaxants are markedly potentiated.** Neostigmine does not reverse the direct effect of ETHRANE.

Biotransformation of ETHRANE (enflurane) in man results in low levels of serum fluoride ions averaging 15 mM/L. These levels are well below the 50 mM/L seen to produce renal damage in normal subjects; however, it is possible that these levels could result in damage in patients with severely impaired renal function or those undergoing renal transplantation.

Indications: ETHRANE (enflurane) may be used for induction and maintenance of general anesthesia. Adequate data have not been developed to establish its application in obstetrical anesthesia.

Contraindications: Seizure disorders (see WARNINGS).

Known sensitivity to ETHRANE (enflurane) or other halogenated anesthetics.

Warnings: Increasing depth of anesthesia with ETHRANE (enflurane) produces a change in the electroencephalogram characterized by high voltage, fast frequency, progressing through spike-dome complexes alternating with periods of electrical silence to frank seizure activity. The latter may or may not be associated with motor movement. Motor activity, when encountered, generally consists of twitching or "jerks" of various muscle groups; it is self-limiting and can be terminated by lowering the anesthetic concentration. This electroencephalographic pattern associated with deep anesthesia is exacerbated by hyperventilation producing low arterial carbon dioxide tension. The pattern serves as a warning that depth of anesthesia is excessive. Cerebral blood flow and metabolism studies in normal volunteers during seizure patterns show no evidence of cerebral hypoxia, and recovery appears to be uncomplicated.

Since levels of anesthesia may be altered easily and rapidly, only calibrated vaporizers which measure output with reasonable accuracy should be used. Hypotension and respiratory exchange can serve as a guide to anesthesia depth. With deep levels of anesthesia, more marked hypotension and respiratory depression are encountered.

The action of nondepolarizing relaxants is augmented by ETHRANE. Less than the usual amounts of these drugs should be used. The time for recovery from the myoneural effect of these relaxants is greater in the presence of ETHRANE than for other commonly used anesthetics.

The safety of the use of epinephrine topically and subcutaneously has not been established in man.

Usage in Pregnancy: Safety in pregnancy has not been established. Reproduction studies have been performed in rats and rabbits, and there is no evidence of harm to the animal fetus. The relevance of these studies to the human is not known. Since there is no adequate experience in pregnant women who have received the drug, safety in pregnancy has not been established.

Precautions: Bromsulfalein (BSP) retention is mildly elevated postoperatively in some cases. There is some elevation of glucose and white blood count intraoperatively. Glucose elevation should be considered in diabetic patients. ETHRANE (enflurane) should be used with caution in patients who by virtue of medical or drug history could be considered more susceptible to cortical stimulation produced by this drug. As with other general anesthetics and some muscle relaxants, hyperpyrexia has been observed with the use of ETHRANE.

Adverse reactions: 1. Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia. 2. Hypotension and respiratory depression have been reported. 3. Arrhythmias, shivering, nausea, and vomiting have been reported. 4. Elevation of the white blood count has been observed. It has not been determined whether this is related to ETHRANE or to surgical stress.

Dosage and administration: The concentration of ETHRANE (enflurane) being delivered during anesthesia from a vaporizer should be known. This may be accomplished by using:

a) vaporizers calibrated specifically for ETHRANE;
b) vaporizers from which delivered flows can easily and readily be calculated.

Maintenance concentration should not exceed 3%. Premedication should be selected according to the need of the individual patient, taking into account that secretions are weakly stimulated by ETHRANE and the heart rate remains constant. The use of anticholinergic drugs is a matter of choice.

Induction: Induction may be achieved using ETHRANE alone with oxygen or in combination with oxygen-nitrous oxide mixtures. Under these conditions some excitement may be encountered. If excitement is to be avoided, a hypnotic dose of a short-acting barbiturate should be used to induce unconsciousness, followed by the ETHRANE mixture. In general, inspired concentrations of 3.5-4.5% ETHRANE produce surgical anesthesia in 7-10 minutes.

Maintenance: Surgical levels of anesthesia may be attained with 1.5-3.0% concentration. If added relaxation is required, supplemental doses of muscle relaxants may be used. Ventilation to maintain the tension of carbon dioxide in arterial blood in the 35-45 mm range is preferred to hyper- or hypoventilation in order to minimize possible CNS excitation.

The level of blood pressure during maintenance is an inverse function of ETHRANE concentration in the absence of other complicating problems. Excessive decreases (unless related to hypovolemia) may be due to depth of anesthesia and in such instances should be corrected by lightening the level of anesthesia.

Overdosage: In the event of overdosage, or what may appear to be overdosage, the following action should be taken:

Stop drug administration; establish that the airway is clear and initiate assisted or controlled ventilation with pure oxygen as circumstances dictate.

Administration equipment: ETHRANE (enflurane) may be administered from a flow-through type vaporizer manufactured and specifically calibrated for ETHRANE. Vaporizers which deliver saturated vapor at reasonable flows but are not specifically calibrated for ETHRANE may be used.

ETHRANE contains no stabilizer. Nothing is present in the agent to alter calibration or affect the operation characteristics of the vaporizer.

Packaging: ETHRANE (enflurane) is packaged in 125 and 250 ml. amber bottles. No additives or stabilizers are present.

THE VULNERABLE EYE.

Lacri-Lube® protects the vulnerable eye of the anesthetized patient.

The under-protected eye is threatened during general anesthesia. Tape alone can leave your patient's eye vulnerable to dehydration and corneal erosion. And with medicated ointments, you unnecessarily risk allergic reactions and possible long-term sensitization.

Lacri-Lube meets your need for a safer, more sophisticated method of protecting and lubricating the eye. Either on its own or as an adjunct to taping. It's the first non-medicated, sterile ophthalmic ointment specifically designed to lubricate and protect the eye — and do nothing more.

In fact, ophthalmologists have established Lacri-Lube as their lubricant-protectant of choice whenever an eye is jeopardized by exposure or dehydration. And the rapid increase in its surgical use indicates that Lacri-Lube fulfills the same need among anesthesiologists.

Lacri-Lube is the ophthalmic for anesthesia.

When you consider the alternatives, you can't make a better choice.

ANTILIRIUM
(Physostigmine Salicylate)

REVERSES MOST POST-OPERATIVE DELIRIUM AND PROLONGED SOMNOLENCE

Before prescribing, please consult complete product information, a summary of which follows:

ACTION: ANTILIRIUM (physostigmine salicylate) is a salicylic acid derivative of an alkaloid extracted from seeds of Physostigma Venenosum (calabar bean). The action of the parasympathetic nerves is intermediated by the formation of acetylcholine at the peripheral end of these nerves. Physostigmine inhibits the destructive action of cholinesterase and thereby prolongs and exaggerates the effect of the acetylcholine.

Physostigmine contains a tertiary amine and easily crosses the blood brain barrier, while neostigmine contains a quaternary amine and is not capable of crossing the structure. This may explain why neostigmine does not cause reversal of anticholinergic-induced delirium while physostigmine does.

INDICATIONS: TO REVERSE THE TOXIC EFFECTS UPON THE CENTRAL NERVOUS SYSTEM CAUSED BY DRUGS IN CLINICAL OR TOXIC DOSAGES CAPABLE OF PRODUCING ANTICHOLINERGIC POISONING.

SEVERE ANTICHOLINERGIC POISONING MAY PRODUCE: COMA, MEDULLARY PARALYSIS AND DEATH.

CENTRAL TOXIC EFFECTS MAY INCLUDE: HALLUCINATIONS, DELIRIUM, DISORIENTATION, ANXIETY AND HYPERACTIVITY.

Dramatic reversal within minutes of coma, hallucinations, and other signs can be expected if the diagnosis is correct and the patient has not suffered anoxia or other insult. Therapeutic doses may be necessary at intervals as life-threatening signs recur. Physostigmine is destroyed in the body in 60 to 120 minutes.

CONTRAINDICATIONS: Physostigmine should not be used in the presence of asthma, gangrene, diabetes, cardiovascular disease, mechanical obstruction of the intestines or urogenital tract or any vagotonic state, and in patients receiving choline esters or depolarizing neuromuscular blocking agents.

WARNING: If excessive symptoms of salivation, emesis, urination and defecation occur, the use of ANTILIRIUM should be terminated. If excessive sweating or nausea occur, the dosage should be reduced.

Intravenous administration should be at a slow, controlled rate, no more than 1 mg. per minute (see dosage). Rapid administration can cause bradycardia, hypersalivation leading to respiratory difficulties and possibly convulsions.

An overdosage of ANTILIRIUM can cause a cholinergic crisis.

PRECAUTIONS: Because of the possibility of hypersensitivity in an occasional patient, atropine sulfate injection should always be at hand since it is an antagonist and antidote for physostigmine.

ADMINISTRATION AND DOSAGE: The usual adult dose of ANTILIRIUM is 0.5 to 2.0 mg. intramuscularly or intravenously. Intravenous administration should be at a slow, controlled rate of no more than 1 mg. per minute. It may be necessary to repeat dosages of 1 mg. to 4 mg. at intervals as life threatening signs such as arrhythmias, convulsions and deep coma recur.

IN ALL CASES OF POISONING, THE USUAL SUPPORTIVE MEASURES SHOULD BE UNDERTAKEN.

SUPPLIED: 2 ml. ampules containing:
PHYSOSTIGMINE SALICYLATE 1 mg. per ml.
Packed 12 ampules per box.

NDC 0456-1037-12

CAUTION: Federal law prohibits dispensing without prescription.

CLASSIFIED ADVERTISING

ANESTHESIOLOGIST — markedly expanding academic medical center located in attractive Midwestern setting requires additional senior and junior faculty; Board certification and teaching experience necessary; salary from $45,000-$75,000 with extraordinary fringe benefit program. Inquiries with curriculum vitae to Box 5-76-B in care of I.A.R.S.

ANESTHESIOLOGIST: Board certified/eligible to join newly formed group of anesthesiologists and nurse anesthetists in New Orleans. Fee for service private practice at 650-bed general hospital and newly opened Pediatric hospital. Write or call Metropolitan Anesthesia Associates, 4520 Melpomene, New Orleans, La. 70185. (504) 822-9331.

ANESTHESIOLOGIST—to join staff in new 400+ bed university affiliated teaching hospital in large metropolitan area. Candidates must be licensed or eligible for licensure in the state of Minnesota at the time they are accepted for employment. Salary commensurate with experience. For further information contact:

Irving Greenfield, Chief of Service
Dept. of Anesthesia
Hennepin County Medical Center
5th and Portland
Minneapolis, MN 55415

FACULTY POSITIONS

Department of Anesthesiology, Charity Hospital, New Orleans, affiliated with LSU and Tulane Medical Schools, has three faculty positions open for board certified/eligible anesthesiologists at Associate-Assistant Professor, Instructor levels. Duties involve teaching, research, clinical supervision. Salaries negotiable. Send inquiries and curriculum vitae to: M. Naraghi, M.D., Director, Department of Anesthesiology, Charity Hospital, New Orleans, Louisiana 70140.

DENTAL ANESTHESIOLOGY RESIDENCY

Available to dentists who have completed no less than one year of an approved internship or residency. Stipend: $15,400 at first year level.

For further details write to: Dr. Leon Eisenbud, Chairman, Department of Dentistry, Long Island Jewish-Hillside Medical Center, New Hyde Park, New York 11040.

MARYLAND: Positions on the Anesthesia Staff at Baltimore City Hospitals. Excellent fringe benefits and salary. Residency fully integrated with the Johns Hopkins Medical School program. Send CV to Peter Chodoff, M.D., Anes-in-Chief, Baltimore City Hospitals, 4940 Eastern Ave., Baltimore, Maryland 21224.

PEDIATRIC ANESTHESIOLOGY RESIDENCY

Childrens Hospital of Los Angeles

Three-phase program: Clinical, Academic, Investigative, emphasizing practical aspects of anesthesiology related to infants and children.

AMA approval for third-year residency. Positions available from two months to one year.

Apply: George B. Lewis, Jr., M.D.
Head, Division of Anesthesiology
Childrens Hospital of Los Angeles
4650 Sunset Boulevard
Los Angeles, California 90054
Phone (213) 660-2450, Ext. 2262

NEBRASKA Opportunity for Anesthesiologist in 450-bed acute care, teaching hospital affiliated with two medical schools; must be board certified or eligible, salary commensurate with education and experience. An equal opportunity employer. Contact J. J. Matoole, M.D., Chief of Staff, Veterans Administration Hospital, 4101 Woolworth Avenue, Omaha, Nebraska 68105. (402) 346-8800, Ext. 442.

5th ANESTHESIOLOGIST—Board certified/eligible. To join hospital based group with new OR in modern 250-bed community hospital. Excellent opportunity. Send CV to Raymond E. Bradley, M.D., Chief Anesthesiologist, The Griffin Hospital, 130 Division St., Derby, Conn. 06418. Equal opportunity employer.

DIRECTOR OF PULMONOLOGY

Responsibility will include developing, supervising and directing acute and chronic pulmonary services for 376-bed acute hospital and 230-bed long term care hospital. Will assist to develop new services to improve pulmonology accessibility to our patients and to physicians and patients of contracting health care institutions in the area. Position requires a Board Certified Pulmonologist. Please direct inquiries to: Dr. John Hoesing, Chairman, Pulmonology Director Search Committee,

Nebraska Methodist Hospital
8300 Dodge Street
Omaha, Nebraska 68114
(402) 397-3000

An Equal Opportunity Employer

ACADEMIC ANESTHESIOLOGIST

Top academic salaries in country, rank commensurate with vitae, any experience level considered, must be A.B.A. certified, type of assignment dependent on interest but especially seeking cardiovascular and O.B. experience, research opportunities also available. Send Vitae, date of availability, and list three references. Contact Box 7-76-A, c/o I.A.R.S.

Current Researches, 3645 Warrensville Center Rd., Cleveland, Ohio 44122.

The local that gives you the longest anesthesia gives your patient longer postoperative analgesia.

Marcaine® hydrochloride (brand of bupivacaine hydrochloride)—available with or without epinephrine—is the local anesthetic that provides the longest duration of action among commonly used local anesthetics. Which minimizes the problems of "continuous" technique or repeat doses.

Marcaine also provides longer postoperative analgesia. Which reduces the need for postoperative narcotics.

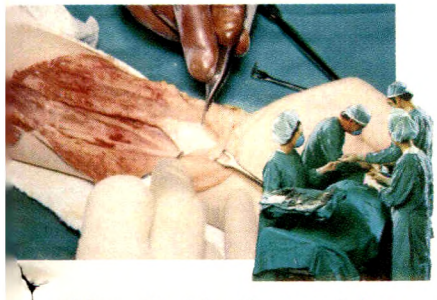
And in data in over 3,000 patients, Marcaine was reported to have excellent or satisfactory results in more than 96% of cases.

Extended anesthesia for the surgeon

In regional blocks, Marcaine, with or without epinephrine, usually provides anesthesia at least 1½ to 2 times longer than lidocaine or mepivacaine. And approximately 20% longer than tetracaine.

In fact, anesthesia may extend up to 9 hours for peridural block and up to 12 hours for peripheral nerve block. This has been established in several thousand surgical and obstetrical patients.[1-4]

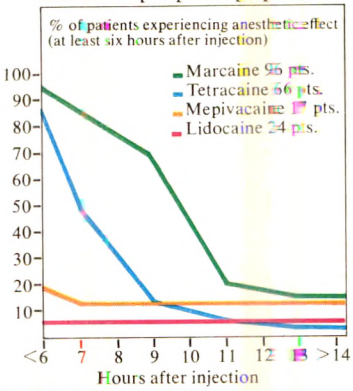
In fact, a single Marcaine epidural injection, with or without epinephrine, may be enough for up to 3½[4] or more[5] hours of anesthesia for surgery, and often provides analgesia that carries over into the recovery room and beyond. When necessary, doses may be repeated up to once every three hours. Caution is advised in administration of repeat doses to patients with severe liver disease. Until further experience is gained, total daily dose of



400 mg. should not be exceeded nor is administration to children under 12 recommended. Also see epinephrine warnings and precautions statements on next page.

This longer anesthetic action can minimize problems of "continuous" technique or repeat doses. Thus, there is the further advantage of a reduced likelihood of introducing infection since injections are less frequent.[6]

Chart I
Duration of anesthesia
Percentage of patients experiencing anesthetic effect—
Comparison of Marcaine with epinephrine and other local anesthetic/epinephrine preparations*



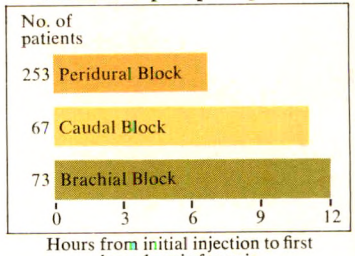
*Equipotent doses used for bilateral, simultaneous blocks of sciatic/femoral, intercostal or brachial/axillary nerves. Adapted from Moore, D. C.: Data in the files of the Sterling-Winthrop Research Institute.

Extended postoperative analgesia for the patient

Marcaine, with or without epinephrine, gives your patient more—considerably more—postanesthetic analgesia than other local anesthetics in various types of nerve block.[3,4,7,8] An analgesia that persists after the return of motor function and even cutaneous sensation.[7] As a result, you may be able to defer[1,5] and sometimes even eliminate,[5] postoperative narcotics. Chart II illustrates the average duration of time between the initial Marcaine injection and the need for postop analgesics. Many of the 67 patients given Marcaine, with or without epinephrine, caudally for rectal surgery did not complain of pain for 11 hours or longer following induction.

In another group of 40 patients[8] given Marcaine or mepivacaine, both with epinephrine, locally for tonsillectomy, Marcaine pain relief lasted 3 to 5 times longer than that provided by mepivacaine. And in a study[1] of 65 patients given 0.5% Marcaine with epinephrine caudally for rectal or other perineal surgery, complete sensation returned in a mean of 8½ hours for the average patient. And the majority of these patients did not require a narcotic for an additional 1 to 3 hours.

Chart II
Duration of time between injection of Marcaine, with or without epinephrine, and need for postop analgesics†



†Average—exclusion of extremes and failures. Adapted from Lund, P.C., *et al.*: *Anesth. Analg.* 49:103, Jan.-Feb. 1970.

Excellent clinical acceptance

Marcaine, with or without epinephrine, was administered to 3,112 patients for various types of local anesthesia.[9] Of these patients, only 2 experienced a systemic reaction. Although Marcaine has a very wide safety margin, adverse reactions characteristic of those associated with other amide local anesthetics may occur.

Marcaine is indicated for most anesthetic blocks; however, until further clinical experience is gained, paracervical block is not recommended.

See important product information concerning warnings, adverse reactions, patient selection, and prescribing and precautionary recommendations on next page.

Extends the limits of time in anesthesia[1-4]
Extends the limits of time in postoperative analgesia[3,4,7,8]

Marcaine® hydrochloride

Brand of
bupivacaine hydrochloride

with or without epinephrine 1:200,000

Winthrop

MARCAINE® Hydrochloride
Brand of **bupivacaine hydrochloride**

Indications: Peripheral nerve block, infiltration, sympathetic block, caudal, or epidural block.

Contraindication: Marcaine is contraindicated in patients with known hypersensitivity to it.

Warnings: RESUSCITATIVE EQUIPMENT AND DRUGS SHOULD BE READILY AVAILABLE WHEN ANY LOCAL ANESTHETIC IS USED.

Usage in Pregnancy. Reproduction studies have been performed in rats and rabbits and there is no evidence of harm to the animal fetus. The relevance to the human is not known. Safe use in pregnant women other than those in labor has not been established.

Until further clinical experience is gained, paracervical block with Marcaine is not recommended. Fetal bradycardia frequently follows paracervical block with some amide-type local anesthetics and may be associated with fetal acidosis. Added risk appears to be present in prematurity, toxemia of pregnancy, and fetal distress.

The obstetrician is warned that severe persistent hypertension may occur after administration of certain oxytocic drugs, if vasopressors have already been used during labor (e.g., in the local anesthetic solution or to correct hypotension).

Solutions containing a vasoconstrictor, particularly epinephrine or norepinephrine, should be used with extreme caution in patients receiving monoamine oxidase (MAO) inhibitors or antidepressants of the triptyline or imipramine types, because severe, prolonged hypertension may result.

Local anesthetics which contain preservatives, i.e., those supplied in multiple dose vials, should not be used for caudal or epidural anesthesia.

Until further experience is gained in children younger than 12 years, administration of Marcaine in this age group is not recommended.

Precautions: The safety and effectiveness of local anesthetics depend upon proper dosage, correct technique, adequate precautions, and readiness for emergencies.

The lowest dosage that gives effective anesthesia should be used in order to avoid high plasma levels and serious systemic side effects. Injection of repeated doses of Marcaine may cause significant increase in blood levels with each additional dose, due to accumulation of the drug or its metabolites or due to slow metabolic degradation. Tolerance varies with the status of the patient. Debilitated, elderly patients and acutely ill patients should be given reduced doses commensurate with age and physical condition.

Solutions containing a vasoconstrictor should be used cautiously in areas with limited blood supply, in the presence of diseases that may adversely affect the patient's cardiovascular system, or in patients with peripheral vascular disease.

Marcaine should be used cautiously in persons with known drug allergies or sensitivities, particularly to the amide-type local anesthetics.

Serious dose-related cardiac arrhythmias may occur if preparations containing a vasoconstrictor such as epinephrine are employed in patients during or following the administration of chloroform, halothane, cyclopropane, trichloroethylene, or other related agents. In deciding whether to use these products concurrently in the same patient, the combined action of both agents upon the myocardium, the concentration and volume of vasoconstrictor used, and the time since injection, when applicable, should be taken into account.

Caution is advised in administration of repeat doses of Marcaine to patients with severe liver disease.

Adverse Reactions: Reactions to Marcaine are characteristic of those associated with other amide-type local anesthetics. A major cause of adverse reactions to this group of drugs is excessive plasma levels, which may be due to overdosage, inadvertent intravascular injection, or slow metabolic degradation.

Excessive plasma levels of the amide-type local anesthetics cause systemic reactions involving the central nervous system and the cardiovascular system. The *central nervous system effects* are characterized by excitation or depression. The first manifestation may be nervousness, dizziness, blurred vision, or tremors, followed by drowsiness, convulsions, unconsciousness, and possibly respiratory arrest. Since excitement may be transient or absent, the first manifestation may be drowsiness, sometimes merging into unconsciousness and respiratory arrest. Other central nervous system effects may be nausea, vomiting, chills, constriction of the pupils, or tinnitus. The *cardiovascular manifestations* of excessive plasma levels may include depression of the myocardium, blood pressure changes (usually hypotension), and cardiac arrest. In obstetrics, cases of fetal bradycardia have occurred (see Warnings).

Allergic reactions, which may be due to hypersensitivity, idiosyncrasy, or diminished tolerance, are characterized by cutaneous lesions (e.g., urticaria), edema, and other manifestations of allergy. Detection of sensitivity by skin testing is of doubtful value.

Reactions following epidural or caudal anesthesia also may include: high or total spinal block; urinary retention; fecal incontinence; loss of perineal sensation and sexual function; persistent analgesia, paresthesia, and paralysis of the lower extremities; headache and backache; and slowing of labor and increased incidence of forceps delivery.

Treatment of Reactions. Toxic effects of local anesthetics require symptomatic treatment; there is no specific cure. The physician should be prepared to maintain an airway and to support ventilation with oxygen and assisted or controlled respiration as required. Supportive treatment of the cardiovascular system includes intravenous fluids and, when appropriate, vasopressors (preferably those that stimulate the myocardium). Convulsions may be controlled with oxygen and intravenous administration, in small increments, of a barbiturate, as follows: preferably, an ultrashort-acting barbiturate such as thiopental or thiamylal; if this is not available, a short-acting barbiturate (e.g., secobarbital or pentobarbital) or diazepam. Intravenous barbiturates or anticonvulsant agents should only be administered by those familiar with their use.

What are you doing in airway management?

You're solving problems ...when you use the **Lanz Controlled Pressure Cuff Endotracheal Tube.**

Unique cuff system automatically compensates for increased volume/pressure caused by diffusion of N_2O or O_2 into cuff.

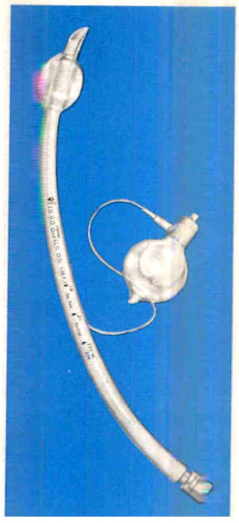
Long-term airway management is a problem. There's always the hazard of tracheal scarring and stenosis...accidental over-inflation. And so on.

Now with the Lanz Controlled-Pressure Cuff Endotracheal Tube, you can help solve your long-term intubation problems.

Dangers of Tracheal Damage Minimized.

The Lanz Endotracheal Tube is unique. It is a controlled-pressure cuff system containing an automatic, pressure regulating valve with an external, pressure-control balloon. This system is designed to eliminate excessive pressure on the tracheal wall due to over-inflation of the cuff. It's also designed to *automatically compensate* for increased volume and pressure caused by diffusion of N_2O or O_2 into the cuff.

When used in the intubation period before tracheostomy, it helps assure protection of the trachea throughout the entire period of airway management.



Patient Safety and Comfort

The Lanz Endotracheal Tube permits quick and easy intubation. The tube will flex, but not kink. It is available with either Murphy or Magill tips.

And it's available now—packaged sterile, and ready to use.

Help solve your long-term airway problems now with the Lanz Disposable Controlled-Pressure Cuff Endotracheal Tube. Write today for complete information, or call your Extracorporeal Representative.

INTRODUCING

the PSI 5000 Recorder

MEASURES & RECORDS

ECG • PULSE •
VITAL PRESSURES

- ARTERIAL
- VENOUS
- INTERCRANIAL
- PULMONARY WEDGE

WHEN VERSATILITY COUNTS

BATTERY OPERATION, VARIABLE AMPLITUDES
VARIABLE SPEEDS AND TREND - 2.5 to 50 mm/Sec.

Whenever precise permanent copies are essential.

The PSI 5000 Recorder is a portable, battery operated, self-contained unit for use in most heart, lung, and blood pressure measurements. The PSI 5000 meets AHA specifications for electrocardiography, assuring superior performance in any application requiring high frequency response. The pen stylus is held in a stress-free mount on a titanium arm to provide exceptional life. It is capable of sustaining up to 1000 G's acceleration. A fully charged battery will provide up to four hours continuous operation.

RALS POWER UNIT

. . . INSTANT ATOMIZATION FOR FAST TOPICAL ANESTHESIA

Fast, measured topical anesthesia is ready at your finger tips in a Rals Power Unit. Forget about pumping bulbs, uneven atomization, and limited spraying duration. The Rals Power Unit uses a non-toxic propellant, dichlorodifluoromethane (freon) to activate standard DeVilbiss Atomizers No's. 151, 152 and 163. Instantly, a fine mistlike spray is produced. A graduated solution vial is available for measuring the amount of solution administered.

The Rals Power Unit has been proven effective in cocainization prior to endotracheal intubation, endoscopic instrumentation, laryngotracheal insufflation, and in a variety of nose and throat procedures.

Rals Power Unit #168 are supplied six to a box with adaptor top and metal base. Illustration shows #152 atomizer. All styles in stock.

Innovar® injection

The two components of INNOVAR® injection, fentanyl and droperidol, have different pharmacologic actions. Before administering INNOVAR injection, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action.

DESCRIPTION

Each cc. contains (in a 1:50 ratio):

Fentanyl ..... 0.05 mg.
as the citrate

Warning: May be habit forming

Droperidol ..... 2.5 mg.

Lactic acid for adjustment of pH to 3.5± 0.3

FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY

Protect from Light

ACTIONS INNOVAR injection is a combination drug containing a narcotic analgesic, fentanyl, and a neuroleptic (major tranquilizer), droperidol. The combined effect, sometimes referred to as neuroleptanalgesia, is characterized by general quiescence, reduced motor activity, and profound analgesia; complete loss of consciousness usually does not occur from use of INNOVAR injection alone. The incidence of early postoperative pain and emesis may be reduced.

A. Fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. Fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. Fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays, and skin wheal testing in man, as well as *in vivo* testing in dogs indicate that histamine release rarely occurs with fentanyl.

Fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours. Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics, it may be considerably longer than the analgesic effect.

B. Droperidol produces marked tranquilization and sedation. It also produces an antiemetic effect as evidenced by the antagonism of apomorphine in dogs. It potentiates other CNS depressants. It also produces mild alpha adrenergic blockade, peripheral vascular dilatation and reduction of the pressor effect of epinephrine. Droperidol can produce hypotension and decreased peripheral vascular resistance. It may decrease pulmonary arterial pressure (particularly if it is abnormally high). It may reduce the incidence of epinephrine-induced arrhythmias but it does not prevent other cardiac arrhythmias. The onset of action is from three to ten minutes following intravenous or intramuscular administration. The full effect, however, may not be apparent for 30 minutes. The duration of the sedative and tranquilizing effects generally is two to four hours. Alteration of consciousness may persist as long as 12 hours. This is in contrast to the much shorter duration of action of fentanyl.

INDICATIONS INNOVAR injection is indicated to produce tranquilization and analgesia for surgical and diagnostic procedures. It may be used as an anesthetic premedication, for the induction of anesthesia, and as an adjunct in the maintenance of general and regional anesthesia. If the supplementation of analgesia is necessary, SUBLIMAZE® (fentanyl) injection alone rather than the combination drug INNOVAR injection should usually be used.

CONTRAINDICATIONS INNOVAR injection should not be used in patients who are hypersensitive to either component.

WARNINGS PATIENTS WHO HAVE RECEIVED *INNOVAR* INJECTION SHOULD BE UNDER APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

The respiratory depressant effect of narcotics persists longer than their measured analgesic effect. When used with INNOVAR injection, the total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, be used initially in reduced doses, as low as 1/4 to 1/3 those usually recommended.

INNOVAR injection may cause muscle rigidity, particularly involving the muscles of respiration. This effect is due to the fentanyl component and is related to the speed of injection. Its incidence can be reduced by the use of slow intravenous injection. Once the effect occurs it is managed by the use of assisted or controlled respiration and by a neuromuscular blocking drug, if necessary.

FLUIDS AND OTHER COUNTERMEASURES TO MANAGE HYPOTENSION SHOULD ALSO BE AVAILABLE.

Drug Dependence: *Fentanyl, the narcotic analgesic component, can produce drug dependence of the morphine type and therefore has the potential for being abused.*

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl, in this regard, has not been established, the use of INNOVAR injection or SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: INNOVAR injection should be used with caution in patients who may be particularly susceptible to respiratory depression such as comatose patients who may have a head injury or brain tumor. In addition, these drugs may obscure the clinical course of patients with head injury.

Usage in Children: The safety of INNOVAR injection in children two years of age or younger has not been established.

Usage in Pregnancy: The safe use of INNOVAR injection has not been established with respect to possible adverse effects upon fetal development.

Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects; therefore, safety for the infant in obstetrics has not been established.

PRECAUTIONS *The initial dose of INNOVAR injection should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and some peridural anesthetics, can alter respiration by blocking intercostal nerves, and can cause peripheral vasodilatation and hypotension because of sympathetic blockade. Through other mechanisms (see Actions) fentanyl and droperidol also depress respiration and blood pressure. Therefore, when INNOVAR injection is used to supplement these forms of anesthesia, the anesthetist must be familiar with the physiological alterations involved, and be prepared to manage them in the patients selected for this form of anesthesia.

The droperidol component of INNOVAR injection may decrease pulmonary arterial pressure. This fact should be considered by those who conduct diagnostic or surgical procedures where interpretation of pulmonary arterial pressure measurements might determine final management of the patient.

Vital signs should be monitored routinely.

INNOVAR injection, and SUBLIMAZE fentanyl, should be used with caution in patients with chronic obstructive pulmonary disease, patients with decreased respiratory reserve, and others with potentially compromised ventilation. In such patients narcotics may additionally decrease respiratory drive and increase airway resistance. During anesthesia this can be managed by assisted or controlled respiration. Postoperatively respiratory depression caused by narcotic analgesics can be reversed by narcotic antagonists (levallorphan, nalorphine, and naloxone); consult individual prescribing information before using.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, and general anesthetics) have additive or potentiating effects with INNOVAR injection. When patients have received such drugs, the dose of INNOVAR injection required will be less than usual. Likewise, following the administration of INNOVAR injection the dose of other CNS depressant drugs should be reduced.

INNOVAR injection should be administered with caution to patients with liver and kidney dysfunction because of the importance of these organs in the metabolism and excretion of drugs.

If hypotension occurs, the possibility of hypovolemia should be considered and managed with appropriate parenteral fluid therapy. Repositioning the patient to improve venous return to the heart should be considered when operative conditions permit. It should be noted that in spinal and peridural anesthesia tilting the patient into a head down position may result in a higher level of anesthesia than is desirable, as well as impair venous return to the heart. Care should be exercised in the moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus these other countermeasures do not correct the hypotension, then the administration of pressor agents other than epinephrine should be considered. Epinephrine may paradoxically decrease the blood pressure in patients treated with INNOVAR injection due to the alpha-adrenergic blocking action of droperidol.

The fentanyl component may produce bradycardia, which may be treated with atropine; however, INNOVAR injection should be used with caution in patients with cardiac bradyarrhythmias.

When the EEG is used for postoperative monitoring, it may be found that the EEG pattern returns to normal slowly.

ADVERSE REACTIONS The most common serious adverse reactions reported to occur with INNOVAR injection are respiratory depression, apnea, muscular rigidity, and hypotension; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have been observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with anti-parkinson agents.

Other adverse reactions that have been reported are dizziness, chills and/or shivering, twitching, blurred vision, hyperactivity on induction, laryngospasm, transient hypertension, nausea and emesis, diaphoresis, emergence delirium and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression).

Postoperative drowsiness is also frequently reported.

OVERDOSAGE ***Manifestations:*** The manifestations of INNOVAR injection overdosage are an extension of its pharmacologic actions.

Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered. A specific narcotic antagonist such as nalorphine, levallorphan or naloxone should be available for use as indicated to manage respiratory depression caused by the narcotic component fentanyl. This does not preclude the use of more immediate countermeasures. Consult the package inserts for the individual narcotic antagonists for details about use.

HOW SUPPLIED INNOVAR® injection is supplied in 2 cc. (**NDC** 0045-0280-20) and 5 cc. (**NDC** 0045-0280-50) ampuls, in packages of 10.

IMPORTANT: Complete dosage information is available in insert which accompanies each package (or on request). The drug is available only upon direction of a physician.

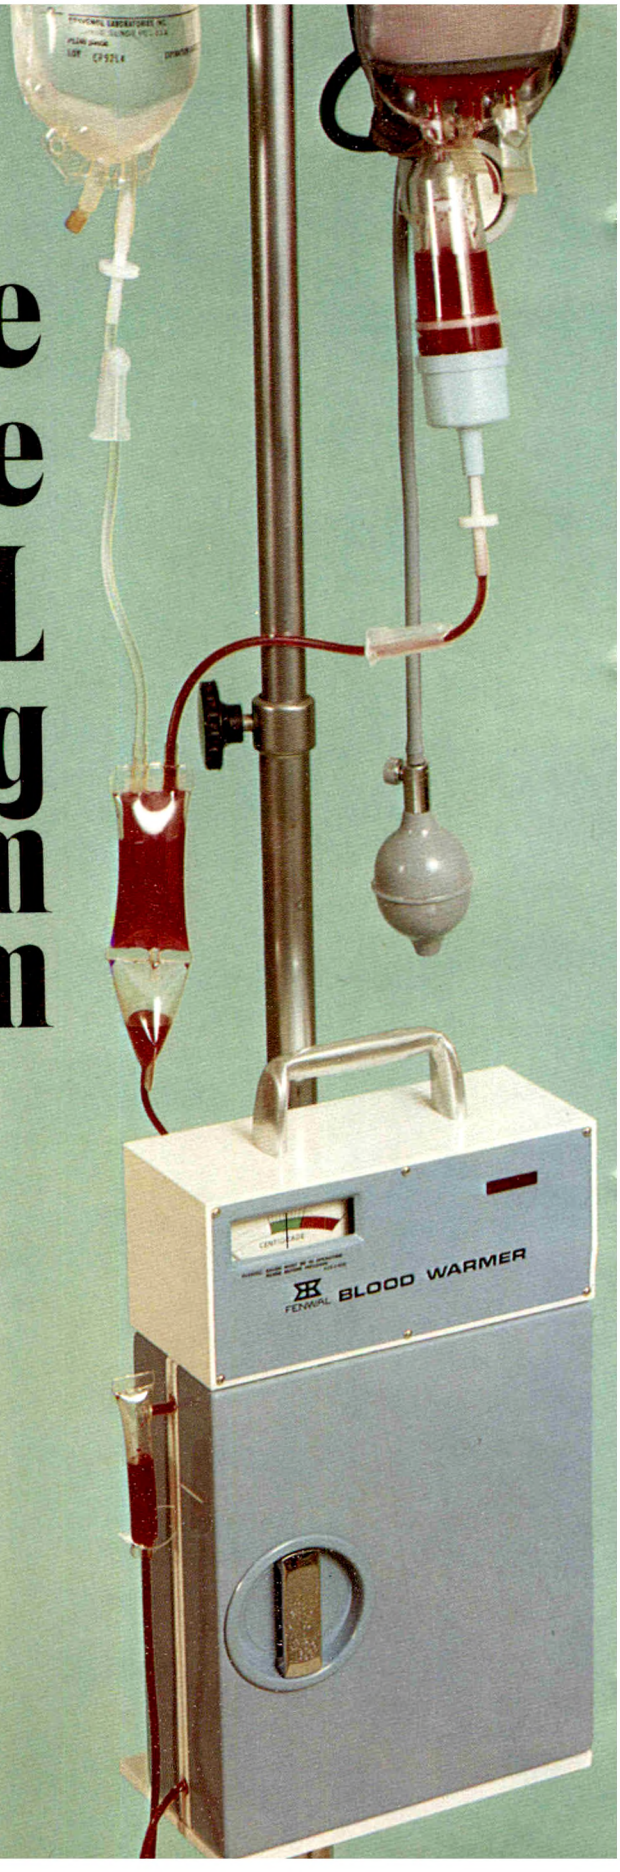
Our best
to your
surgical
patients

The complete FENWAL operating room system



The Fenwal Dry Heat Blood Warmer is designed for use during single or multiple transfusions when precise regulation of blood temperature and flow rate is indicated. It utilizes a disposable plastic blood-warming pathway.

Fenwal Recipient Sets are available to accommodate your infusion requirements. The Single Lead Set is to be used for the intravenous administration of one unit of whole blood, red cells or plasma. The "Y" Recipient Set is designed to permit dual hookups for simultaneous administration of blood and/or solutions. The Triple Lead Set may be employed in multiple infusion procedures, i.e., blood, solutions, blood components and medication.

The Fenwal Microaggregate Blood Filter is designed to remove microaggregates down to 20 microns in size during intravenous administration of stored whole blood or red cells.

Fenwal Pressure Infusors provide an efficient non-air-dependent method for the rapid infusion of whole blood or red cells.

The Fenwal TYPENEX™ Blood Recipient Identification System ties together the identity of the transfusion candidate, his cross-match request form, blood sample and up to 10 cross-matched units of blood.

The Fenwal Venous Pressure Manometer Set is a disposable, preassembled unit that permits continuous monitoring of the patient's venous pressure while performing one simple hookup.

The Fenwal Platelet Recipient Set is designed specifically for the infusion of fresh blood and pool platelet concentrates.

Our best to you

Fenwal Laboratories has long been identified with innovation in modern blood handling systems. Our knowledge and experience in developing and providing sophisticated blood processing systems have earned a reputation for excellence. Thoroughly researched and tested to meet the demands of the medical profession, you can expect the same quality in Fenwal operating room devices that helped achieve our recognition with the nation's blood banks.

The Fenwal Specialist in your hospital can provide you and the other members of the operating team with completely detailed information on all of our products. Intensive training makes him fully qualified to answer your most involved questions regarding up-to-date blood transfusion procedure. Be sure to see your Fenwal Specialist the next time he visits your department.

NARCOTIC ANESTHESIA

- Despite many advantages, the use of opioids to supplement nitrous oxide anesthesia may be associated with significant postoperative depression.

NARCAN® (naloxone HCl)

- Narcan® in sufficient doses will antagonize opioid effects, including all degrees of respiratory depression and analgesia.
- The degree of narcotic antagonism exhibited by NARCAN® is dose dependent.

A recent study of surgical patients receiving narcotic-nitrous oxide anesthesia was undertaken to determine whether careful titration of naloxone would reverse post-operative narcotic depression and maintain a subjective level of analgesia.[1]

THE OBJECTIVES:

- Restore consciousness
- Reverse narcotic-induced respiratory depression as evidenced by $PaCO_2$
- Maintain *subjective* analgesia

THE METHOD:

- 12 unpremedicated patients received INNOVAR® (fentanyl/droperidol) 5-10 ml I.V. followed by thiopental for induction. Anesthesia was maintained with N_2O-O_2. Increments of 0.1 mg *fentanyl* were given I.V. every 10 minutes during surgery.

Following the procedure, naloxone (0.1 mg/ml) was given in 0.1 mg I.V. increments at 1 minute intervals until the patient was awake, lucid and had adequate tidal and minute volumes. Additional naloxone

1. Heisterkamp DV, Cohen PJ: *Anesth Analg* (Cleve) 53:12-18, Jan-Feb 1974.

NARCAN® is an Endo registered U.S. trademark; U.S. Pat. 3,254,088.

was given I.V. as needed in the first 6 patients; a second group of 6 patients received supplemental naloxone I.M. 30 minutes after the initial I.V. dose.

- 11 patients received 10 mg *morphine* I.M., as well as secobarbital and atropine, 1½ hours preoperatively. Anesthesia was induced by 30 mg morphine given slowly I.V. followed by thiopental and was maintained by N_2O-O_2. Additional morphine was given in divided increments to total 1 mg/kg in the first hour. Further morphine was given as needed. For initial narcotic reversal, naloxone was given as above except at 2 minute intervals. Supplemental naloxone was given I.M. 30 minutes later.

THE RESULTS (fentanyl group):

- When fentanyl was used as the sole narcotic supplement during anesthesia, an I.M. dose of naloxone equal to half the I.V. reversal dose and given ½ hour later provided adequate narcotic reversal.

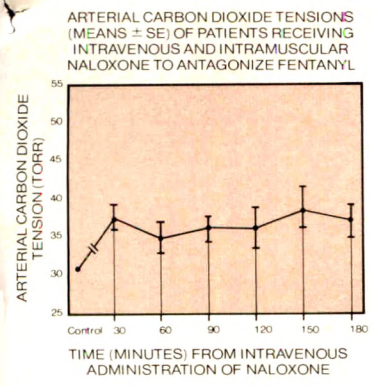

Fig. 1. Control and postoperative $PaCO_2$ in 6 patients receiving I.V. and I.M. naloxone following fentanyl.

THE RESULTS (morphine group):

- "After other narcotics, such as morphine, an I.M. dose of naloxone equal to the I.V. dose appears appropriate."

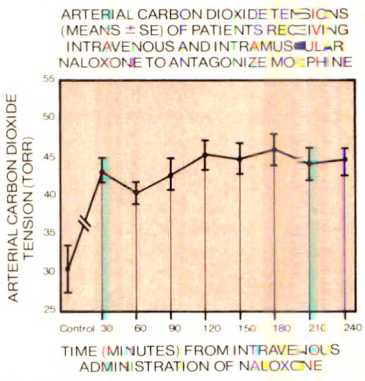

Fig. 2. Control and postoperative $PaCO_2$ in 11 patients receiving I.V. and I.M. naloxone following morphine.

THE CONCLUSIONS:

- "Naloxone provides fast, potent, and reliable antagonism to narcotic-induced respiratory depression."
- "By careful titration, this antagonism can be achieved while acceptable analgesia is maintained."
- "Both morphine and fentanyl groups had adequate analgesia, with only 2 patients [of total 21] requiring pain medication in the recovery room."

- **reverses all degrees of narcotic-induced respiratory depression**
- **does not cause narcotic-like effects**
- **does not augment non-narcotic depression**
- **acts rapidly—generally within 2 minutes following I.V. use and slightly less rapidly when given I.M.**
- **does not lead to tolerance**
- **does not produce psychotomimetic effects or pupillary constriction**
- **can be repeated if initial dose doesn't produce desired degree of narcotic reversal and improvement in respiratory function**
- **following satisfactory response patient should be observed closely and given repeat doses, if necessary, since the duration of action of some narcotics may exceed that of NARCAN®**

Please see next page for complete prescribing information.

DUPONT

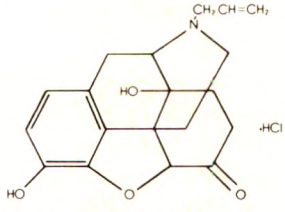
·restored consciousness
·reversed narcotic-induced respiratory depression
·maintained subjective analgesia

NARCAN®
(naloxone HCl)

can reverse narcotic-induced respiratory depression while maintaining subjective analgesia

NARCAN® (naloxone HCl)

DESCRIPTION NARCAN® (naloxone hydrochloride), a narcotic antagonist, is a synthetic congener of oxymorphone. In structure it differs from oxymorphone in that the methyl group on the nitrogen atom is replaced by an allyl group.



NALOXONE HYDROCHLORIDE
(N-allyl-nor-oxymorphone HCl)

Naloxone hydrochloride occurs as slightly off-white crystals, and is soluble in water, slightly soluble in alcohol and practically insoluble in ether.

NARCAN® (naloxone hydrochloride) Injection is available in two concentrations, 0.02 mg and 0.4 mg of naloxone hydrochloride per ml. Each ml of either strength contains 8.6 mg of sodium chloride; and 2.0 mg of methylparaben and propylparaben as preservatives in a ratio of 9 to 1. pH is adjusted with hydrochloric acid.

ACTIONS NARCAN® (naloxone hydrochloride) is an essentially pure narcotic antagonist, i.e., it does not possess the "agonistic" or morphine-like properties characteristic of other narcotic antagonists; NARCAN® (naloxone hydrochloride) does not produce respiratory depression, psychotomimetic effects or pupillary constriction. In the absence of narcotics or agonistic effects of other narcotic antagonists it exhibits essentially no pharmacologic activity.

In the presence of physical dependence on narcotics NARCAN® (naloxone hydrochloride) will produce withdrawal symptoms; it has not been shown to produce tolerance nor to cause physical or psychological dependence.

When NARCAN® (naloxone hydrochloride) is administered intravenously the onset of action is generally apparent within two minutes; the onset of action is only slightly less rapid when it is administered subcutaneously or intramuscularly. The duration of action is dependent upon the dose and route of administration of NARCAN® (naloxone hydrochloride). Intramuscular administration produces a more prolonged effect than intravenous administration. The requirement for repeat doses of NARCAN® (naloxone hydrochloride), however, will also be dependent upon the amount, type and route of administration of the narcotic being antagonized.

INDICATIONS NARCAN® (naloxone hydrochloride) is indicated for the complete or partial reversal of narcotic depression, including respiratory depression, induced by natural and synthetic narcotics, propoxyphene and the narcotic-antagonist analgesic pentazocine.
NARCAN® (naloxone hydrochloride) is also indicated for the diagnosis of suspected acute opiate overdosage.

CONTRAINDICATIONS NARCAN® (naloxone hydrochloride) is contraindicated in patients known to be hypersensitive to it.

WARNINGS NARCAN® (naloxone hydrochloride) should be administered cautiously to persons including newborns of mothers who are known or suspected to be physically dependent on opioids. In such cases an abrupt and complete reversal of narcotic effects may precipitate an acute abstinence syndrome.

The patient who has satisfactorily responded to NARCAN® (naloxone hydrochloride) should be kept under continued surveillance and repeated doses of NARCAN® (naloxone hydrochloride) should be administered, as necessary, since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydrochloride).

NARCAN® (naloxone hydrochloride) is not effective against respiratory depression due to non-opioid drugs.

Usage in Pregnancy Safe use of NARCAN® (naloxone hydrochloride) during pregnancy (other than labor) has not been established. Animal reproduction studies have not demonstrated teratogenic or other embryotoxic effects (See ANIMAL PHARMACOLOGY AND TOXICOLOGY). However, NARCAN® (naloxone hydrochloride) should be administered to pregnant patients only when, in the judgment of the physician, the potential benefits outweigh the possible hazards.

PRECAUTIONS In addition to NARCAN® (naloxone hydrochloride), other resuscitative measures such as maintenance of a free airway, artificial ventilation, cardiac massage, and vasopressor agents should be available and employed when necessary to counteract acute narcotic poisoning.

In an isolated report two patients with pre-existing ventricular irritability requiring lidocaine, and either isoproterenol or epinephrine for hypotension following cardiopulmonary bypass procedures, developed ventricular tachycardia or fibrillation when given NARCAN® (naloxone hydrochloride) I.V. at 9 and 14 hours, respectively, postoperatively for persistent unresponsiveness. Although a direct cause and effect relationship has not been established, NARCAN® (naloxone hydrochloride) should be used with caution in patients with cardiac irritability.

ADVERSE REACTIONS In rare instances nausea and vomiting have been reported in postoperative patients receiving NARCAN® (naloxone hydrochloride) in doses higher than that recommended; a cause and effect relationship has not been established.

DOSAGE AND ADMINISTRATION NARCAN® (naloxone hydrochloride) may be administered intravenously, intramuscularly, or subcutaneously. The most rapid onset of action is achieved by intravenous administration and it is recommended in emergency situations.

Since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydrochloride) the patient should be kept under continued surveillance and repeated doses of NARCAN® (naloxone hydrochloride) should be administered, as necessary.

USAGE IN ADULTS Narcotic Overdose—Known or Suspected The usual initial adult dose is 0.4 mg (1 ml) NARCAN® (naloxone hydrochloride) administered I.V., I.M. or S.C. If the desired degree of counteraction and improvement in respiratory function is not obtained immediately following I.V. administration, it may be repeated intravenously at 2 to 3 minute intervals. Failure to obtain significant improvement after 2 or 3 doses suggests that the condition may be due partly or completely to other disease processes or non-opioid drugs.

Post Operative Narcotic Depression For the partial reversal of narcotic depression following the use of narcotics during surgery, smaller doses of NARCAN® (naloxone hydrochloride) are usually sufficient. The dose of NARCAN® (naloxone hydrochloride) should be titrated according to the patient's response. Excessive dosage of NARCAN® (naloxone hydrochloride) may result in significant reversal of analgesia and increase in blood pressure. Similarly, too rapid reversal may induce nausea, vomiting, sweating or tachycardia.

For the initial reversal of respiratory depression, NARCAN® (naloxone hydrochloride) should be injected in increments of 0.1 to 0.2 mg intravenously at two to three minute intervals to the desired degree of reversal i.e., adequate ventilation and alertness without significant pain or discomfort.

Repeat doses of NARCAN® (naloxone hydrochloride) may be required within one to two hour intervals depending upon the amount, type (i.e., short or long acting) and time interval since last administration of narcotic. Supplemental intramuscular doses have been shown to produce a longer lasting effect.

USAGE IN CHILDREN Narcotic Overdose—Known or Suspected The usual initial child dose is 0.01 mg/kg body weight given I.V., I.M. or S.C. This dose may be repeated in accordance with the adult administration guideline. If necessary, NARCAN® (naloxone hydrochloride) can be diluted with sterile water for injection.

USAGE IN NEONATES Narcotic-induced depression The usual initial dose is 0.01 mg/kg body weight administered I.V., I.M. or S.C. This dose may be repeated in accordance with adult administration guidelines.

HOW SUPPLIED 0.4 mg/ml of NARCAN® (naloxone hydrochloride) for intravenous, intramuscular and subcutaneous administration.

Available in 1 ml ampuls in boxes of 10 and 100.

0.02 mg/ml of NARCAN® (naloxone hydrochloride) NEONATAL INJECTION for intravenous, intramuscular and subcutaneous administration.

Available in 2 ml ampuls in boxes of 10 and 100 ampuls.

ANIMAL PHARMACOLOGY AND TOXICOLOGY In the mouse and rat the intravenous LD_{50} is 150 ± 5 mg/kg and 109 ± 4 mg/kg respectively. In acute subcutaneous toxicity studies in newborn rats the LD_{50} (95% CL) is 260 (228-296) mg/kg. Subcutaneous injection of 100 mg/kg/day in rats for 3 weeks produced only transient salivation and partial ptosis following injections; no toxic effects were seen at 10 mg/kg/day for 3 weeks.

Reproductive studies including fertility, general reproductive performance, embryotoxicity, teratogenicity and lactation did not show any abnormality in mice and rats at 10 mg/kg/day.

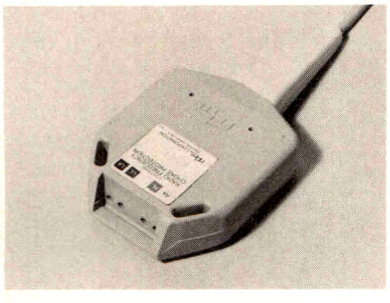
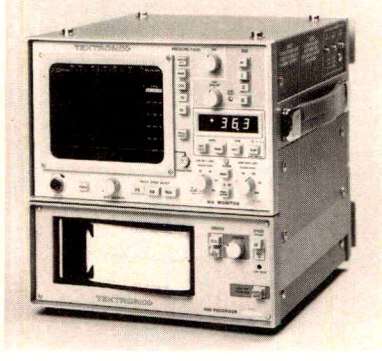
SOMETHING NEW

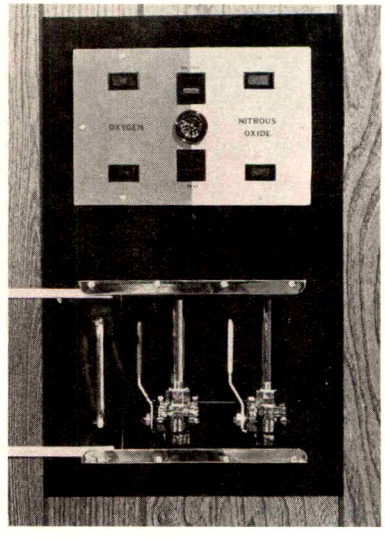


Protection against radio frequency burns at ECG electrode sites as a result of electrosurgery is provided by the RF Choke cable, which incorporates a radio frequency choke (inductor) in series with each monitoring lead. It is available from the NDM Hospital Supply, Dayton, Ohio. According to the manufacturer, the RF Choke cable will effectively block the passage of electrosurgical current through ECG leads, thereby reducing this radio frequency patient burn hazard. Cables are available to fit most of the ECG monitors currently in use in the United States.

★ ★ ★

Permanent hard copies of monitored patient data are available in a portable format with Tektronix' new 400-Series Recorders. These compact recorders attach directly to the company's portable patient monitors without a separate power cord or external interconnect wiring. The entire 18 lb. monitor-recorder package may be hand-carried and will operate on either AC line or the monitor's internal battery pack.

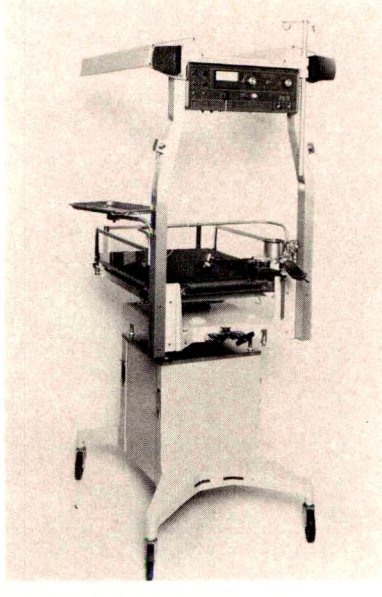




McKesson, Moncks Corner, South Carolina, introduces a Hi/Lo Warning System for conscious dental sedation systems. The system is spliced into the main oxygen and nitrous oxide piping lines and if in-line pressure drops or fails, or rises above normal operating ranges, an audible alarm is sounded and a visual warning mode illuminated. It responds to variations of about 20% above or below normal (50 to 55 psig) set points.

It is claimed that the McKesson Hi/Lo Warning System meets or surpasses all standards established by the National Fire Protection Association for N_2O and O_2 warning systems and zone valves.

★ ★ ★



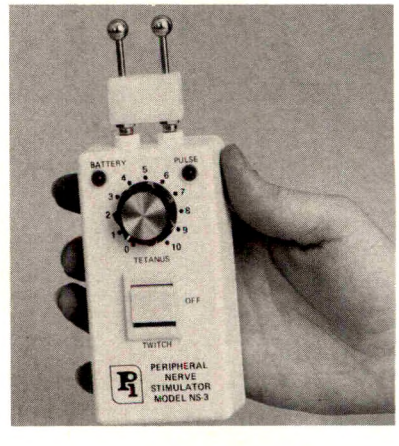
Ohio Medical Products, Madison, Wisconsin, has introduced an operating room model of their Neonatal Intensive Care Center designed to meet the specific needs of the surgeon and anesthetist. The new N.I.C.C. unit incorporates the essential life support systems and complete infant accessibility of the other OHIO units, while offering optimum surgical procedural capability.

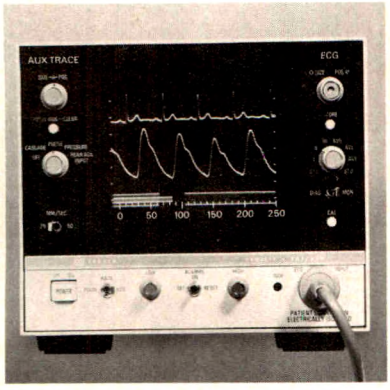
The N.I.C.C. control console, which incorporates the infant "Servo" temperature control module, indicator lights and necessary alarm signals, has been repositioned for observation by the anesthetist during the surgical procedure.

An adjustable anesthesia screen support is included that can be removed when not needed. The rear stainless steel bed rail has been replaced with a 2-inch wide, mattress height panel, for the convenience of the anesthetist.

★ ★ ★

Professional Instruments Company, Inc., Houston, Texas, have added the Model NS-3 to its line of Peripheral Nerve Stimulators. The NS-3 features monophasic square wave stimulus pulses of short duration and a low battery voltage indicator. The instrument may be used with ball-type electrodes, hypodermic needles or pregelled electrodes.



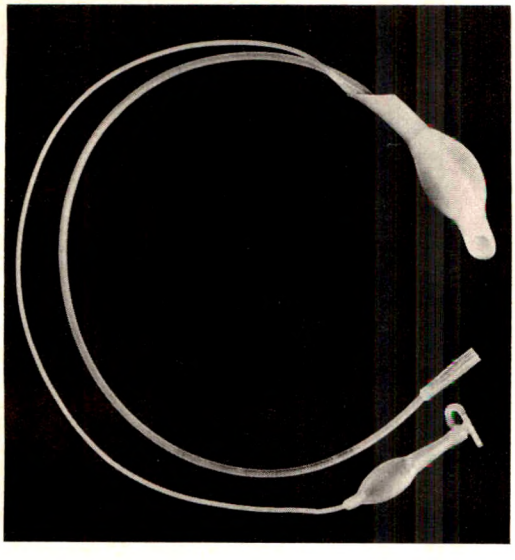


Multiparameter monitoring, including ECG, EEG, pulse and heart rate, is offered on a new Hewlett-Packard two-channel patient monitor. When used with external processing amplifiers, pressure and respiration also may be displayed simultaneously with the ECG tracing.

The HP 78332A monitor has bright, nonfade displays and operates in either fixed or moving-trace modes. Waveforms may be held on the screen for closer examination or the ECG display time may be doubled by continuing the upper channel information on the auxiliary channel. Useful in studying time/event relationships, the unit can superimpose ECG waveforms and auxiliary-channel information such as pulse pressure or respiration waveforms. Heart rate is indicated by a lighted bar graph.

The diagnostic or monitoring bandwidth is switch selectable to adjust fine detail in the display trace. Other simple-to-use controls alter size, position, intensity and sweep speed of the trace and allow calibration and selection of the heart-rate source. An optional beeper sounds when a preset alarm level has been reached or when an R wave is detected. Using pitch variation, the beeper also serves as an audible arrhythmia detection system.

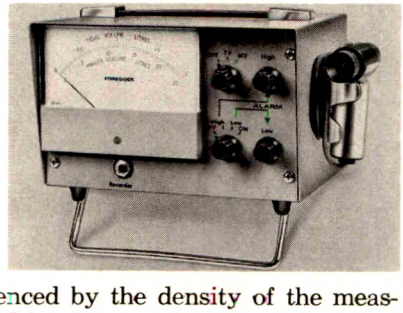
★ ★ ★



The Surgitek® Carden Laryngoscopy tube is now available with the exclusive Surgitek® Low trauma cuff from Medical Engineering Corporation, Racine, Wisconsin. It is claimed that these all silicone tubes are much less likely to cause necrosis than are tubes manufactured from PVC, Latex or red rubber. The Surgitek® tubes are reuseable and may be steam or gas sterilized.

★ ★ ★

The FOREGGER® 510 Electronic Spirometer, a low-cost, unidirectional spirometer that monitors continuous ventilation and measures intermandatory ventilation (IMV) has been introduced by Air Products and Chemicals, Inc., Allentown, Pennsylvania.



This unit provides an accurate means of measuring patient tidal and minute volume during continuous or intermittent ventilation. When placed in the expiratory side of a patient's breathing circuit, the FOREGGER spirometer's specially-designed, unidirectional sensor accurately reads the volumetric—instead of mass-flow rate of a gas. Resulting measured values are not influenced by the density of the measured gas or gas mixtures. Accuracy is claimed to be within plus or minus five percent of the indicated value.

INJECTION, equivalent to 10 mg metaraminol per ml

Aramine® (Metaraminol Bitartrate | MSD)

a vasopressor with positive inotropic effect

Indications: Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
Effective: ARAMINE is indicated for prevention and treatment of the acute hypotensive state occurring with spinal anesthesia. Adjunctive treatment of hypotension due to hemorrhage; reactions to medications; surgical complications; and shock associated with brain damage due to trauma or tumor.
"Probably" effective: It may also be useful as an adjunct in the treatment of hypotension due to cardiogenic shock or septicemia.
Final classification of the less-than-effective indications requires further investigation.

Contraindications: Use should be avoided with cyclopropane or halothane anesthesia, unless clinical circumstances demand such use.

Precautions: Use with caution to avoid excessive blood pressure response. Rapidly induced hypertensive responses have been reported to cause acute pulmonary edema, arrhythmias, and cardiac arrest. Use with caution in digitalized patients, since the combination of digitalis and sympathomimetic amines is capable of causing ectopic arrhythmic activity. Treat cirrhotic patients cautiously; if diuresis ensues, restore electrolytes. Fatal ventricular arrhythmia has been reported in one patient with Laennec's cirrhosis. In several instances, ventricular extrasystoles that appeared during infusion have subsided promptly on reduction of infusion rate. Since metaraminol has prolonged duration of action, a cumulative effect is possible, leading to prolonged elevation of blood pressure even with discontinuation of therapy. Monoamine oxidase inhibitors have been reported to potentiate action of sympathomimetic amines.
When vasopressor amines are used for long periods, resulting vasoconstriction may prevent adequate expansion of circulating volume and may cause perpetuation of the shock state. Plasma volume may be reduced in all types of shock, and measurement of central venous pressure is the most useful means of assessing the adequacy of the circulating blood volume; blood or plasma volume expanders should be employed for hypotension or shock due mainly to decreased circulating volume. Because of its vasoconstrictor effect, metaraminol should be used with caution in heart or thyroid disease, hypertension, or diabetes. Sympathomimetic amines may provoke relapse in patients with history of malaria.

Adverse Reactions: Sinus or ventricular tachycardia, or other arrhythmias, especially in patients with myocardial infarction. Abscess formation, tissue necrosis, or sloughing may rarely follow use. In choosing the site of injection, it is important to avoid those areas recognized as *not* suitable for use of any pressor agent, and to discontinue infusion immediately if infiltration or thrombosis occurs. The larger veins of the antecubital fossa or the thigh are preferred to veins in the dorsum of the hand or ankle veins, particularly in patients with peripheral vascular disease, diabetes mellitus, Buerger's disease, or conditions with coexistent hypercoagulability.

Note: Response to vasopressors may be poor in patients with coexistent shock and acidosis. Established methods of shock management, such as blood or fluid replacement when indicated, and other measures directed to the specific cause of the shock state also should be used. *Only Sodium Chloride Injection or 5 percent Dextrose Injection should be used as a diluent.*

How Supplied: Injection, in 1-ml ampuls and 10-ml vials, containing per ml: metaraminol bitartrate equivalent to 10.0 mg metaraminol; inactive ingredients: sodium chloride, 4.4 mg; water for injection, q.s. ad 1.0 ml; and 0.15% methylparaben, 0.02% propylparaben, and 0.2% sodium bisulfite added as preservatives.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

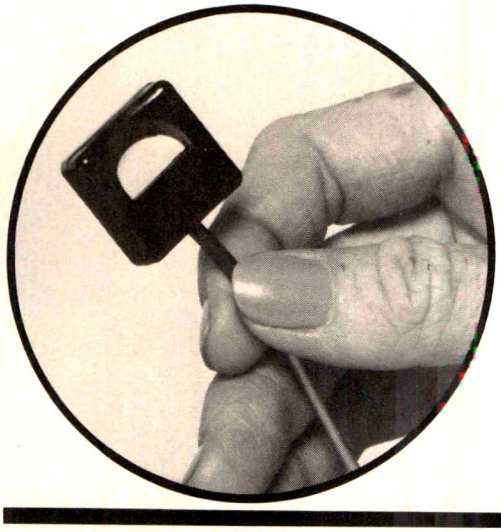
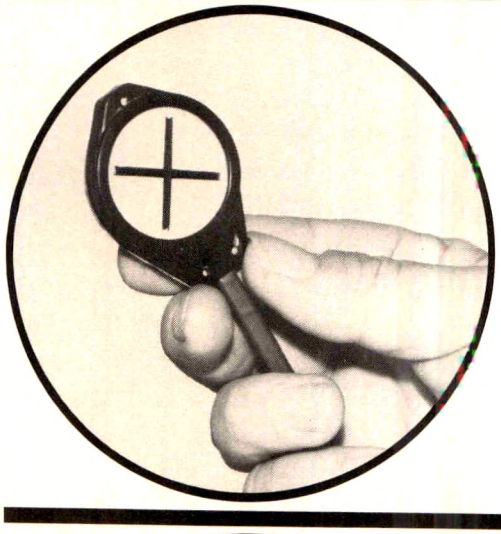
VERSATONE® MULTI-PURPOSE DOPPLER INSTRUMENT



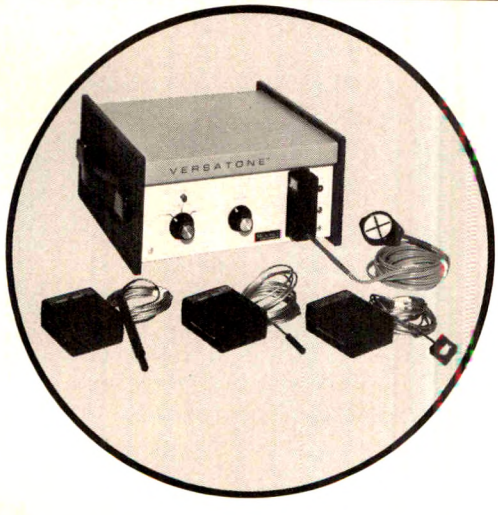
FOR MONITORING DOPPLER SOUNDS OF BLOOD FLOW AND TO TAKE DOPPLER SYSTOLIC BLOOD PRESSURE

This sensitive Doppler probe is easy to tape in position for non-invasive detection and monitoring of arterial blood flow during surgery. Used with an occlusive cuff and manometer, systolic blood pressures may be obtained even on infants and hypotensive patients.



FOR EARLY DETECTION OF VENOUS AIR EMBOLISM

This sensitive wide-angle Doppler probe is particularly well suited for the detection of venous air emboli which may occur during neurosurgical procedures performed with the patient in the upright position. It also detects motion of the heart muscle, heart valves and blood flow.



VERSATONE D8 DOPPLER

The Model D8 VERSATONE Doppler instrument is designed to use interchangeable probes of various frequencies and configurations. It is powered by a rechargeable battery and has a built-in loudspeaker. Options include an electrocautery sensor and cut-out, a molded earset for private listening, and a chart recording circuit. The two probes shown above are particularly useful to the anesthesiologist. Two sizes of pencil shaped probes are also available. These are useful for intraoperative assessment of flow in exposed vessels, as well as for transcutaneous flow detection.

PI Peripheral Nerve Stimulator

Monitors Muscle Relaxants

The PI Peripheral Nerve Stimulator monitors effects of skeletal muscle relaxants on the neuromuscular junction, detects abnormal response to muscle relaxants and distinguishes between depolarizing and non-depolarizing blockade.

Model NS-2

The NS-2 is now in use in many hospitals throughout the U. S. and abroad. It is designed primarily for use during surgery and delivers stimuli automatically at 5-second intervals. One or fifty pulses-per-second may be selected by momentary push-button switches. Output is a monophasic square wave pulse. Amplitude of the pulse is linearly adjustable. A flashing red light indicates low battery voltage. The NS-2 is solid state, rugged, battery powered, portable and lightweight.

Model NS-3

The NS-3 represents the latest in solid state technology. Use of integrated circuits has made it possible to build a very compact and versatile stimulator. Its miniature size makes the NS-3 more convenient for preoperative and postoperative testing. It delivers stimili at one second intervals when the rocker switch is depressed to the TWITCH position. A fifty-pulses-per-second rate may be selected by depressing the rocker switch to the momentary TETANUS position. Output is a monophasic square wave pulse. Amplitude of the pulse is linearly adjustable. The NS-3 also has a low-battery-voltage indicator.

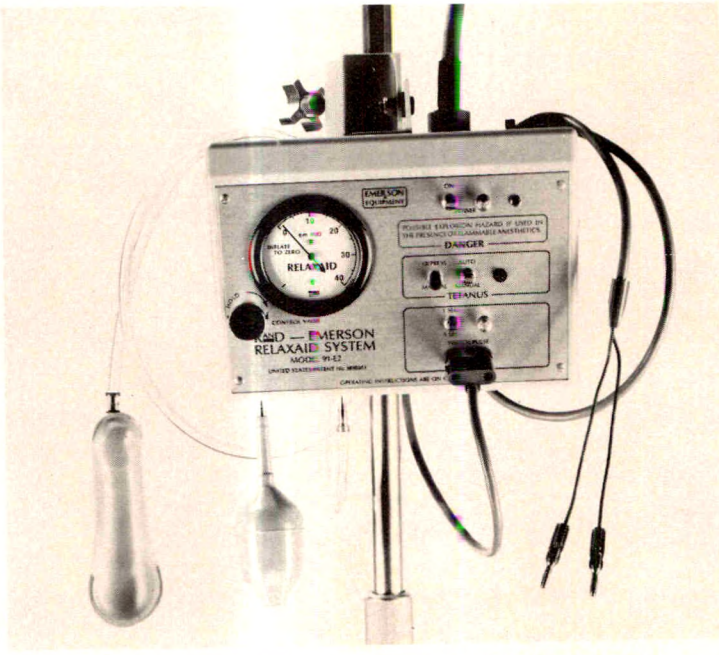
R AND D-EMERSON RELAXAID ™



for CORRECT RELAXANT DOSAGE—
AVOIDANCE OF OVERDOSE—
PROMPT RECOVERY—

The stimulator is programed to deliver pulses, through electrodes, to the ulnar nerve. A flexible pneumatic bulb is placed in the patient's hand, with his fingers held against it by tape. The bulb is then air-filled to a pressure of 20 cm. H_2O. As the fingers flex, even slightly, compression of the bulb is registered on an aneroid gauge. The pattern of these responses keeps the anesthetist informed of the relaxant's effectiveness.

The more precise monitoring provided by the RELAXAID™ enables relaxant levels to be kept adequate but without overdose. During recovery the RELAXAID™ shows the return of strength to the patient's muscles.

When to use the word Phär′mà·sēal.

For components, features, "performance" in single-use anesthesia trays, just say the word.

The trays you've counted on from the start now offer you even more to go on.

Back in 1963 we introduced the world's first single-use, regional anesthesia trays.

Today, with a record of safe performance difficult to equal, we offer you an even wider selection of components and features—just as difficult to match—in spinal, caudal and epidural trays.

All with our all-new spinal needle. The needle that's been called the cleanest spinal needle yet. The one with a cannula with almost uncanny smoothness, a cartridge pack with an exceptional point protector, a matched-ground point, metal hub and more.

Trays that offer you a new fenestrated drape with its own adhesive tabs.

A large, moisture-resistant hospital wrap with a new "wrinkle" for better procedure.

Plus, a specially designed introducer needle, a clear 5-cc. Stylex® syringe, a unique aseptic transfer carton...and a variety of other first-quality components and drugs.

But see for yourself what we're talking about. See the trays with performance you can count on. For samples, just call or write.

You know the word to use.

If You're Confused About O.R. Pollution, Cut It Out.

Get a compilation of data on the problems of trace anesthetic gas and OR pollution control. Send for our Positive Response Program.

Besides reports and studies to help you put the problem in perspective, our "PRP" plan of action provides an up-to-date look at our products which help you detect and scavenge trace gas in your OR. Key to our program is the Foregger 410 N_2O Trace Gas Monitor, a basic requirement for any efficient trace gas monitoring program. It's designed to provide rapid and continuous sampling of the OR air you breathe.

The machine has two sensing modes—Monitor (0-100 ppm) and Leak Test (0-1,000 ppm). The first mode continuously monitors the ambient air through the gas inlet of the machine. The second permits probing of local concentrations and sounds a repetitive burst alarm as the gas concentration increases.

In short, the Foregger 410 N_2O Trace Gas Monitor is a logical first step in solving your OR pollution problem. And there's more. The Scaveng-OR™ Gas Evacuator System, the Protect-OR™ Filter, Wall Suction Systems, and Air-CARE™ Preventive Maintenance Service.

Based on current data, it's likely that routine monitoring of pollution levels and scavenging of waste anesthetic gases will soon be standard Operating Room procedure. We're ready to help you now.

Fill out this ad coupon or ask our Representative for a Foregger PRP Folder. You'll get the problem in perspective and a plan of action to help correct it.

NARCOTIC ANESTHESIA

- Despite many advantages, the use of opioids to supplement nitrous oxide anesthesia may be associated with significant postoperative depression.

NARCAN® (naloxone HCl)

- Narcan® in sufficient doses will antagonize opioid effects, including all degrees of respiratory depression and analgesia.
- The degree of narcotic antagonism exhibited by NARCAN® is dose dependent.

A recent study of surgical patients receiving narcotic-nitrous oxide anesthesia was undertaken to determine whether careful titration of naloxone would reverse post-operative narcotic depression and maintain a subjective level of analgesia.[1]

THE OBJECTIVES:

- Restore consciousness
- Reverse narcotic-induced respiratory depression as evidenced by $PaCO_2$
- Maintain *subjective* analgesia

THE METHOD:

- 12 unpremedicated patients received INNOVAR® (fentanyl/droperidol) 5-10 ml I.V. followed by thiopental for induction. Anesthesia was maintained with N_2O-O_2. Increments of 0.1 mg *fentanyl* were given I.V. every 10 minutes during surgery.

Following the procedure, naloxone (0.1 mg/ml) was given in 0.1 mg I.V. increments at 1 minute intervals until the patient was awake, lucid and had adequate tidal and minute volumes. Additional naloxone

1. Heisterkamp DV, Cohen PJ: *Anesth Analg* (Cleve) 53:12-18, Jan-Feb 1974

NARCAN® is an Endo registered U.S. trademark; U.S. Pat. 3,254,088

was given I.V. as needed in the first 6 patients; a second group of 6 patients received supplemental naloxone I.M. 30 minutes after the initial I.V. dose.

- 11 patients received 10 mg *morphine* I.M., as well as secobarbital and atropine, 1½ hours preoperatively. Anesthesia was induced by 30 mg morphine given slowly I.V. followed by thiopental and was maintained by N_2O-O_2. Additional morphine was given in divided increments to total 1 mg/kg in the first hour. Further morphine was given as needed. For initial narcotic reversal, naloxone was given as above except at 2 minute intervals. Supplemental naloxone was given I.M. 30 minutes later.

THE RESULTS (fentanyl group):

- When fentanyl was used as the sole narcotic supplement during anesthesia, an I.M. dose of naloxone equal to half the I.V. reversal dose and given ½ hour later provided adequate narcotic reversal.

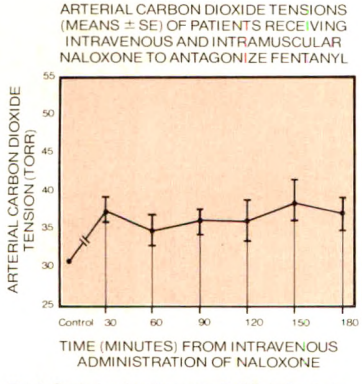

Fig. 1. Control and postoperative $PaCO_2$ in 6 patients receiving I.V. and I.M. naloxone following fentanyl.

THE RESULTS (morphine group):

- "After other narcotics, such as morphine, an I.M. dose of naloxone equal to the I.V. dose appears appropriate."

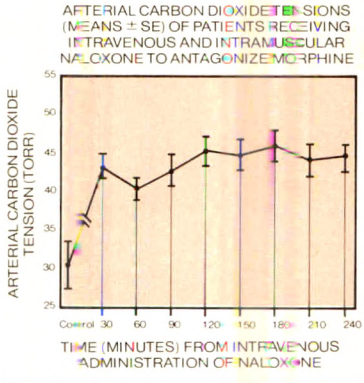

Fig. 2. Control and postoperative $PaCO_2$ in 6 patients receiving I.V. and I.M. naloxone following morphine.

THE CONCLUSIONS:

- "Naloxone provides fast, potent, and reliable antagonism to narcotic-induced respiratory depression."
- "By careful titration, this antagonism can be achieved while acceptable analgesia is maintained."
- "Both morphine and fentanyl groups had adequate analgesia, with only 2 patients [of total 21] requiring pain medication in the recovery room."

- **reverses all degrees of narcotic-induced respiratory depression**
- **does not cause narcotic-like effects**
- **does not augment non-narcotic depression**
- **acts rapidly—generally within 2 minutes following I.V. use and slightly less rapidly when given I.M.**
- **does not lead to tolerance**
- **does not produce psychotomimetic effects or pupillary constriction**
- **can be repeated if initial dose doesn't produce desired degree of narcotic reversal and improvement in respiratory function**
- **following satisfactory response patient should be observed closely and given repeat doses, if necessary, since the duration of action of some narcotics may exceed that of NARCAN®**

Please see next page for complete prescribing information.

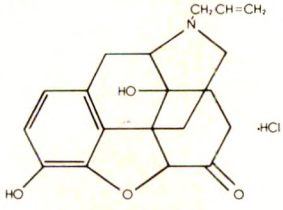
·restored consciousness
·reversed narcotic-induced respiratory depression
·maintained subjective analgesia

NARCAN®
(naloxone HCl)

can reverse narcotic-induced respiratory depression while maintaining subjective analgesia

NARCAN® (naloxone HCl)

DESCRIPTION NARCAN® (naloxone hydrochloride), a narcotic antagonist, is a synthetic congener of oxymorphone. In structure it differs from oxymorphone in that the methyl group on the nitrogen atom is replaced by an allyl group.



NALOXONE HYDROCHLORIDE
(N-allyl-nor-oxymorphone HCl)

Naloxone hydrochloride occurs as slightly off-white crystals, and is soluble in water, slightly soluble in alcohol and practically insoluble in ether.

NARCAN® (naloxone hydrochloride) Injection is available in two concentrations, 0.02 mg and 0.4 mg of naloxone hydrochloride per ml. Each ml of either strength contains 8.6 mg of sodium chloride; and 2.0 mg of methylparaben and propylparaben as preservatives in a ratio of 9 to 1. pH is adjusted with hydrochloric acid.

ACTIONS NARCAN® (naloxone hydrochloride) is an essentially pure narcotic antagonist, i.e., it does not possess the "agonistic" or morphine-like properties characteristic of other narcotic antagonists; NARCAN® (naloxone hydrochloride) does not produce respiratory depression, psychotomimetic effects or pupillary constriction. In the absence of narcotics or agonistic effects of other narcotic antagonists it exhibits essentially no pharmacologic activity.

In the presence of physical dependence on narcotics NARCAN® (naloxone hydrochloride) will produce withdrawal symptoms; it has not been shown to produce tolerance nor to cause physical or psychological dependence.

When NARCAN® (naloxone hydrochloride) is administered intravenously the onset of action is generally apparent within two minutes; the onset of action is only slightly less rapid when it is administered subcutaneously or intramuscularly. The duration of action is dependent upon the dose and route of administration of NARCAN® (naloxone hydrochloride). Intramuscular administration produces a more prolonged effect than intravenous administration. The requirement for repeat doses of NARCAN® (naloxone hydrochloride), however, will also be dependent upon the amount, type and route of administration of the narcotic being antagonized.

INDICATIONS NARCAN® (naloxone hydrochloride) is indicated for the complete or partial reversal of narcotic depression, including respiratory depression, induced by natural and synthetic narcotics, propoxyphene and the narcotic-antagonist analgesic pentazocine.
NARCAN® (naloxone hydrochloride) is also indicated for the diagnosis of suspected acute opiate overdosage.

CONTRAINDICATIONS NARCAN® (naloxone hydrochloride) is contraindicated in patients known to be hypersensitive to it.

WARNINGS NARCAN® (naloxone hydrochloride) should be administered cautiously to persons including newborns of mothers who are known or suspected to be physically dependent on opioids. In such cases an abrupt and complete reversal of narcotic effects may precipitate an acute abstinence syndrome.

The patient who has satisfactorily responded to NARCAN® (naloxone hydrochloride) should be kept under continued surveillance and repeated doses of NARCAN® (naloxone hydrochloride) should be administered, as necessary, since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydrochloride).

NARCAN® (naloxone hydrochloride) is not effective against respiratory depression due to non-opioid drugs.

Usage in Pregnancy Safe use of NARCAN® (naloxone hydrochloride) during pregnancy (other than labor) has not been established. Animal reproduction studies have not demonstrated teratogenic or other embryotoxic effects (See ANIMAL PHARMACOLOGY AND TOXICOLOGY). However, NARCAN® (naloxone hydrochloride) should be administered to pregnant patients only when, in the judgment of the physician, the potential benefits outweigh the possible hazards.

PRECAUTIONS In addition to NARCAN® (naloxone hydrochloride), other resuscitative measures such as maintenance of a free airway, artificial ventilation, cardiac massage, and vasopressor agents should be available and employed when necessary to counteract acute narcotic poisoning.

In an isolated report two patients with pre-existing ventricular irritability requiring lidocaine, and either isoproterenol or epinephrine for hypotension following cardiopulmonary bypass procedures, developed ventricular tachycardia or fibrillation when given NARCAN® (naloxone hydrochloride) I.V. at 9 and 14 hours, respectively, postoperatively for persistent unresponsiveness. Although a direct cause and effect relationship has not been established, NARCAN® (naloxone hydrochloride) should be used with caution in patients with cardiac irritability.

ADVERSE REACTIONS In rare instances nausea and vomiting have been reported in postoperative patients receiving NARCAN® (naloxone hydrochloride) in doses higher than that recommended; a cause and effect relationship has not been established.

DOSAGE AND ADMINISTRATION NARCAN® (naloxone hydrochloride) may be administered intravenously, intramuscularly, or subcutaneously. The most rapid onset of action is achieved by intravenous administration and it is recommended in emergency situations.

Since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydrochloride) the patient should be kept under continued surveillance and repeated doses of NARCAN® (naloxone hydrochloride) should be administered, as necessary.

USAGE IN ADULTS Narcotic Overdose—Known or Suspected The usual initial adult dose is 0.4 mg (1 ml) NARCAN® (naloxone hydrochloride) administered I.V., I.M. or S.C. If the desired degree of counteraction and improvement in respiratory function is not obtained immediately following I.V. administration, it may be repeated intravenously at 2 to 3 minute intervals. Failure to obtain significant improvement after 2 or 3 doses suggests that the condition may be due partly or completely to other disease processes or non-opioid drugs.

Post Operative Narcotic Depression For the partial reversal of narcotic depression following the use of narcotics during surgery, smaller doses of NARCAN® (naloxone hydrochloride) are usually sufficient. The dose of NARCAN® (naloxone hydrochloride) should be titrated according to the patient's response. Excessive dosage of NARCAN® (naloxone hydrochloride) may result in significant reversal of analgesia and increase in blood pressure. Similarly, too rapid reversal may induce nausea, vomiting, sweating or tachycardia.

For the initial reversal of respiratory depression, NARCAN® (naloxone hydrochloride) should be injected in increments of 0.1 to 0.2 mg intravenously at two to three minute intervals to the desired degree of reversal i.e., adequate ventilation and alertness without significant pain or discomfort.

Repeat doses of NARCAN® (naloxone hydrochloride) may be required within one to two hour intervals depending upon the amount, type (i.e., short or long acting) and time interval since last administration of narcotic. Supplemental intramuscular doses have been shown to produce a longer lasting effect.

USAGE IN CHILDREN Narcotic Overdose—Known or Suspected The usual initial child dose is 0.01 mg/kg body weight given I.V., I.M. or S.C. This dose may be repeated in accordance with the adult administration guideline. If necessary, NARCAN® (naloxone hydrochloride) can be diluted with sterile water for injection.

USAGE IN NEONATES Narcotic-induced depression The usual initial dose is 0.01 mg/kg body weight administered I.V., I.M. or S.C. This dose may be repeated in accordance with adult administration guidelines.

HOW SUPPLIED 0.4 mg/ml of NARCAN® (naloxone hydrochloride) for intravenous, intramuscular and subcutaneous administration.

Available in 1 ml ampuls in boxes of 10 and 100.

0.02 mg/ml of NARCAN® (naloxone hydrochloride) NEONATAL INJECTION for intravenous, intramuscular and subcutaneous administration.

Available in 2 ml ampuls in boxes of 10 and 100 ampuls.

ANIMAL PHARMACOLOGY AND TOXICOLOGY In the mouse and rat the intravenous LD_{50} is 150 ±5 mg/kg and 109 ±4 mg/kg respectively. In acute subcutaneous toxicity studies in newborn rats the LD_{50} (95% CL) is 260 (228-296) mg/kg. Subcutaneous injection of 100 mg/kg/day in rats for 3 weeks produced only transient salivation and partial ptosis following injections; no toxic effects were seen at 10 mg/kg/day for 3 weeks.

Reproductive studies including fertility, general reproductive performance, embryotoxicity, teratogenicity, and lactation did not show any abnormality in mice and rats at 10 mg/kg/day.

SEND FOR COMPLETE LITERATURE

THE UNPROTECTED EYE THAT WAS "PROTECTED" WITH TAPE.

After tape removal, corneal damage is not evident on gross inspection.

After fluorescein staining, the green band delineates area of epithelial injury.

Corneal abrasion...the most common ocular complication of general anesthesia.[1,2] "It is painful, may progress to inflammation of the uveal tract, and in the presence of contamination may lead to a serious infection."[1]

This patient's eyes were taped shut and monitored throughout a surgical procedure that lasted several hours. No ocular lubricant was used.[3] The cause of the corneal abrasion is unknown...but it might have been prevented if Lacri-Lube® sterile ophthalmic ointment had been used as an added precaution before the tape was applied.

Lacri-Lube. The first sterile, nonmedicated ophthalmic ointment designed solely to lubricate the eye and protect it against the risk of chemical insult, dehydration, or corneal abrasion.

Whether you tape or not, make Lacri-Lube a part of your standard procedures to minimize the risks of general anesthesia.

LACRI-LUBE®
sterile ophthalmic ointment

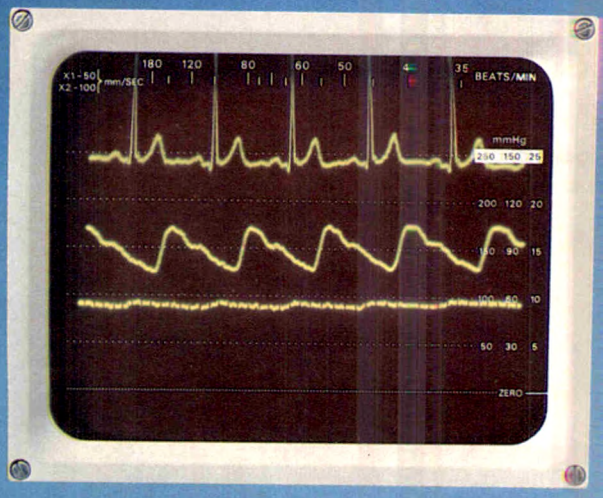
Only Tektronix gives you all three in a portable



ECG with One or Two Pressure Displays

Digital Readout of Vital Signs

Optional Recorder with Alphanumeric Printout

Tektronix' new 414 Single Pressure and 414FA Dual Pressure Monitors with hard copy recorder. Just compare for yourself: at $4200 and $4800 you won't find more capability in a portable instrument—and you won't find it in a more compact, easy-to-operate package. (Prices of the 414 and 414FA without recorders are only $2700 and $3200.)

Compare these features with any other monitor's:

- Two or three-trace crt display: ECG, arterial/venous, and the third trace arterial pressure channel
- Digital readout of heart rate, temperature, mean blood pressure, or alternating systolic/diastolic blood pressures
- Three selectable sweep speeds
- Heart rate and pulse pressure failure alarms
- Ac or battery operation
- Measures only 9.5 x 9.0 x 11.7 in. Weight: 18 lb.
- Recorder option providing single channel analog (printout) of ECG or pressure channels, plus alphanumeric printout of elapsed time, patient temperature, heart rate, systolic/diastolic and mean blood pressures

If you *really* compare, Tektronix Medical Products are

In a Class by Themselves

TEKTRONIX®
committed to technical excellence

Nesacaine®
(Chloroprocaine Hydrochloride)

1% and 2% solution in 30-ml. multiple-dose vials

For Infiltration and Regional Anesthesia

Nesacaine®-CE
(Chloroprocaine Hydrochloride)

2% and 3% solution in 30-ml. single-dose vials

For Caudal and Epidural Anesthesia

INDICATIONS

NESACAINE in multiple dose vials and NESACAINE-CE in single dose vials without preservatives are indicated for production of local anesthesia by infiltration injection and nerve block.*

*NESACAINE in multiple dose vials with preservatives is not to be used for caudal or epidural anesthesia. NESACAINE-CE contains no preservatives and the unused portion must be discarded after initial use.

CONTRAINDICATIONS

NESACAINE and NESACAINE-CE are contraindicated in patients hypersensitive to drugs of the PABA ester group. Central nervous system disease is generally considered a contraindication to caudal or epidural nerve block.

WARNINGS

RESUSCITATIVE EQUIPMENT AND DRUGS SHOULD BE IMMEDIATELY AVAILABLE WHEN ANY LOCAL ANESTHETIC IS USED. As NESACAINE-CE contains no preservative, discard unused drug remaining in vial after initial use. Equipment and drugs necessary for the treatment of inadvertent intravascular injection, intrathecal injection, or excessive dosage should be immediately available.

Usage in Pregnancy: Safe use of chloroprocaine hydrochloride has not been established with respect to adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential unless in the judgment of the physician the potential benefits outweigh the unknown hazards. In obstetrics, if vasoconstrictor drugs are used either to correct hypotension or are added to the local anesthetic solution, the obstetrician should be warned that some oxytocic drugs may cause severe persistent hypertension and even rupture of a cerebral blood vessel may occur during the post partum period.

Solutions containing vasoconstrictors, particularly epinephrine and norepinephrine, should be used with extreme caution in patients receiving certain antidepressants such as MAO inhibitors, and tricyclic compounds since a severe prolonged hypertension may occur.

PRECAUTIONS

The lowest dosage that results in effective anesthesia should be used to avoid high plasma levels and serious undesirable systemic side effects. Tolerance varies with the status of the patient. Debilitated patients, elderly patients, acutely ill patients, and children should be given reduced doses commensurate with their age and physical status.

Solutions containing vasoconstrictors should be used cautiously in the presence of disease which may adversely affect the patient's cardiovascular system.

Chloroprocaine hydrochloride should be employed cautiously in persons with known drug allergies or sensitivities.

The decision whether or not to use local anesthesia in the following conditions depends on the physician's appraisal of the advantages as opposed to the risk:

Paracervical block when fetal distress is anticipated or when predisposing factors causative of fetal distress are present (i.e., toxemia, prematurity, diabetes, etc.). Injection of solutions containing epinephrine in areas where the blood supply is limited (i.e., ears, nose, digits, etc.) or when peripheral vascular disease is present.

ADVERSE REACTIONS

Adverse reactions result from high plasma levels due to rapid absorption, inadvertent intravascular injection or excessive dosage. Hypersensitivity, idiosyncrasy, or diminished tolerance are other causes of reactions. Reactions due to overdosage (high plasma levels) are systemic and involve the central nervous system and the cardiovascular system.

Reactions involving the central nervous system are characterized by excitation and/or depression. Nervousness, dizziness, blurred vision or tremors may occur followed by drowsiness, convulsions, unconsciousness and possibly respiratory arrest. Since excitement may be transient or absent, the first manifestations may be drowsiness merging into unconsciousness and respiratory arrest.

Reactions involving the cardiovascular system include depression of the myocardium, hypotension, bradycardia and even cardiac arrest.

Treatment of a patient with toxic manifestations consists of maintaining an airway, and supporting ventilation using oxygen and assisted or controlled respiration as required. Supportive treatment of the cardiovascular system consists of using vasopressors, preferably those that stimulate the myocardium (e.g., ephedrine) and intravenous administration in small increments of an ultrashort acting barbiturate (i.e., thiopental, thiamylal) or a short acting barbiturate if these are not available (secobarbital, pentobarbital) or a short acting muscle relaxant (succinylcholine), together with oxygen. Muscle relaxants and intravenous barbiturates should be used only by those familiar with their use.

Allergic reactions are characterized by cutaneous lesions, urticaria, edema and other manifestations of allergy. The detection of sensitivity by skin testing is of doubtful value.

DOSAGE AND ADMINISTRATION

The maximum single recommended doses of chloroprocaine hydrochloride are: without epinephrine, 800 mg.; with epinephrine (1:200,000), 1000 mg. The recommended dosage is based on requirements for the average adult and should be reduced for elderly or debilitated patients and children.

The recommended doses given below serve only as a guide to the amount of anesthetic required for most routine procedures.

1. INFILTRATION AND NERVE BLOCK (NESACAINE)

Type of Block	Volume	Concentration
Occipital	3-5 ml.	1%-2%
Mandibular	2-3 ml.	2%
Maxillary	2-3 ml.	2%
Infra-orbital	0.5-1 ml.	2%
Cervical	3-4 ml. (for each segment)	1%-2%
Brachial plexus	30-40 ml.	2%
Ulnar nerve	3-5 ml.	2%
Paravertebral	3-5 ml.	2%
Intercostal	3 ml.	1%-2%
Sciatic nerve	10-15 ml.	2%
Stellate ganglion	5-10 ml.	1%-2%
Lumbar sympathetic (1 needle technic)	15-20 ml.	1%-2%
Interdigital	3-4 ml. (without epinephrine)	1%-2%

Fractional doses, up to 300 to 600 mg., may be given at 50 minute intervals.

2. CAUDAL AND EPIDURAL BLOCK (NESACAINE-CE)

For *caudal anesthesia* the initial dose is 15 to 25 ml. of a 2% or 3% solution. Repeated doses may be given at 40 to 60 minute intervals.

For *epidural anesthesia* in the lumbar and sacral regions 2.0 to 2.5 ml. per segment of a 2% or 3% solution can be used. The usual total volume of Nesacaine-CE is from 15 to 25 ml. Repeated doses 2 to 6 ml. less than the original dose may be given at 40 to 50 minute intervals.

HOW SUPPLIED

Nesacaine is supplied as follows:

1% solution (10 mg/ml.) in 30 ml. multiple-dose vials, 12 vials per carton.

2% solution (20 mg/ml.) in 30 ml. multiple-dose vials, 12 vials per carton.

Nesacaine-CE is supplied as follows:

2% solution (20 mg/ml.) in 30 ml. single-dose vials, 12 vials per carton.

3% solution (30 mg/ml.) in 30 ml. single-dose vials, 12 vials per carton.

PENNWALT

A local anesthetic should meet your needs...

Rapid Onset of Action. Saves doctor, nurse and patient time.

Effective Anesthesia. Nesacaine (Chloroprocaine Hydrochloride) offers 80% to 90% pain-free procedures at recommended doses.

Exceptional Safety. Less potential for postoperative complications. Nesacaine is rapidly hydrolized in plasma, whereas lidocaine and other amide-type local anesthetics are metabolized in the liver. With Nesacaine, therefore, there is minimal potential risk of systemic toxicity, accumulation of metabolites, stimulation of CNS or cardiovascular effects.

Excellent Penetration. Chloroprocaine's lipid solubility and ionization characteristics impart it with excellent penetration.

Minimal Irritation at Injection Site. Few patient complaints about procedural pain, little soreness and inflammation after procedure.

Rapid and Complete Wear-Off. No residual numbness, patient back to normal faster.

See opposite page for brief prescribing information.

(Chloroprocaine Hydrochloride)

It meets your needs.

Documented Compatibility
with Epinephrine
Ethra

Unlike some anesthetic agents, ETHRANE® (enflurane) does not significantly increase myocardial sensitivity to exogenous epinephrine.*[1-4] Thus ETHRANE allows an adequate margin of safety during anesthesia when epinephrine is used under the conditions prescribed for local hemostasis—with or without concomitant use of lidocaine.*[1-4] Of course, all customary precautions in the use of vasoconstrictor substances should be observed.

Similarly, reported data has also supported the use of ETHRANE anesthesia in the resection of a pheochromocytoma without significant increase in myocardial sensitivity to endogenous catecholamines.[5-7]

ETHRANE anesthesia also ensures: fast induction, quick recovery, maintenance of cardiac rhythm, excellent muscle relaxation, and few aftereffects.[8]

These advantages of ETHRANE—plus its compatibility with subcutaneously administered epinephrine—demonstrate its versatility in concept and performance.

WARNING: Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia. For additional warnings, contraindications, and precautions, see following page.

AIRCO®

Ethrane® (enflurane)

CAUTION: Federal Law Prohibits Dispensing without Prescription

DESCRIPTION

ETHRANE (enflurane) is a nonflammable anesthetic agent. It is 2-chloro-1,1,2-trifluoroethyl difluoromethyl ether, and its structural formula is:

Some physical constants of the compound are:

Molecular weight		184.5
Boiling point 760 mm Hg.		56.5°C
Refractive index n_D^{20}		1.3026-1.3030
Specific gravity 25°/25°C		1.517
Vapor pressure in mm Hg.**	20°C	174.5
	25°C	217.7
	36°C	345.2

**Equation for calculation of enflurane vapor pressures:

$\log_{10} P = A + \frac{B}{T}$

A = 7.967
B = −1678.4
T = °C + 273.16 (Kelvin)

Partition coefficients @ 37°C	
Water-gas	0.82
Blood-gas	1.91
Oil-gas	98.5
Partition coefficients @ 25°C-rubber and plastic	
Conductive rubber	74.0
Butyl rubber	90.0
Polyvinylchloride	120.0
Polyethylene	∼2.0
Polyurethane	∼1.5
Polyolefin	∼1.2
Butyl acetate	∼3.0
Solubility of enflurane in H_2O at 22°C	0.275%
Solubility of H_2O in enflurane	0.13%
Purity by gas chromatography	>99.9%
Flammability in air	None
Flammability in oxygen (Entire concentration range to saturation at 71 and 113°F and 743 mm Hg. pressure.)	None
M.A.C. (Minimum alveolar concentration)	
Man with pure oxygen	1.68
Man with 70% nitrous oxide	0.56 (est.)

ETHRANE is a clear, colorless, stable liquid without added chemical stabilizers. ETHRANE has a mild, sweet odor. Storage of samples in indirect sunlight in clear, colorless glass for a five year period, as well as direct exposure for 30 hours to a 2 amp, 115 V., 60 cycle long wave U.V. light, produced no changes in composition detectable by gas chromatography. ETHRANE in one normal sodium methoxide-methanol solution, a strong base, for over six months consumed none of the alkali, indicative of strong base stability. ETHRANE does not decompose in contact with soda lime. ETHRANE does not attack aluminum, tin, brass, iron or copper.

ACTIONS

ETHRANE (enflurane) is an inhalation anesthetic. Induction and recovery from anesthesia with ETHRANE are rapid. ETHRANE does not appear to stimulate excess salivation or tracheobronchial secretions, or affect bronchomotor tone. Pharyngeal and laryngeal reflexes are readily obtunded. The level of anesthesia changes rapidly with ETHRANE. ETHRANE reduces ventilation as depth of anesthesia increases. ETHRANE provokes a sigh response reminiscent of that seen with diethyl ether.

There is a decrease in blood pressure with induction of anesthesia, followed by a return to near normal with surgical stimulation. Progressive increases in depth of anesthesia produce corresponding increases in hypotension. Heart rate remains relatively constant without significant bradycardia. Electrocardiographic monitoring or recordings indicate that cardiac rhythm remains stable. Elevation of the carbon dioxide level in arterial blood does not alter cardiac rhythm.

While ETHRANE has been shown to sensitize the myocardial conduction system to epinephrine in the dog and may produce serious arrhythmias, studies in cats and man indicate considerable margin of safety in the administration of epinephrine containing solutions during ETHRANE anesthesia. ETHRANE anesthesia has been used in medical conditions involving high levels of endogenous catecholamines, as well as surgical procedures involving carefully administered quantities of epinephrine containing solutions. On the basis of this experience, up to 10 ml. of 1:100,000 or 1:200,000 epinephrine containing solution alone or in conjunction with local anesthetics may be injected subcutaneously at a rate of not more than 10 ml. per minute and no more than 30 ml. per hour. More dilute solutions and reduced dosages should be used in highly vascular areas. All customary precautions in the use of vasoconstrictor substances should be observed.

Muscle relaxation is adequate for intra-abdominal operation at normal levels of anesthesia. Should greater relaxation be necessary, minimal doses of muscle relaxants may be used. All commonly used muscle relaxants are compatible with ETHRANE. **THE NONDEPOLARIZING MUSCLE RELAXANTS ARE MARKEDLY POTENTIATED.** Neostigmine does not reverse the direct effect of ETHRANE.

Biotransformation of ETHRANE in man results in low levels of serum fluoride ions averaging 15 mM/L. These levels are well below the 50 mM/L seen to produce renal damage in normal subjects; however, it is possible that these levels could result in damage in patients with severely impaired renal function or those undergoing renal transplantation.

INDICATIONS

ETHRANE (enflurane) may be used for induction and maintenance of general anesthesia. Adequate data have not been developed to establish its application in obstetrical anesthesia.

CONTRAINDICATIONS

Seizure disorders (see WARNINGS).

Known sensitivity to ETHRANE (enflurane) or other halogenated anesthetics.

WARNINGS

Increasing depth of anesthesia with ETHRANE (enflurane) produces a change in the electroencephalogram characterized by high voltage, fast frequency, progressing through spike-dome complexes alternating with periods of electrical silence to frank seizure activity. The latter may or may not be associated with motor movement. Motor activity, when encountered, generally consists of twitching or "jerks" of various muscle groups; it is self-limiting and can be terminated by lowering the anesthetic concentration. This electroencephalographic pattern associated with deep anesthesia is exacerbated by hyperventilation producing low arterial carbon dioxide tension. The pattern serves as a warning that depth of anesthesia is excessive. Cerebral blood flow and metabolism studies in normal volunteers during seizure patterns show no evidence of cerebral hypoxia, and recovery appears to be uncomplicated.

Since levels of anesthesia may be altered easily and rapidly, only calibrated vaporizers which measure output with reasonable accuracy should be used. Hypotension and respiratory exchange can serve as a guide to anesthesia depth. With deep levels of anesthesia, more marked hypotension and respiratory depression are encountered.

The action of nondepolarizing relaxants is augmented by ETHRANE. Less than the usual amounts of these drugs should be used. The time for recovery from the myoneural effect of these relaxants is greater in the presence of ETHRANE than for other commonly used anesthetics.

Usage in Pregnancy: Safety in pregnancy has not been established. Reproduction studies have been performed in rats and rabbits, and there is no evidence of harm to the animal fetus. The relevance of these studies to the human is not known. Since there is no adequate experience in pregnant women who have received the drug, safety in pregnancy has not been established.

PRECAUTIONS

Bromsulfalein (BSP) retention is mildly elevated postoperatively in some cases. There is some elevation of glucose and white blood count intraoperatively. Glucose elevation should be considered in diabetic patients. ETHRANE (enflurane) should be used with caution in patients who by virtue of medical or drug history could be considered more susceptible to cortical stimulation produced by this drug. As with other general anesthetics and some muscle relaxants, hyperpyrexia has been observed with the use of ETHRANE.

ADVERSE REACTIONS

1. Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia.
2. Hypotension and respiratory depression have been reported.
3. Arrhythmias, shivering, nausea, and vomiting have been reported.
4. Elevation of the white blood count has been observed. It has not been determined whether this is related to ETHRANE or to surgical stress.

DOSAGE AND ADMINISTRATION

The concentration of ETHRANE (enflurane) being delivered during anesthesia from a vaporizer should be known. This may be accomplished by using:

a) vaporizers calibrated specifically for ETHRANE;
b) vaporizers from which delivered flows can easily and readily be calculated.

Maintenance concentration should not exceed 3%. Premedication should be selected according to the need of the individual patient, taking into account that secretions are weakly stimulated by ETHRANE and the heart rate remains constant. The use of anticholinergic drugs is a matter of choice.

Induction: Induction may be achieved using ETHRANE alone with oxygen or in combination with oxygen-nitrous oxide mixtures. Under these conditions some excitement may be encountered. If excitement is to be avoided, a hypnotic dose of a short-acting barbiturate should be used to induce unconsciousness, followed by the ETHRANE mixture. In general, inspired concentrations of 3.5-4.5% ETHRANE produce surgical anesthesia in 7-10 minutes.

Maintenance: Surgical levels of anesthesia may be attained with 1.5-3.0% concentration. If added relaxation is required, supplemental doses of muscle relaxants may be used. Ventilation to maintain the tension of carbon dioxide in arterial blood in the 35-45 mm range is preferred to hyper- or hypoventilation in order to minimize possible CNS excitation.

The level of blood pressure during maintenance is an inverse function of ETHRANE concentration in the absence of other complicating problems. Excessive decreases (unless related to hypovolemia) may be due to depth of anesthesia and in such instances should be corrected by lightening the level of anesthesia.

Overdosage: In the event of overdosage, or what may appear to be overdosage, the following action should be taken:

Stop drug administration; establish that the airway is clear and initiate assisted or controlled ventilation with pure oxygen as circumstances dictate.

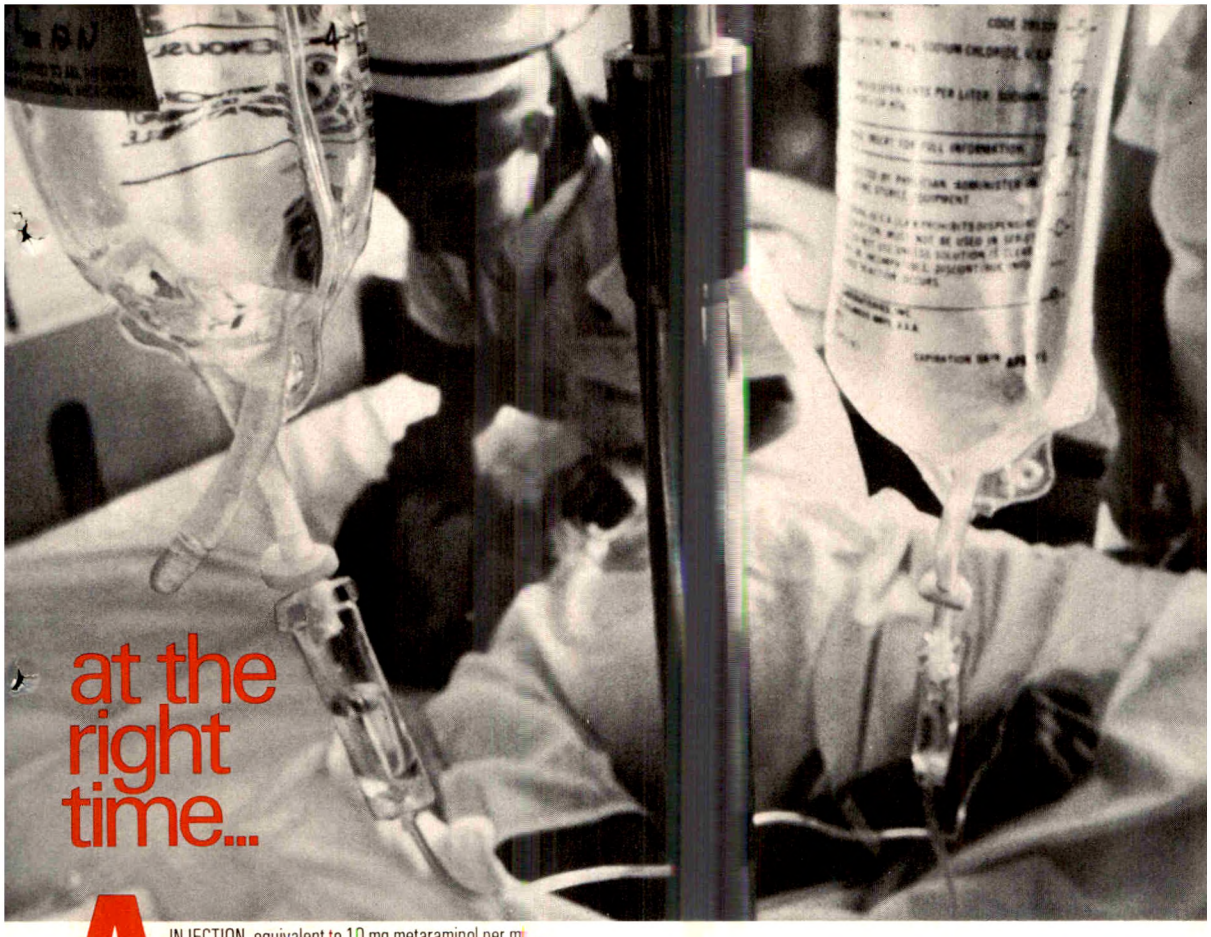
ADMINISTRATION EQUIPMENT

ETHRANE (enflurane) may be administered from a flow-through type vaporizer manufactured and specifically calibrated for ETHRANE. Vaporizers which deliver saturated vapor at reasonable flows but are not specifically calibrated for ETHRANE may be used. A reasonably accurate estimation of delivered ETHRANE concentration may be made by use of the nomograph on the reverse side.

ETHRANE contains no stabilizer. Nothing is present in the agent to alter calibration or affect the operation characteristics of the vaporizer.

PACKAGING

ETHRANE (enflurane) is packaged in 125 and 250 ml. amber bottles. No additives or stabilizers are present.



INJECTION, equivalent to 10 mg metaraminol per ml

Aramine® (Metaraminol Bitartrate | MSD)

a vasopressor with positive inotropic effect

Indications: Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
Effective: ARAMINE is indicated for prevention and treatment of the acute hypotensive state occurring with spinal anesthesia. Adjunctive treatment of hypotension due to hemorrhage; reactions to medications; surgical complications; and shock associated with brain damage due to trauma or tumor.
"Probably" effective: It may also be useful as an adjunct in the treatment of hypotension due to cardiogenic shock or septicemia.
Final classification of the less-than-effective indications requires further investigation.

Contraindications: Use should be avoided with cyclopropane or halothane anesthesia, unless clinical circumstances demand such use.

Precautions: Use with caution to avoid excessive blood pressure response. Rapidly induced hypertensive responses have been reported to cause acute pulmonary edema, arrhythmias, and cardiac arrest. Use with caution in digitalized patients, since the combination of digitalis and sympathomimetic amines is capable of causing ectopic arrhythmic activity. Treat cirrhotic patients cautiously; if diuresis ensues, restore electrolytes. Fatal ventricular arrhythmia has been reported in one patient with Laennec's cirrhosis. In several instances, ventricular extrasystoles that appeared during infusion have subsided promptly on reduction of infusion rate. Since metaraminol has prolonged duration of action, a cumulative effect is possible, leading to prolonged elevation of blood pressure even with discontinuation of therapy. Monoamine oxidase inhibitors have been reported to potentiate action of sympathomimetic amines.
When vasopressor amines are used for long periods resulting volume and may cause perpetuation of the shock state. Plasma volume may be reduced in all types of shock, and measurement of central venous pressure is the most useful means of assessing the adequacy of the circulating blood volume; blood or plasma volume expanders should be employed for hypotension or shock due mainly to decreased circulating volume. Because of its vasoconstrictor effect, metaraminol should be used with caution in heart or thyroid disease, hypertension, or diabetes. Sympathomimetic amines may provoke relapse in patients with history of malaria.

Adverse Reactions: Sinus or ventricular tachycardia, or other arrhythmias, especially in patients with myocardial infarction. Abscess formation, tissue necrosis, or sloughing may rarely follow use. In choosing the site of injection, it is important to avoid those areas recognized as *not* suitable for use of any pressor agent, and to discontinue infusion immediately if infiltration or thrombosis occurs. The larger veins of the antecubital fossa or the thigh are preferred to veins in the dorsum of the hand or ankle veins, particularly in patients with peripheral vascular disease, diabetes mellitus, Buerger's disease, or conditions with coexistent hypercoagulability.

Note: Response to vasopressors may be poor in patients with coexistent shock and acidosis. Established methods of shock management, such as blood or fluid replacement when indicated, and other measures directed to the specific cause of the shock state also should be used. *Only Sodium Chloride Injection or 5 percent Dextrose Injection should be used as a diluent.*

How Supplied: Injection, in 1-ml ampuls and 10-ml vials, containing per ml: metaraminol bitartrate equivalent to 10.0 mg metaraminol; inactive ingredients: sodium chloride, 4.4 mg; water for injection, q.s. ad 1.0 ml; and 0.15% methylparaben, 0.02% propylparaben and 0.2% sodium bisulfite added as preservatives.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division

MSD
MERCK SHARP&

The local that gives you the longest anesthesia gives your patient longer postoperative analgesia.

Marcaine® hydrochloride (brand of bupivacaine hydrochloride)—available with or without epinephrine—is the local anesthetic that provides the longest duration of action among commonly used local anesthetics. Which minimizes the problems of "continuous" technique or repeat doses.

Marcaine also provides longer postoperative analgesia. Which reduces the need for postoperative narcotics.

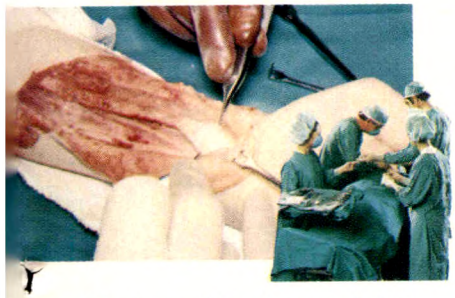
And in data in over 3,000 patients, Marcaine was reported to have excellent or satisfactory results in more than 96% of cases.

Extended anesthesia for the surgeon

In regional blocks, Marcaine, with or without epinephrine, usually provides anesthesia at least 1½ to 2 times longer than lidocaine or mepivacaine. And approximately 20% longer than tetracaine.

In fact, anesthesia may extend up to 9 hours for peridural block and up to 12 hours for peripheral nerve block. This has been established in several thousand surgical and obstetrical patients.[1-4]

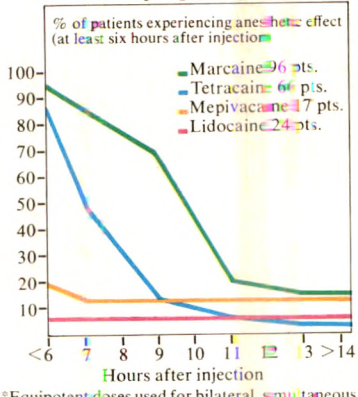
In fact, a single Marcaine epidural injection, with or without epinephrine, may be enough for up to 3½[4] or more[5] hours of anesthesia for surgery, and often provides analgesia that carries over into the recovery room and beyond. When necessary, doses may be repeated up to once every three hours. Caution is advised in administration of repeat doses to patients with severe liver disease. Until further experience is gained, total daily dose of



400 mg. should not be exceeded nor is administration to children under 12 recommended. Also see epinephrine warnings and precautions statements on next page.

This longer anesthetic action can minimize problems of "continuous" technique or repeat doses. Thus, there is the further advantage of a reduced likelihood of introducing infection since injections are less frequent.[6]

Chart I
Duration of anesthesia
Percentage of patients experiencing anesthetic effect–
Comparison of Marcaine with epinephrine and other local anesthetic/epinephrine preparations*



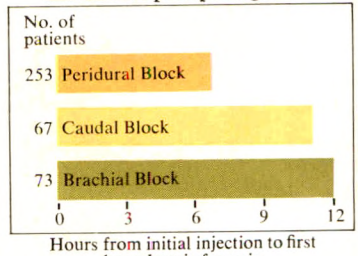
*Equipotent doses used for bilateral, simultaneous blocks of sciatic/femoral, intercostal, or brachial/axillary nerves. Adapted from Moore, D. C.: Data in the files of the Sterling-Winthrop Research Institute.

Extended postoperative analgesia for the patient

Marcaine, with or without epinephrine, gives your patient more—considerably more—postanesthetic analgesia than other local anesthetics in various types of nerve block.[3,4,7,8] An analgesia that persists after the return of motor function and even cutaneous sensation.[7] As a result, you may be able to defer[1,5] and sometimes even eliminate,[5] postoperative narcotics. Chart II illustrates the average duration of time between the initial Marcaine injection and the need for postop analgesics. Many of the 67 patients given Marcaine with or without epinephrine, caudally for rectal surgery did not complain of pain for 11 hours or longer following induction.

In another group of 40 patients[8] given Marcaine or mepivacaine, both with epinephrine, locally for tonsillectomy, Marcaine pain relief lasted 3 to 5 times longer than that provided by mepivacaine. And in a study[1] of 65 patients given 0.5% Marcaine with epinephrine caudally for rectal or other perineal surgery, complete sensation returned in a mean of 8½ hours for the average patient. And the majority of these patients did not require a narcotic for an additional 1 to 3 hours.

Chart II
Duration of time between injection of Marcaine, with or without epinephrine, and need for postop analgesics†



†Average—exclusion of extremes and failures. Adapted from Lund, P.C., *et al.*: *Anesth. Analg.* 49:103, Jan.-Feb. 1970.

Excellent clinical acceptance

Marcaine, with or without epinephrine, was administered to 3,112 patients for various types of local anesthesia.[9] Of these patients, only 2 experienced a systemic reaction. Although Marcaine has a very wide safety margin, adverse reactions characteristic of those associated with other amide local anesthetics may occur.

Marcaine is indicated for most anesthetic blocks; however, until further clinical experience is gained paracervical block is not recommended.

See important product information concerning warnings, adverse reactions, patient selection, and prescribing and precautionary recommendations on next page.

Extends the limits of time in anesthesia[1-4]
Extends the limits of time in postoperative analgesia[3,4,7,8]

Marcaine® hydrochloride

Brand of
bupivacaine hydrochloride

with or without epinephrine 1:200,000

Winthrop

MARCAINE® Hydrochloride
Brand of **bupivacaine hydrochloride**

Indications: Peripheral nerve block, infiltration, sympathetic block, caudal, or epidural block.

Contraindication: Marcaine is contraindicated in patients with known hypersensitivity to it.

Warnings: RESUSCITATIVE EQUIPMENT AND DRUGS SHOULD BE READILY AVAILABLE WHEN ANY LOCAL ANESTHETIC IS USED.

Usage in Pregnancy. Reproduction studies have been performed in rats and rabbits and there is no evidence of harm to the animal fetus. The relevance to the human is not known. Safe use in pregnant women other than those in labor has not been established.

Until further clinical experience is gained, paracervical block with Marcaine is not recommended. Fetal bradycardia frequently follows paracervical block with some amide-type local anesthetics and may be associated with fetal acidosis. Added risk appears to be present in prematurity, toxemia of pregnancy, and fetal distress.

The obstetrician is warned that severe persistent hypertension may occur after administration of certain oxytocic drugs, if vasopressors have already been used during labor (e.g., in the local anesthetic solution or to correct hypotension).

Solutions containing a vasoconstrictor, particularly epinephrine or norepinephrine, should be used with extreme caution in patients receiving monoamine oxidase (MAO) inhibitors or antidepressants of the triptyline or imipramine types, because severe, prolonged hypertension may result.

Local anesthetics which contain preservatives, i.e., those supplied in multiple dose vials, should not be used for caudal or epidural anesthesia.

Until further experience is gained in children younger than 12 years, administration of Marcaine in this age group is not recommended.

Precautions: The safety and effectiveness of local anesthetics depend upon proper dosage, correct technique, adequate precautions, and readiness for emergencies.

The lowest dosage that gives effective anesthesia should be used in order to avoid high plasma levels and serious systemic side effects. Injection of repeated doses of Marcaine may cause significant increase in blood levels with each additional dose, due to accumulation of the drug or its metabolites or due to slow metabolic degradation. Tolerance varies with the status of the patient. Debilitated, elderly patients and acutely ill patients should be given reduced doses commensurate with age and physical condition.

Solutions containing a vasoconstrictor should be used cautiously in areas with limited blood supply, in the presence of diseases that may adversely affect the patient's cardiovascular system, or in patients with peripheral vascular disease.

Marcaine should be used cautiously in persons with known drug allergies or sensitivities, particularly to the amide-type local anesthetics.

Serious dose-related cardiac arrhythmias may occur if preparations containing a vasoconstrictor such as epinephrine are employed in patients during or following the administration of chloroform, halothane, cyclopropane, trichloroethylene, or other related agents. In deciding whether to use these products concurrently in the same patient, the combined action of both agents upon the myocardium, the concentration and volume of vasoconstrictor used, and the time since injection, when applicable, should be taken into account.

Caution is advised in administration of repeat doses of Marcaine to patients with severe liver disease.

Adverse Reactions: Reactions to Marcaine are characteristic of those associated with other amide-type local anesthetics. A major cause of adverse reactions to this group of drugs is excessive plasma levels, which may be due to overdosage, inadvertent intravascular injection, or slow metabolic degradation.

Excessive plasma levels of the amide-type local anesthetics cause systemic reactions involving the central nervous system and the cardiovascular system. The *central nervous system effects* are characterized by excitation or depression. The first manifestation may be nervousness, dizziness, blurred vision, or tremors, followed by drowsiness, convulsions, unconsciousness, and possibly respiratory arrest. Since excitement may be transient or absent, the first manifestation may be drowsiness, sometimes merging into unconsciousness and respiratory arrest. Other central nervous system effects may be nausea, vomiting, chills, constriction of the pupils, or tinnitus. The *cardiovascular manifestations* of excessive plasma levels may include depression of the myocardium, blood pressure changes (usually hypotension), and cardiac arrest. In obstetrics, cases of fetal bradycardia have occurred (see Warnings).

Allergic reactions, which may be due to hypersensitivity, idiosyncrasy, or diminished tolerance, are characterized by cutaneous lesions (e.g., urticaria), edema, and other manifestations of allergy. Detection of sensitivity by skin testing is of doubtful value.

Reactions following epidural or caudal anesthesia also may include: high or total spinal block; urinary retention; fecal incontinence; loss of perineal sensation and sexual function; persistent analgesia, paresthesia, and paralysis of the lower extremities; headache and backache; and slowing of labor and increased incidence of forceps delivery.

Treatment of Reactions. Toxic effects of local anesthetics require symptomatic treatment; there is no specific cure. The physician should be prepared to maintain an airway and to support ventilation with oxygen and assisted or controlled respiration as required. Supportive treatment of the cardiovascular system includes intravenous fluids and, when appropriate, vasopressors (preferably those that stimulate the myocardium). Convulsions may be controlled with oxygen and intravenous administration, in small increments, of a barbiturate, as follows: preferably, an ultrashort-acting barbiturate such as thiopental or thiamylal; if this is not available, a short-acting barbiturate (e.g., secobarbital or pentobarbital) or diazepam. Intravenous barbiturates or anticonvulsant agents should only be administered by those familiar with their use.

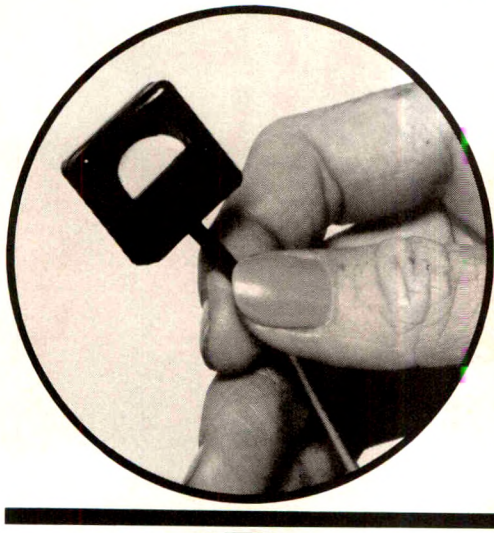
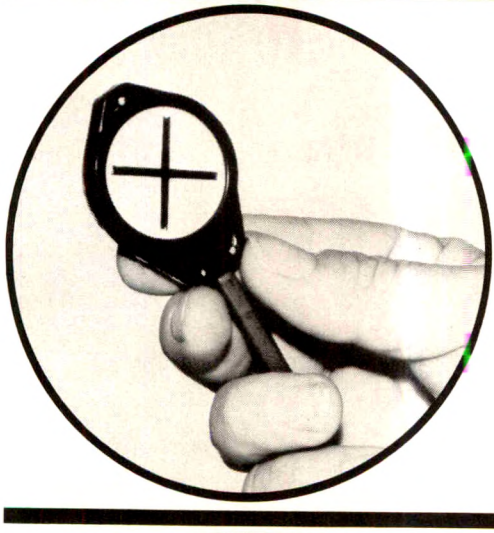
VERSATONE® MULTI-PURPOSE DOPPLER INSTRUMENT



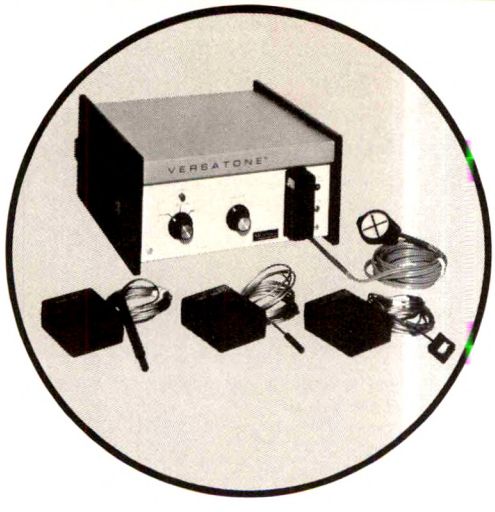
FOR MONITORING DOPPLER SOUNDS OF BLOOD FLOW AND TO TAKE DOPPLER SYSTOLIC BLOOD PRESSURE

This sensitive Doppler probe is easy to tape in position for non-invasive detection and monitoring of arterial blood flow during surgery. Used with an occlusive cuff and manometer, systolic blood pressures may be obtained even on infants and hypotensive patients.



FOR EARLY DETECTION OF VENOUS AIR EMBOLISM

This sensitive wide-angle Doppler probe is particularly well suited for the detection of venous air emboli which may occur during neurosurgical procedures performed with the patient in the upright position. It also detects motion of the heart muscle, heart valves and blood flow.



VERSATONE D8 DOPPLER

The Model D8 VERSATONE Doppler instrument is designed to use interchangeable probes of various frequencies and configurations. It is powered by a rechargeable battery and has a built-in loudspeaker. Options include an electrocautery sensor and cut-out, a molded earset for private listening, and a chart recording circuit. The two probes shown above are particularly useful to the anesthesiologist. Two sizes of pencil shaped probes are also available. These are useful for intraoperative assessment of flow in exposed vessels, as well as for transcutaneous flow detection.

For prescribing information including Contraindications, Warnings, Precautions and Adverse Reactions, please turn page.

Innovar® injection

The two components of INNOVAR® injection, fentanyl and droperidol, have different pharmacologic actions. Before administering INNOVAR injection, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action.

DESCRIPTION

Each cc. contains (in a 1:50 ratio):

Fentanyl ..... 0.05 mg.
as the citrate

Warning: May be habit forming

Droperidol ..... 2.5 mg.
Lactic acid for adjustment of pH to 3.5± 0.3

FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY

Protect from Light

ACTIONS INNOVAR injection is a combination drug containing a narcotic analgesic, fentanyl, and a neuroleptic (major tranquilizer), droperidol. The combined effect, sometimes referred to as neuroleptanalgesia, is characterized by general quiescence, reduced motor activity, and profound analgesia; complete loss of consciousness usually does not occur from use of INNOVAR injection alone. The incidence of early postoperative pain and emesis may be reduced.

A. Fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. Fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. Fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays, and skin wheal testing in man, as well as *in vivo* testing in dogs indicate that histamine release rarely occurs with fentanyl.

Fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours. Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics, it may be considerably longer than the analgesic effect.

B. Droperidol produces marked tranquilization and sedation. It also produces an antiemetic effect as evidenced by the antagonism of apomorphine in dogs. It potentiates other CNS depressants. It also produces mild alpha adrenergic blockade, peripheral vascular dilatation and reduction of the pressor effect of epinephrine. Droperidol can produce hypotension and decreased peripheral vascular resistance. It may decrease pulmonary arterial pressure (particularly if it is abnormally high). It may reduce the incidence of epinephrine-induced arrhythmias but it does not prevent other cardiac arrhythmias. The onset of action is from three to ten minutes following intravenous or intramuscular administration. The full effect, however, may not be apparent for 30 minutes. The duration of the sedative and tranquilizing effects generally is two to four hours. Alteration of consciousness may persist as long as 12 hours. This is in contrast to the much shorter duration of action of fentanyl.

INDICATIONS INNOVAR injection is indicated to produce tranquilization and analgesia for surgical and diagnostic procedures. It may be used as an anesthetic premedication, for the induction of anesthesia, and as an adjunct in the maintenance of general and regional anesthesia. If the supplementation of analgesia is necessary, SUBLIMAZE® (fentanyl) injection alone rather than the combination drug INNOVAR injection should usually be used.

CONTRAINDICATIONS INNOVAR injection should not be used in patients who are hypersensitive to either component.

WARNINGS PATIENTS WHO HAVE RECEIVED *INNOVAR* INJECTION SHOULD BE UNDER APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

The respiratory depressant effect of narcotics persists longer than their measured analgesic effect. When used with INNOVAR injection, the total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, be used initially in reduced doses, as low as 1/4 to 1/3 those usually recommended.

INNOVAR injection may cause muscle rigidity, particularly involving the muscles of respiration. This effect is due to the fentanyl component and is related to the speed of injection. Its incidence can be reduced by the use of slow intravenous injection. Once the effect occurs it is managed by the use of assisted or controlled respiration and by a neuromuscular blocking drug, if necessary.

FLUIDS AND OTHER COUNTERMEASURES TO MANAGE HYPOTENSION SHOULD ALSO BE AVAILABLE.

Drug Dependence: *Fentanyl, the narcotic analgesic component, can produce drug dependence of the morphine type and therefore has the potential for being abused.*

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl, in this regard, has not been established, the use of INNOVAR injection or SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: INNOVAR injection should be used with caution in patients who may be particularly susceptible to respiratory depression such as comatose patients who may have a head injury or brain tumor. In addition, these drugs may obscure the clinical course of patients with head injury.

Usage in Children: The safety of INNOVAR injection in children two years of age or younger has not been established.

Usage in Pregnancy: The safe use of INNOVAR injection has not been established with respect to possible adverse effects upon fetal development.

Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects; therefore, safety for the infant in obstetrics has not been established.

PRECAUTIONS *The initial dose of INNOVAR injection should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and some peridural anesthetics, can alter respiration by blocking intercostal nerves, and can cause peripheral vasodilatation and hypotension because of sympathetic blockade. Through other mechanisms (see Actions) fentanyl and droperidol also depress respiration and blood pressure. Therefore, when INNOVAR injection is used to supplement these forms of anesthesia, the anesthetist must be familiar with the physiological alterations involved, and be prepared to manage them in the patients selected for this form of anesthesia.

The droperidol component of INNOVAR injection may decrease pulmonary arterial pressure. This fact should be considered by those who conduct diagnostic or surgical procedures where interpretation of pulmonary arterial pressure measurements might determine final management of the patient.

Vital signs should be monitored routinely.

INNOVAR injection, and SUBLIMAZE fentanyl, should be used with caution in patients with chronic obstructive pulmonary disease, patients with decreased respiratory reserve, and others with potentially compromised ventilation. In such patients narcotics may additionally decrease respiratory drive and increase airway resistance. During anesthesia this can be managed by assisted or controlled respiration. Postoperatively respiratory depression caused by narcotic analgesics can be reversed by narcotic antagonists (levallorphan, nalorphine, and naloxone); consult individual prescribing information before using.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, and general anesthetics) have additive or potentiating effects with INNOVAR injection. When patients have received such drugs, the dose of INNOVAR injection required will be less than usual. Likewise, following the administration of INNOVAR injection the dose of other CNS depressant drugs should be reduced.

INNOVAR injection should be administered with caution to patients with liver and kidney dysfunction because of the importance of these organs in the metabolism and excretion of drugs.

If hypotension occurs, the possibility of hypovolemia should be considered and managed with appropriate parenteral fluid therapy. Repositioning the patient to improve venous return to the heart should be considered when operative conditions permit. It should be noted that in spinal and peridural anesthesia, tilting the patient into a head down position may result in a higher level of anesthesia than is desirable, as well as impair venous return to the heart. Care should be exercised in the moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus these other countermeasures do not correct the hypotension, then the administration of pressor agents other than epinephrine should be considered. Epinephrine may paradoxically decrease the blood pressure in patients treated with INNOVAR injection due to the alpha-adrenergic blocking action of droperidol.

The fentanyl component may produce bradycardia, which may be treated with atropine; however, INNOVAR injection should be used with caution in patients with cardiac bradyarrhythmias.

When the EEG is used for postoperative monitoring, it may be found that the EEG pattern returns to normal slowly.

ADVERSE REACTIONS The most common serious adverse reactions reported to occur with INNOVAR injection are respiratory depression, apnea, muscular rigidity, and hypotension; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have been observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with anti-parkinson agents.

Other adverse reactions that have been reported are dizziness, chills and/or shivering, twitching, blurred vision, hyperactivity on induction, laryngospasm, transient hypertension, nausea and emesis, diaphoresis, emergence delirium, and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression).

Postoperative drowsiness is also frequently reported.

OVERDOSAGE ***Manifestations:*** The manifestations of INNOVAR injection overdosage are an extension of its pharmacologic actions.

Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered. A specific narcotic antagonist such as nalorphine, levallorphan or naloxone should be available for use as indicated to manage respiratory depression caused by the narcotic component fentanyl. This does not preclude the use of more immediate countermeasures. Consult the package inserts for the individual narcotic antagonists for details about use.

HOW SUPPLIED INNOVAR® injection is supplied in 2 cc. (**NDC** 0045-0280-20) and 5 cc. (**NDC** 0045-0280-50) ampuls, in packages of 10.

IMPORTANT: Complete dosage information is available in insert which accompanies each package (or on request). The drug is available only upon direction of a physician.

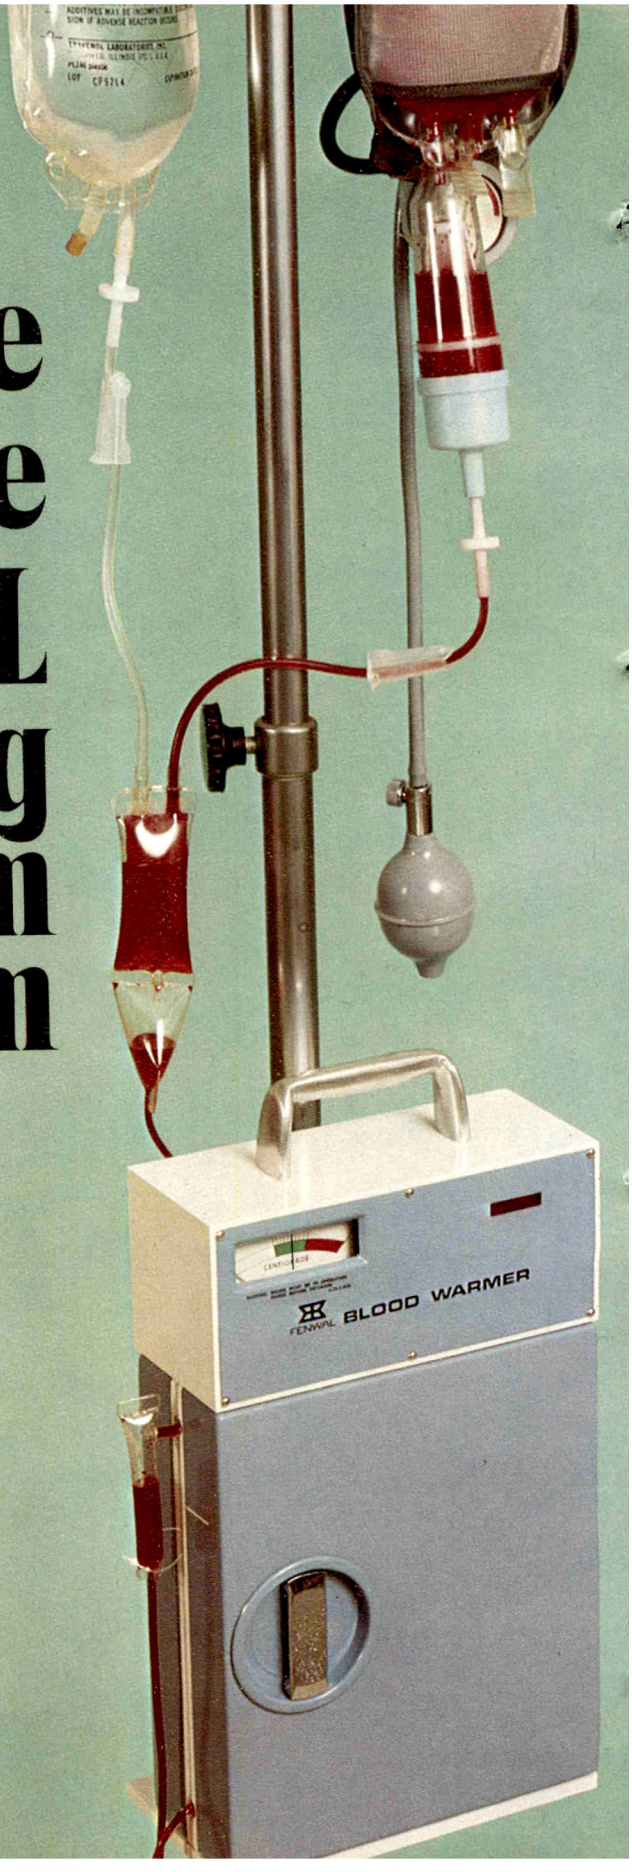
BLOOD WARMER

The complete FENWAL operating room system



The Fenwal Dry Heat Blood Warmer is designed for use during single or multiple transfusions when precise regulation of blood temperature and flow rate is indicated. It utilizes a disposable plastic blood-warming pathway.

Fenwal Recipient Sets are available to accommodate your infusion requirements. The Single Lead Set is to be used for the intravenous administration of one unit of whole blood, red cells or plasma. The "Y" Recipient Set is designed to permit dual hookups for simultaneous administration of blood and/or solutions. The Triple Lead Set may be employed in multiple infusion procedures, i.e., blood, solutions, blood components and medication.

The Fenwal Microaggregate Blood Filter is designed to remove microaggregates down to 20 microns in size during intravenous administration of stored whole blood or red cells.

Fenwal Pressure Infusors provide an efficient non-air-dependent method for the rapid infusion of whole blood or red cells.

The Fenwal TYPENEX™ Blood Recipient Identification System ties together the identity of the transfusion candidate, his cross-match request form, blood sample and up to 10 cross-matched units of blood.

The Fenwal Venous Pressure Manometer Set is a disposable, preassembled unit that permits continuous monitoring of the patient's venous pressure while performing one simple hookup.

The Fenwal Platelet Recipient Set is designed specifically for the infusion of fresh blood and pool platelet concentrates.

Our best to you

Fenwal Laboratories has long been identified with innovation in modern blood handling systems. Our knowledge and experience in developing and providing sophisticated blood processing systems have earned a reputation for excellence. Thoroughly researched and tested to meet the demands of the medical profession, you can expect the same quality in Fenwal operating room devices that helped achieve our recognition with the nation's blood banks.

The Fenwal Specialist in your hospital can provide you and the other members of the operating team with completely detailed information on all of our products. Intensive training makes him fully qualified to answer your most involved questions regarding up-to-date blood transfusion procedure. Be sure to see your Fenwal Specialist the next time he visits your department.

Selected cases for Ketalar® (ketamine HCl injection)

(and a caution)

There are certain situations where the advantages of Ketalar suggest its serious consideration.

Four such hypothetical situations are detailed here. A fifth hypothetical case illustrates a situation in which Ketalar probably should be used only with caution.

Geriatric surgical procedure

Ketalar offers advantages in minor rectal surgery on elderly patients. When properly administered, Ketalar usually does not depress the patient's blood pressure or pulse rate, which can be a distinct advantage with any patient who is likely to develop hypotension. Further, emergence reactions normally are not a problem with patients in the older age group (over 65).

Severely burned patients

Patients with severe burns—and particularly children—are often excellent cases for Ketalar. In children, Ketalar offers rapid surgical anesthesia (generally within three to four minutes) at a range of 9 to 13 mg/kg, with the effect lasting from 12 to 25 minutes (the time intervals are for IM, not IV). Intramuscular administration avoids the possible difficulty in locating the vein in burn patients (particularly helpful in children where the veins are small). IM administration is also convenient and effective for repeated short-term anesthesia for such procedures as changing burn dressings, and skin grafts.

Manipulative diagnostic procedure

Ketalar facilitates diagnostic procedures in which the patient must be moved freely, and in which the maintenance of unaided respiration is essential. The pneumoencephalogram is an example. Once anesthesia is established, the patient can be transferred from a supine to an upright, supported position with ease since Ketalar maintains adequate unaided respiration, and there is minimal relaxation of the skeletal muscles.

Emergency room treatment

A good case for Ketalar can be made for use in accident victims with unknown medical histories brought to the emergency room. In the absence of positive medical history, Ketalar can be a useful agent because of its wide margin of safety. Consideration should be given to the effects of a significant increase in blood pressure, hypersensitivity to the drug, and an elevation in cerebrospinal fluid pressure. Ketalar also provides the benefit of rapid onset, and decreases the chance of aspiration because of active laryngeal-pharyngeal reflexes.

A caution:

Caution should be exercised when administering Ketalar to patients who are known to be alcoholics or who are acutely alcohol-intoxicated as such patients may be prone to untoward reactions.

advancement in anesthesiology

Ketalar
(Ketamine HCl injection)

Brief summary of prescribing information.

SPECIAL NOTE

EMERGENCE REACTIONS HAVE OCCURRED IN APPROXIMATELY 12% OF PATIENTS.

THE PSYCHOLOGICAL MANIFESTATIONS VARY IN SEVERITY BETWEEN PLEASANT, DREAMLIKE STATES, VIVID IMAGERY, HALLUCINATIONS, AND EMERGENCE DELIRIUM. IN SOME CASES, THESE STATES HAVE BEEN ACCOMPANIED BY CONFUSION, EXCITEMENT, AND IRRATIONAL BEHAVIOR WHICH A FEW PATIENTS RECALL AS AN UNPLEASANT EXPERIENCE. THE DURATION ORDINARILY LASTS NO MORE THAN A FEW HOURS; IN A FEW CASES, HOWEVER, RECURRENCES HAVE TAKEN PLACE UP TO 24 HOURS POSTOPERATIVELY. NO RESIDUAL PSYCHOLOGICAL EFFECTS ARE KNOWN TO HAVE RESULTED FROM USE OF KETALAR.

THE INCIDENCE OF THESE EMERGENCE PHENOMENA IS LEAST IN THE YOUNG (15 YEARS OF AGE OR LESS) AND ELDERLY (OVER 65 YEARS OF AGE) PATIENT. ALSO, THEY ARE LESS FREQUENT WHEN THE DRUG IS GIVEN INTRAMUSCULARLY.

THESE REACTIONS MAY BE REDUCED IF VERBAL, TACTILE, AND VISUAL STIMULATION OF THE PATIENT IS MINIMIZED DURING THE RECOVERY PERIOD. THIS DOES NOT PRECLUDE THE MONITORING OF VITAL SIGNS. IN ADDITION, THE USE OF A SMALL HYPNOTIC DOSE OF A SHORT-ACTING OR ULTRASHORT-ACTING BARBITURATE MAY BE REQUIRED TO TERMINATE A SEVERE EMERGENCE REACTION. THE INCIDENCE OF EMERGENCE REACTIONS IS REDUCED AS EXPERIENCE WITH THE DRUG IS GAINED.

WHEN KETALAR IS USED ON AN OUTPATIENT BASIS, THE PATIENT SHOULD NOT BE RELEASED UNTIL RECOVERY FROM ANESTHESIA IS COMPLETE AND THEN SHOULD BE ACCOMPANIED BY A RESPONSIBLE ADULT.

INDICATIONS

Ketalar (ketamine HCl injection) is recommended:

1. as the sole anesthetic agent for diagnostic and surgical procedures that do not require skeletal muscle relaxation. Ketalar is best suited for short procedures but it can be used, with additional doses, for longer procedures;

2. for the induction of anesthesia prior to the administration of other general anesthetic agents;

3. to supplement low-potency agents, such as nitrous oxide.

CONTRAINDICATIONS

Ketamine hydrochloride is contraindicated in those in whom a significant elevation of blood pressure would constitute a serious hazard and those who have shown hypersensitivity to the drug.

WARNINGS

1. Ketalar should be used by or under the direction of physicians experienced in administering general anesthetics and in maintenance of an airway and in the control of respiration.

2. Cardiac function should be continually monitored during the procedure in patients found to have hypertension or cardiac decompensation.

3. Barbiturates and Ketalar, being chemically incompatible because of precipitate formation, *should not* be injected from the same syringe.

4. Prolonged recovery time may occur if barbiturates and/or narcotics are used concurrently with Ketalar.

5. Postoperative confusional states may occur during the recovery period.

6. Respiratory depression may occur with overdosage or too rapid a rate of administration of Ketalar, in which case supportive ventilation should be employed. Mechanical support of respiration is preferred to administration of analeptics.

Usage in Pregnancy

Since the safe use in pregnancy, including obstetrics (either vaginal or abdominal delivery), has not been established, such use is not recommended.

PRECAUTIONS

1. Because pharyngeal and laryngeal reflexes are usually active, Ketalar (ketamine HCl injection) should not be used alone in surgery or diagnostic procedures of the pharynx, larynx, or bronchial tree. Mechanical stimulation of the pharynx should be avoided, whenever possible, if Ketalar is used alone. Muscle relaxants, with proper attention to respiration, may be required in both of these instances.

2. Resuscitative equipment should be ready for use.

3. ***The incidence of emergence reactions may be reduced*** if verbal and tactile stimulation of the patient is minimized during the recovery period. This does not preclude the monitoring of vital signs (see Special Note).

4. The intravenous dose should be administered over a period of 60 seconds. More rapid administration may result in respiratory depression or apnea and enhanced pressor response.

5. In surgical procedures involving visceral pain pathways, Ketalar should be supplemented with an agent which obtunds visceral pain.

6. Use with caution in the chronic alcoholic and the acutely alcohol-intoxicated patient.

7. An increase in cerebrospinal fluid pressure has been reported following administration of ketamine hydrochloride. Use with extreme caution in patients with preanesthetic elevated cerebrospinal fluid pressure.

ADVERSE REACTIONS

Cardiovascular: Blood pressure and pulse rate are frequently elevated following administration of Ketalar. However, hypotension and bradycardia have been observed. Arrhythmia has also occurred.

Respiration: Although respiration is frequently stimulated, severe depression of respiration or apnea may occur following rapid intravenous administration of high doses of Ketalar (ketamine HCl injection). Laryngospasms and other forms of airway obstruction have occurred during Ketalar anesthesia.

Eye: Diplopia and nystagmus have been noted following Ketalar administration. It also may cause a slight elevation in intraocular pressure measurement.

Psychological: (See Special Note).

Neurological: In some patients, enhanced skeletal muscle tone may be manifested by tonic and clonic movements sometimes resembling seizures (see Dosage and Administration).

Gastrointestinal: Anorexia, nausea and vomiting have been observed; however this is not usually severe and allows the great majority of patients to take liquids by mouth shortly after regaining consciousness (see Dosage and Administration).

General: Local pain and exanthema at the injection site have infrequently been reported. Transient erythema and/or morbilliform rash have also been reported.

DOSAGE AND ADMINISTRATION

Preoperative Preparations:

1. While vomiting has been reported following Ketalar administration, airway protection is usually afforded because of active laryngeal-pharyngeal reflexes. However, since these reflexes may also be diminished by supplementary anesthetics or muscle relaxants, the possibility of aspiration must be considered. Ketalar is recommended for use in the patient whose stomach is not empty when, in the judgment of the practitioner, the benefits of the drug outweigh the possible risks.

2. Atropine, scopolamine, or other drying agent should be given at an appropriate interval prior to induction.

Dosage

As with other general anesthetic agents, the individual response to Ketalar (ketamine HCl injection) is somewhat varied depending on the dose, route of administration, and age of patient, so that dosage recommendation cannot be absolutely fixed. The drug should be titrated against the patient's requirements.

Onset and Duration:

Because of rapid induction following the initial intravenous injection, the patient should be in a supported position during administration.

The onset of action of Ketalar (ketamine HCl injection) is rapid; an intravenous dose of 2 mg/kg (1 mg/lb) of body weight usually produces surgical anesthesia within 30 seconds after injection, with the anesthetic effect usually lasting five to ten minutes. If a longer effect is desired, additional increments can be administered intravenously or intramuscularly to maintain anesthesia without producing significant cumulative effects.

Intramuscular doses, from experience primarily in children, in a range of 9 to 13 mg/kg (4 to 6 mg/lb) usually produce surgical anesthesia within three to four minutes following injection, with the anesthetic effect usually lasting 12 to 25 minutes.

Induction:

Intravenous Route: The initial dose of Ketalar administered intravenously may range from 1 mg/kg to 4.5 mg/kg (0.5 to 2 mg/lb). The average amount required to produce five to ten minutes of surgical anesthesia has been 2 mg/kg (1 mg/lb).

NOTE: The 100 mg/ml concentration (S-V 1585) of Ketalar, *should not* be injected intravenously without proper dilution. It is recommended the drug be diluted with an equal volume of either Sterile Water for Injection, USP, Normal Saline, or 5% Dextrose in Water.

Rate of Administration: It is recommended that Ketalar be administered slowly (over a period of 60 seconds). More rapid administration may result in respiratory depression and enhanced pressor response.

Intramuscular Route: The initial dose of Ketalar administered intramuscularly may range from 6.5 to 13 mg/kg (3 to 6 mg/lb). A dose of 10 mg/kg (5 mg/lb) will usually produce 12 to 25 minutes of surgical anesthesia.

Maintenance of Anesthesia:

Increments of one half to the full induction dose may be repeated as needed for maintenance of anesthesia. However, it should be noted that purposeless and tonic-clonic movements of extremities may occur during the course of anesthesia. These movements do not imply a light plane and are not indicative of the need for additional doses of the anesthetic.

It should be recognized that the larger the total dose of Ketalar (ketamine HCl injection) administered, the longer will be the time to complete recovery.

Supplementary Agents:

Ketalar is clinically compatible with the commonly used general and local anesthetic agents when an adequate respiratory exchange is maintained.

HOW SUPPLIED

Ketalar is supplied as the hydrochloride in concentrations equivalent to ketamine base.

N 0071-4581-15—Each 50-ml vial contains 10 mg/ml. Supplied in cartons of 10.

N 0071-4581-12—Each 20-ml vial contains 10 mg/ml. Supplied in cartons of 10.

N 0071-4582-10—Each 10-ml vial contains 50 mg/ml. Supplied in cartons of 10.

N 0071-4585-08—Each 5-ml vial contains 100 mg/ml. Supplied in cartons of 10.

PI Peripheral Nerve Stimulator

Monitors Muscle Relaxants

The PI Peripheral Nerve Stimulator monitors effects of skeletal muscle relaxants on the neuromuscular junction, detects abnormal response to muscle relaxants and distinguishes between depolarizing and non-depolarizing blockade.

Model NS-2

The NS-2 is now in use in many hospitals throughout the U. S. and abroad. It is designed primarily for use during surgery and delivers stimuli automatically at 5-second intervals. One or fifty pulses-per-second may be selected by momentary push-button switches. Output is a monophasic square wave pulse. Amplitude of the pulse is linearly adjustable. A flashing red light indicates low battery voltage. The NS-2 is solid state, rugged, battery powered, portable and lightweight.

Model NS-3

The NS-3 represents the latest in solid state technology. Use of integrated circuits has made it possible to build a very compact and versatile stimulator. Its miniature size makes the NS-3 more convenient for preoperative and postoperative testing. It delivers stimili at one second intervals when the rocker switch is depressed to the TWITCH position. A fifty-pulses-per-second rate may be selected by depressing the rocker switch to the momentary TETANUS position. Output is a monophasic square wave pulse. Amplitude of the pulse is linearly adjustable. The NS-3 also has a low-battery-voltage indicator.

Professional Medical and Scientific Instrumentation

ANTILIRIUM
(Physostigmine Salicylate)

REVERSES MOST POST-OPERATIVE DELIRIUM AND PROLONGED SOMNOLENCE

Before prescribing, please consult complete product information, a summary of which follows:

ACTION: ANTILIRIUM (physostigmine salicylate) is a salicylic acid derivative of an alkaloid extracted from seeds of Physostigma Venenosum (calabar bean). The action of the parasympathetic nerves is intermediated by the formation of acetylcholine at the peripheral end of these nerves. Physostigmine inhibits the destructive action of cholinesterase and thereby prolongs and exaggerates the effect of the acetylcholine.

Physostigmine contains a tertiary amine and easily crosses the blood brain barrier, while neostigmine contains a quaternary amine and is not capable of crossing the structure. This may explain why neostigmine does not cause reversal of anticholinergic-induced delirium while physostigmine does.

INDICATIONS: TO REVERSE THE TOXIC EFFECTS UPON THE CENTRAL NERVOUS SYSTEM CAUSED BY DRUGS IN CLINICAL OR TOXIC DOSAGES CAPABLE OF PRODUCING ANTICHOLINERGIC POISONING.

SEVERE ANTICHOLINERGIC POISONING MAY PRODUCE: COMA, MEDULLARY PARALYSIS AND DEATH.

CENTRAL TOXIC EFFECTS MAY INCLUDE: HALLUCINATIONS, DELIRIUM, DISORIENTATION, ANXIETY AND HYPERACTIVITY.

Dramatic reversal within minutes of coma, hallucinations, and other signs can be expected if the diagnosis is correct and the patient has not suffered anoxia or other insult. Therapeutic doses may be necessary at intervals as life-threatening signs recur. Physostigmine is destroyed in the body in 60 to 120 minutes.

CONTRAINDICATIONS: Physostigmine should not be used in the presence of asthma, gangrene, diabetes, cardiovascular disease, mechanical obstruction of the intestines or urogenital tract or any vagotonic state, and in patients receiving choline esters or depolarizing neuromuscular blocking agents.

WARNING: If excessive symptoms of salivation, emesis, urination and defecation occur, the use of ANTILIRIUM should be terminated. If excessive sweating or nausea occur, the dosage should be reduced.

Intravenous administration should be at a slow, controlled rate, no more than 1 mg. per minute (see dosage). Rapid administration can cause bradycardia, hypersalivation leading to respiratory difficulties and possibly convulsions.

An overdosage of ANTILIRIUM can cause a cholinergic crisis.

PRECAUTIONS: Because of the possibility of hypersensitivity in an occasional patient, atropine sulfate injection should always be at hand since it is an antagonist and antidote for physostigmine.

ADMINISTRATION AND DOSAGE: The usual adult dose of ANTILIRIUM is 0.5 to 2.0 mg. intramuscularly or intravenously. Intravenous administration should be at a slow, controlled rate of no more than 1 mg. per minute. It may be necessary to repeat dosages of 1 mg. to 4 mg. at intervals as life threatening signs such as arrhythmias, convulsions and deep coma recur.

IN ALL CASES OF POISONING, THE USUAL SUPPORTIVE MEASURES SHOULD BE UNDERTAKEN.

SUPPLIED: 2 ml. ampules containing:
PHYSOSTIGMINE SALICYLATE 1 mg. per ml.
Packed 12 ampules per box.
NDC 0456-1037-12

CAUTION: Federal law prohibits dispensing without prescription.

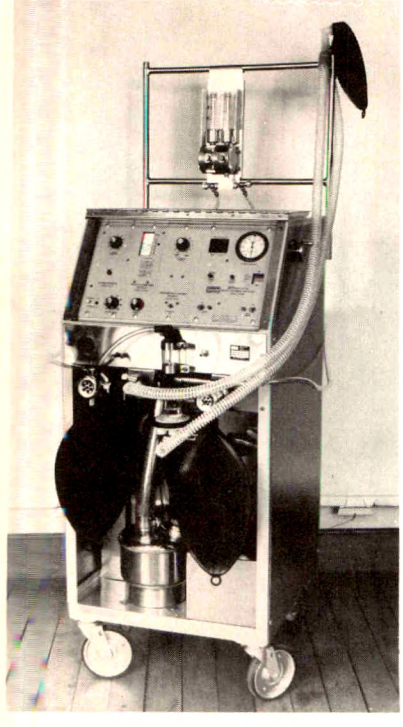
EMERSON IMV Ventilator

Intermittent Mandatory Ventilation

Continuous-flow voluntary ventilation, with intermittent forced breaths, is an alternative to assisted or controlled respiration. It has been found especially valuable for infants and for use in "weaning" adults as they improve.

Air fully humidified (and usually enriched with oxygen) flows continuously to a reservoir bag, and is available for unobstructed inspiration by the patient. A slight expiratory back-pressure (PEEP) may be added, to keep the lungs expanded. At intervals the ventilator delivers a "mandatory" breath, which supplements the patient's own breathing activity and increases minute volume. The machine does not have to "take over". The patient maintains his own homeostasis, without interference from drugs or hyperventilation.[1]

At first the ventilator is generally set to supply mandatory breaths at a normal controlled rate. This controlled respiration is then gradually changed, by lengthening the interval between breaths (a second or two at a time) as the patient's condition improves. Eventually mandatory breaths are spaced so far apart that the patient scarcely relies on them at all — and "weaning" is completed.[2]



VERSUS ASSIST

Triggering an assistor has often been a problem, particularly for infants, since their rates are rapid and their inspiratory impulses are slight. If synchronization is less than perfect, the patient inhales (at least part of the time) with no fresh gas available. Under such circumstances, blood levels of CO_2 rise, as noted by Kirby and associates.[1]

VERSUS CONTROL

For apneic patients, control is obviously needed. But to take over, when a patient is breathing spontaneously, drugs have to be used or the patient has to be hyperventilated. Either procedure has drawbacks. Paralytic or sedative agents may obscure signs of neurological or metabloic disorders. Lowered muscle tone may impair venous return, and hence cardiac output. The effects of such drugs are particularly hard to predict in infants.

Hyperventilation (often used to suppress spontaneous breathing efforts) has drawbacks, too. The resultant alkalosis reduces cerebral blood flow. Blood levels of calcium and magnesium are altered. Airway resistance increases and pulmonary compliance decreases with hypocarbia.[3] Finally, there is evidence of a shift in the carbon dioxide response curve, which makes weaning more difficult.

All of these pit-falls can be avoided by using continuous-flow IMV.

51ST CONGRESS

MARCH 6-10, 1977

International Anesthesia Research Society

DIPLOMAT RESORT AND COUNTRY CLUBS
HOLLYWOOD, FLORIDA

IMPORTANT INFORMATION ON THE 51st CONGRESS

Pre-registration Material, Program, Hotel Card—will be mailed in mid-December to all I.A.R.S. members, associate members, and educational members. (Members outside of U.S., Canada and Mexico who plan to attend, please advise I.A.R.S. Cleveland office by December 1 to assure timely arrival of pre-registration material.)

Scientific Exhibits—Application forms are available from B. B. Sankey, M.D., Executive Secretary, I.A.R.S., 3645 Warrensville Center Rd., Cleveland, Ohio 44122. There is no deadline for applications; however, applications received after November 1, 1976, are subject to exhibit space availability.

Technical (Commercial) Exhibits—Applications available from Charles B. Slack, Inc., Exhibit Manager, 6900 Grove Rd., Thorofare, New Jersey 08086.

C.M.E. Credit—This Continuing Medical Education offering meets the criteria for Category 1 credit (22 hours est.) for the Physician's Recognition Award of the American Medical Association.

Anesthesia for the Patient with Cardiac Disease: Preamble

EMERSON A. MOFFITT, MD*

THE number of people with coronary arterial disease including those who have had a myocardial infarction, increases as the total population increases and as more people live to an older age. Hence, the number of patients with cardiac disease requiring some form of anesthesia for operation or diagnostic procedure should continue to grow steadily.

In 1974, there were 16,486,045 surgical procedures in the United States,[1] in a total population of approximately 215,000,000. That is, 1 person in 7 had an operation. Tarhan's group[2] showed that in a large-volume anesthetic practice, 13 patients per 1000, over 30 years of age, came for operation with evidence of a previous myocardial infarction. There are no reasons to believe that this incidence is different for the surgical population of North America in general. Hence, in the United States in 1974, about 214,500 patients with a previous infarction had a surgical procedure. Tarhan's work also identified the high incidence of recurrent infarction (6.6%) in this patient group, and the inordinately high mortality rate (54%) compared to infarction without operation.

In addition to the candidates for anesthesia who have had a previous infarction, a much larger group of patients have serious heart disease without having had a frank coronary occlusion. With approximately 5 percent of the population over 18 years having known or suspected coronary disease[2] and 1/7 undergoing an operation, several million patients with cardiac disease are anesthetized each year in the United States.

Everyone practicing anesthesia faces the patient with cardiac disease every week—perhaps almost every day. It behooves us to be perceptive of their increased risk of anesthesia and operation, so that we may best assure a safe course. For these reasons, the panel will examine the sound principles and good practices essential to successful management of the cardiac patient having an operation for other than cardiac surgery.

The Patient with Heart Disease: Preoperative Evaluation and Preparation

ALAN H. GOLDBERG, MD, PhD*

THE surgical patient with heart disease and diminished cardiac compensation has decreased cardiac output and decreased tissue perfusion.

We are concerned about this patient for several reasons. Because of his increased intravascular volume, the management of his fluid and electrolyte replacement becomes very complicated. He is a candidate for thromboembolic phenomena such as pulmonary emboli. With decreased ventilation, there is increased likelihood for hypoxia and hypercarbia as well as respiratory infections and pneumonia. He has impaired liver and kidney function, which can change the effects of drugs. In addition, the various stresses to which a surgical patient is exposed can push him into acute heart failure. Failure may be precipitated by pain, fear, or apprehension, or with the induction of general anesthesia. He may be inadvertently given too much fluid for his cardiac status.

This patient may also get into trouble in the postoperative period. Inability to achieve a needed rise in cardiac output may result in acute pulmonary edema or the low output-cardiac failure syndrome, with low urine volume, vasoconstriction, and hypotension. There appears to be a significantly greater postoperative mortality in patients who are not able to increase their cardiac output in response to the metabolic demands of operation and postoperative stress.

However, it is not the patient with overt failure whose cardiac status will be missed and who will come to surgery without some form of therapy; it is easy to recognize the patient with severe dyspnea, edema, enlarged heart, or a loud murmur. It is the patient with borderline incipient failure who was not recognized immediately as being in failure who may go on to have stress-precipitated severe failure.

The typical patient who gets into trouble is one of the following:

(1) The patient with rheumatic heart disease with mitral stenosis.

(2) The patient with aortic stenosis, particularly an elderly patient who may not have a very impressive murmur. This patient is in a precarious state and tolerates operation, anesthesia, and acute trauma poorly.

(3) The patient with chronic lung disease. He may have some hypoxia, and some pulmonary hypertension. This patient may be in borderline right-sided compensation and may not be recognized as having serious underlying pulmonary and cardiac disease.

With these patients, it is important to keep in mind the concept of cardiac reserve. As cardiac capacity fails, compensatory adjustments take place. Increased adrenergic activity develops, the heart increases in size, and the heart rate increases. The individual may continue to carry out his regular activities and may be free of severe symptoms of failure, yet he may have pretty well used up his cardiac reserve, so that if any more stress is superimposed, he will go into failure.

Assessment of Cardiac Function.—In the past decade, many new technics have been developed for assessment of myocardial function. These are mainly sophisticated laboratory technics, for the catheterization

*Clinical Director, Department of Anesthesiology, Boston City Hospital; Professor and Associate Chairman, Department of Anesthesiology, Boston University School of Medicine, Boston, Massachusetts 02118.

laboratory. In the clinical situation, however, we must still employ simple bedside tools, primarily the history and the physical examination.

Concerning the history, a major warning symptom in the patient with incipient failure is cough, particularly nocturnal cough. If you elicit the history of a patient who has started to cough at night but is not raising much in the way of sputum, and each time he assumes the recumbent position he starts to cough, that suggests he is developing a shift of edema fluid into the pulmonary vasculature and that his cough reflex is being stimulated. This patient may have normal physical findings on chest auscultation and even on chest x-ray.

Insomnia is another insidious symptom of impending left heart failure. This may be related to restlessness due to respiratory distress which is not recognized as dyspnea or cough. In the absence of any history of prostatism or bladder infection, the person who has to get up 2 or 3 times at night to void may be describing early evidence of congestive heart failure. The mechanism for regulating salt and water balance is disturbed in patients with incipient heart failure and no longer follows the normal pattern of urine volume formation. This patient will form more urine at night and will therefore have to get up to void.

Unexplained fatigue is another manifestation of incipient heart failure. Irritability or restlessness can be due to decreased cerebral blood flow due to inadequate cardiac output.

Abdominal discomfort, indigestion, or pain, particularly right upper quadrant pain, suggests distention of the liver capsule.

One of the compensatory mechanisms in failure is increased sympathetic activity. This results in increased perspiration. In the absence of fever or other reasons for sweating, a patient who perspires heavily may be in early failure.

The patient may describe dyspnea on effort, but you have to distinguish this from hyperventilation. The patient with dyspnea is breathing rapidly and shallowly, whereas the person with hyperventilation sighs and takes deep breaths. He tells you he cannot get enough air and he may say that breath goes only half way down. This type of complaint is not characteristic of dyspnea on exertion.

Also the rapidity of onset of dyspnea is a valuable clue. Dyspnea due to chronic lung disease generally has a slow onset and is progressive over a long period of time. Recent onset of dyspnea suggests cardiac disease.

Looking further into the history, has the patient been receiving any medication that might impair cardiac function? For example, propranolol, a beta-adrenergic blocking agent, is used as therapy in a number of disorders, as well as for prophylaxis against arrhythmias. Taken over an extended period of time, particularly in large doses, this drug can impair ventricular function. If the drug can be discontinued, especially in the patient who is in a low output state with decreased left ventricular reserve and compensated failure, this should be done 2 or 3 days before operation. If it cannot be discontinued (as in the patient with angina), the antagonist is isoproterenol, which is a beta-adrenergic stimulant.

Physical Examination.—One of the subtle findings of heart failure is persistent unexplained sinus tachycardia. A rate of 90 to 100 bpm may be a manifestation of increased sympathetic activity, which is compensating for impaired cardiac reserve. If this cannot be related to something like fear, apprehension, or fever, think of borderline failure.

Some patients with incipient left heart failure have a potent element of bronchoconstriction that may present as asthma or wheezing, when in fact it reflects pulmonary vascular distention due to the cardiac condition.

Pulsus alternans, observed when feeling the arterial pulse, also detects impaired left ventricular function. The rhythm of the beat in pulsus alternans is perfectly regular, without any interruption. It is not a bigeminal rhythm, but manifests in alternating variations in the peak systolic pressure and the rate of rise of pressure. This can be detected with the blood pressure cuff when a larger systolic peak alternates with a smaller one. In palpation also, you get the impression of a slightly alternating forcefulness of the arterial pulse. It is more easily detected in the carotid or the brachial than in the radial pulse.

If the patient has a slight murmur across the outflow tract of the left ventricle, as in an elderly patient, for example, with some atherosclerotic change in the aorta or the

aortic valve, pulsus alternans translates itself into murmur alternans. If you listen carefully, the faint systolic murmur, which is of no hemodynamic consequence, may give you the clue that the left ventricle is alternating its forcefulness of ejection. The rhythm is regular but the forcefulness or intensity of the murmur varies, showing that the left ventricular myocardium is functioning poorly. This subtle sign of failure may be present even though the patient may not be in overt failure with pulmonary edema or congestion.

The neck veins should be examined. The external jugular vein, which is often tortuous and partly compressed, may be distended even in the *absence* of true elevaof venous pressure. Also, the presence of competent valves at the lower ends of these veins prevents a satisfactory retrograde transmission of the venous pulse wave. At the bedside, elevation of venous pressure can best be observed in the area between the 2 insertions of the sternocleidomastoid muscle, which lies over the internal jugular vein. The pulsations of the internal jugular vein cause fairly diffuse pulsations of the skin overlying this area, reflecting the underlying venous pulsations. If you can see these pulsations extending upward into the middle of the neck or up to the angle of the jaw, in a patient sitting upright, this is an important clue that central venous pressure is significantly elevated.

Auscultation of the Heart.—Gallops are diastolic events related to 2 periods of filling of the ventricles. S_3, related to the rapid filling phase, is the ventricular diastolic gallop. S_4, related to the presystolic filling phase and atrial systole, is the atrial gallop. These are low-frequency sounds and are best heard over the ventricle at the apex, listening with a very light pressure with the bell piece of your stethoscope. A gallop rhythm is one of the earliest clinical clues to heart disease and affords valuable bedside information concerning diagnosis, prognosis, and treatment.

The ventricular diastolic gallop (S_3) is frequently one of the first detectable signs of serious heart disease and/or cardiac decompensation. If you listen carefully in the patient turned in the left lateral position, and hear this type of triple rhythm, significant left ventricular disease is possibly present, especially if the patient is over age 40.

The ECG should of course be examined. However, this does not really tell you much about failure. If it shows left ventricular hypertrophy or intraventricular conduction disturbance, these suggest left ventricular impairment, but the ECG cannot tell you whether the patient is well compensated or not. It can, however, alert you to the possibility of infarction, ischemic disease, or rhythm disturbance.

The Value of Chest X-ray.—Characteristic of a patient in congestive heart failure is the so-called butterfly pattern, in which the heart is considered to be the body of the butterfly and the pulmonary edema is the wings. This pattern, due to intra-alveolar edema, results in radiodensities that are most prominent in the inner and middle zones of the lung. This is not a subtle sign of failure, as the patient will be in pulmonary edema.

A sign seen very early in the course of failure is the Kerley-B line, a linear density caused by thickening of the intralobular septa due to an increase in pulmonary venous pressure. These densities are represented by fine horizontal lines in the costophrenic angles.

What To Do About Heart Failure.—If you have the time, it is better to undertake digitalization and diuretic therapy deliberately over a period of 2 to 3 days, rather than to have to move in with acute digitalization. But if the patient requires early and immediate operation, you can digitalize rapidly, using IV digoxin. Given IV, this drug has a rapid onset of action, reaching its peak effect in about 2 to 3 hours and has a strong effect even before that. Since you can continue to use the same drug thereafter, it probably represents the agent of choice even in the circumstances of fairly rapid digitalization.

Diuretics should also be given. However, these may cause a loss of potassium, which represents a hazard through digitalis intoxication, with consequent arrhythmias. For this reason, it is advisable to monitor the serum K^+ levels carefully and replace K^+ as needed.

Another problem associated with the use of diuretics is excessive reduction of effective circulating blood volume. The physician's zeal to obtain a dry weight, to eliminate peripheral edema, and to lower distended neck veins may carry the patient too far back on the ascending limb of the Starling curve and may deprive the patient

of needed ventricular filling pressure. Because these patients may need a somewhat increased filling pressure, it is best to hedge on the side of under- rather than overdiuresis.

The same principle applies to digitalis. It is wise to underdigitalize rather than overdigitalize, to avoid such problems associated with digitoxicity as ventricular premature contractions or heart block.

Many subtle signs and symptoms of diminished cardiac compensation may be present before the onset of decompensation. These should be looked for and the appropriate therapy instituted before overt heart failure occurs.

AORTOCORONARY VEIN GRAFT FLOW. Flow through aortocoronary saphenous vein grafts and augmentation by direct intragraft injection of coronary vasodilators has prognostic importance with respect to subsequent graft closure. Following injection of sodium nitroprusside, 50 μg, directly into the graft, flow increased from 40.1 ± 4.5 to 81.3 ± 8.5 ml/min. This effect dissipated in 1.5 to 4 minutes and was not associated with statistically significant changes in blood pressure or heart rate and cardiac dysrhythmias did not occur. Similar flow changes occurred with 30 mg papaverine but the response required longer to be manifest and was associated with a greater decrease in blood pressure and a higher incidence of dysrhythmias. Furthermore, the pH of sodium nitroprusside is 7.6 and thus less likely to irritate vein intima than the more acidotic papaverine (pH 3.4). Nitroprusside may be the drug of choice for intragraft injection when immediate flow augmentation is necessary. *(Larsen PB, Yeh BK, Gentsch TO et al: Sodium nitroprusside as a coronary vasodilator in man: A comparison to the effects of sodium nitroprusside and papaverine hydrochloride on aortocoronary saphenous vein graft flow. Ann Thor Surg 21:16-18, 1976)*

Anesthetic Management

WENDELL C. STEVENS, MD*

"INADEQUATE cardiac performance can result from a severe stress imposed upon a subsystem with normal reserves, a mild stress upon one with minimal reserves, or something in between."[1] The majority of patients with heart disease tolerate anesthesia, operation, and the postoperative period without apparent irreversible worsening of cardiac function. This is true even when the heart itself is the site of operation. Although stress occurs, cardiac reserves are usually adequate to allow the patient to tolerate the stress.

Sechzer's group,[2] studying whether any of a number of events served to predict myocardial stress in patients with arteriosclerotic vascular disease, undergoing major vascular operations, found no relationship between myocardial injury and the degree of intraoperative circulatory lability, duration of hypotension, duration of operation, or volume of blood replacement. Perhaps the failure to correlate these events means stress cannot be thought of in terms of only one variable.

For example, lowering arterial pressure (AP) may decrease coronary blood flow if coronary vasodilation cannot occur. However, if myocardial O_2 demand decreases appropriate to the decrease in coronary perfusion, myocardial injury may not occur. On the other hand, increasing AP may increase coronary blood flow, but if myocardial O_2 demand increases disproportionately, myocardial ischemia may develop. The greatest threat of ischemia exists in those portions of the myocardium subject to the greatest intramural pressures relative to coronary perfusion pressure.[3]

My goal will be to describe some of the circulatory changes we expect from anesthesia, to comment briefly on the stress of operative and recovery periods, and to describe the options available when a patient with cardiac disease requires anesthesia. Some of the changes these drugs induce might be thought of as stresses; some, in fact, may be salutary. Much of the data must be extrapolated from patients with circulatory diseases investigated while about to undergo or while undergoing heart operations.

Anesthetic Agents.—The nonflammable, potent inhaled agents, halothane and enflurane, reduce cardiac output and AP.[4-6] Halothane increases right atrial pressure, apparently because the myocardial depression exceeds the ability of halothane to produce vasodilation. Enflurane also decreases cardiac output to the same degree as halothane, but decreases peripheral vascular resistance to a greater degree than halothane. Enflurane produces enough venodilation to prevent increases in right atrial pressure.

Stoelting's group,[7] measuring the intraoperative circulatory effects of halothane alone in patients undergoing heart-valve replacement, found that, at an alveolar halothane concentration of 0.55 percent, cardiac output was maintained, total peripheral resistance (TPR) decreased, and AP decreased slightly. Conahan's group[8] found that patients with valvular heart disease who received 50 percent N_2O and up to 1 percent inspired halothane showed significant decreases of AP, although the exact changes in cardiac output were not described. However, when compared with morphine, halothane tended to maintain cardiac output at a higher level, presumably because of the greater decrease of TPR with halothane.

Kemmotsu and associates[9] showed that the depression of myocardial function produced by heart failure was similar to that produced by halothane or enflurane when tested in isolated muscle strips. If failing muscle is exposed to halothane or enflurane, the drug-induced depression of contractility *begins* at a level of depressed heart function. Therefore, one can expect greater total depression from smaller doses of inhaled agents in failing than in normal hearts.

*Associate Professor, Department of Anesthesia, University of California, San Francisco, California 94143.

One may occasionally encounter profound hypotension with halothane, as with other agents, for reasons somewhat as follows: The heart uses a number of reserves in an effort to maintain cardiac output.[10] These include the Frank-Starling mechanism, development of myocardial hypertrophy, increased venous tone and arteriolar constriction, and increased sympathetic drive to the heart. The latter results in both contractility and heart-rate effects. Since parasympathetic control of the failing heart is defective[11] and decreased amounts of adrenergic transmitter are present in failing hearts,[12] these combined reserves function to maintain cardiac output and perfusion pressure. Anesthetic agents will alter one or more of these reserves. For example, if the reserve of increased blood volume has been reduced by diuretics and anesthesia produces a significant decrease in venous tone, one may see an inordinate decrease of cardiac output and blood pressure (BP).

While the addition of N_2O raises AP in healthy young volunteers,[13] N_2O may cause decrease of AP in patients with sick hearts under certain circumstances.[14] This may represent direct myocardial depression[15] or increased pulmonary or peripheral vascular resistances. The latter increases in afterload may result in reduced cardiac output.

These few data indicate that the stress imposed by potent inhaled agents will be primarily hypotension. However, because myocardial O_2 requirement will probably be reduced, the hypotension usually will be well tolerated.

Narcotic analgetics have been used for anesthesia in patients with heart disease, with an eye to maintenance of circulatory variables at awake levels.[14,16] The predominant circulatory effect of morphine is an early reduction of TPR, which returns to control values and may well rise above control values when operation begins. Lowenstein's group[17] demonstrated that cardiac output was maintained or increased and that only minor AP changes occurred, usually with decreases of TPR and increases of vascular capacitance in patients with valvular heart disease.

Comparison of Anesthetic Agents.—Somewhat greater decreases in AP will occur with halothane or enflurane; better preserved, or, with the onset of operation, increased AP may be expected with morphine. If pressure does increase during morphine anesthesia, one may be unable to reduce pressure consistently with additions of morphine.

In patients with valvular or coronary artery disease, ketamine can be expected to raise AP, primarily through increasing the heart rate.[18-20] According to Reves,[21] one is more likely to see decreases of AP with morphine than with ketamine in coronary artery disease patients, while in valvular heart disease patients, the circulatory effects, at least in terms of AP, are similar with morphine and ketamine.

Which is better: BP at or above awake values or decreased BP? Reves[21] measured the myocardial O_2 supply/demand ratio by application of the relation between diastolic pressure time index/tension time index.[3] The higher the ratio the better. Better indices occurred with the lower BP seen with morphine. The ECG showed reversal of injury patterns as well. It is likely that a BP at or slightly below awake values combined with a slow heart rate is favorable in such patients. Stanley[22] reported that when ketamine is administered concomitantly with halothane, greater circulatory depression will occur than if halothane alone is used.

Hence, one can choose an inhaled agent providing decrease of AP and cardiac output, morphine providing maintained or elevated BP and cardiac output, ketamine providing elevated BP primarily due to an increase of cardiac output from increased heart rate.

Barbiturates given by rapid IV injection influence circulatory variables significantly by producing venodilation.[23,24] Large doses of thiopental may produce myocardial depression.[25] Although a direct smooth-muscle constriction may be produced by thiopental,[26] the predominant circulatory effect of bolus administration will be vasodilation.

Diazepam[27] produces minor circulatory effects if given slowly and in small doses. It is used as a supplement to narcotic anesthesia, since narcotics produce sedation which is unpredictable in intensity or speed of onset.

The circulatory stress induced by spinal or epidural anesthesia is hypotension, which occurs because of sympathetic blockade with resultant venodilation and decreased cardiac output.[28] It is here, again, that the relation of myocardial O_2 demand to coronary perfusion is so important. Decreased myocardial O_2 demand due to slowing of heart rate,

decreased cardiac output, decreased filling pressure which may lead to decreased myocardial stretch or tension, and decreased ventricular afterload appears generally to allow tolerance of decreased coronary perfusion pressure. A patient with heart disease who has increased ventricular filling pressures, enlarged central blood volume, and relatively high systemic vascular resistance may be improved by sympathetic blockade. The circulatory effects of regional anesthesia are altered by epidural epinephrine administration, in that a greater loss of TPR and increased heart rates will occur.[29]

Sympathetic blockade can be avoided by peripheral nerve blocks—for instance, multiple intercostal blocks. In order to exploit this advantage of peripheral nerve block, however, several considerations apply. It may be important in a patient whose condition is precarious from ischemic heart disease to blunt the sympathetic stimulation of multiple injections by thorough explanation, use of a particularly gentle technic, and premedication.

Sapala and colleagues[30] recently described the incidence of cardiopulmonary complications in patients with arteriosclerotic vascular disease. Similar complication rates occurred after general or spinal anesthesia. Sapala measured a lower incidence of complications after local anesthesia but did not offer data on how anesthetics were chosen. Patients who exhibited arrhythmias or congestive heart failure without myocardial infarction had the lowest complication rates.

Effects of Operative Procedures.—Some events may enhance the stress of operation. Perhaps paramount is change of blood volume. The usual directional change is decreased blood volume resulting in reduced preload. Another stress which may not be apparent until the recovery period is change of body temperature. If temperature is increased intraoperatively, O_2 demand and hence need for increased cardiac output exist. More commonly, the temperature decreases in relation to exposure of viscera to ambient temperatures, increased duration of operation, use of muscle relaxants, cold IV solutions, and increased patient age.

Details of the effects of hypocapnea, hypercapnea, hypoxemia, changes in intrathoracic pressure and of adjuvant drugs, such as epinephrine, are beyond the scope of this discussion.

Postoperative Recovery.—Apparently, the greatest circulatory stresses occur in the postoperative period. For example, recurrent myocardial infarction occurs with greater frequency postoperatively than intraoperatively.[31] Events which place demands on the cardiac reserves include decreased body temperature, as mentioned above. Roe and coworkers[32] found that a temperature fall of between 0.3 to 1.2° C doubled postoperative O_2 consumption. Greater decreases in temperature occur in older patients; interestingly, elderly patients are less likely to increase O_2 consumption than young patients. Bay's group,[33] measuring requirements for cardiac output in postoperative patients who shiver, found 300 to 400 percent increases over normal values. The implications of this demand seem clear, although documentation of morbidity related to such increased cardiac work is not readily available.

Increased temperature will increase O_2 demand and hence cardiovascular stress. Tissue trauma also increases O_2 demand. It has long been known that demand for increased cardiac output follows operations.[34] Venous Po_2 falls postoperatively, suggesting that increased cardiac output may not compensate for increased O_2 demand. In any event, cardiac reserves are called into play.

Marshall and Wyche[35] nicely synthesized the usual postoperative hypoxemic events, showing that when hypoxemia occurs, cardiac reserves must be operative if O_2 delivery to the heart and other tissues is to be maintained. Of special significance is the relation of hypoxemia to site of operation. In subjects undergoing nonabdominal procedures, the maximum decrease in Pao_2 occurred immediately postoperatively and then rapidly returned toward normal. In abdominal operations, there was a much slower return to normal. The pulmonary complication rate also was greater following abdominal operations. With regional anesthesia, Pao_2 began to decrease several hours postoperatively and the sequence of changes thereafter was similar to that after general anesthesia used for similar operations.

Postoperative respiratory complications leading to deterioration of mechanical properties of lung will increase O_2 cost of breathing. Wilson and associates,[36] in studies done immediately after cardiac surgery, found this cost to be 29.7 $ml/m^2/min$, or 18 percent of the total O_2 requirement, compared with values of 1.4 to 4.2 $ml/m^2/min$ in subjects with normal lungs. The latter is equivalent to 1 to 3 percent of the total O_2 consumption.

Anesthesia for Patients with Heart Block and Artificial Cardiac Pacemakers

J. E. WYNANDS, MD*

MARCUS GERBEZIUS, of Germany, first described heart block in 1719. Lown and Kosowsky[1] have briefly traced the history of heart block and the various attempts to electrically stimulate the heart. The writings of Robert Adams, in 1826, and William Stokes, in 1846, firmly focused attention on the fact that a slow heart rate could produce apoplectic symptoms.

Callaghan and Bigelow,[2] in 1951, initiated the modern era of artificial cardiac pacing, while Chardack[3] developed the first fully implantable pacemaker in 1960. Since this development, great strides have been made. Electronic wizardry built into today's pacemakers has made anesthetizing a patient with heart block a relatively safe event.

Although special considerations must be given the patient with a pacemaker undergoing anesthesia, the problems presented by this situation are minor compared to those that may be encountered in the patient with heart block who does not have a pacemaker. To understand these problems, a brief review of heart block is necessary.

Heart Block.—The coordinated contractions of the atria and ventricles are accomplished by an impulse originating in the sinoatrial SA node and passing via 3 distinct pathways to the atrioventricular AV node, where the rate of propagation is slowed, the atria having contracted. The impulse then traverses the His-Purkinje system to initiate contraction of the ventricles. The His system consists of a common bundle which divides into right and left bundles. The left bundle then further subdivides into a left anterior superior fascicle and a left posterior inferior fascicle. Heart block may occur at any point in this pathway (fig 1).

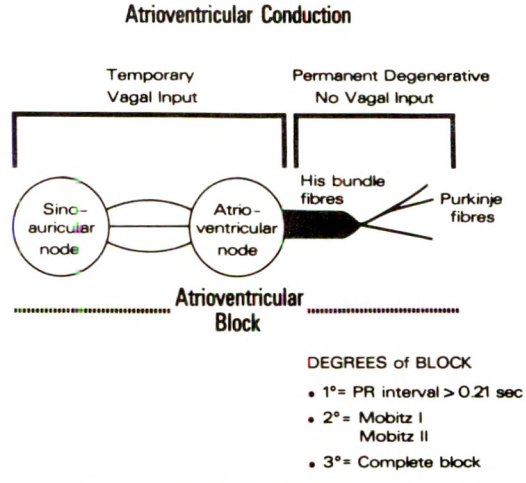

FIG 1. Atrioventricular Conduction.

When the block occurs either in the SA node, the internodal conducting system or the AV node, it tends to be of a temporary nature. Impulse formation in the SA node is greatly influenced by the level of vagal tone. Block occurring in the His-Purkinje system is termed infranodal block and is usually permanent and progressive. The His bundle electrogram[4] has made possible the precise location of the site of block in the His system and its correlation with events on the scalar electrocardiogram (ECG). Left axis deviation greater than minus 45° in the absence of an inferior infarct and pulmonary emphysema is indicative of left anterosuperior fascicle block.

Right axis deviation of plus 120° in the absence of an anterolateral infarct, pulmonary emphysema, and right ventricular hypertrophy is indicative of left posteroinferior fascicle block. This latter fascicle is anatomically the larger of the two and physiologically the more stable. Hearts that have

*Associate Professor, Department of Anesthesia McGill University, Senior Anesthetist, Royal Victoria Hospital, Montreal, Quebec, Canada.

right bundle branch block (RBBB) and left posterior fascicular block usually go on to trifascicular block. Only 10 percent of hearts with RBBB and left anterior fascicular block progress to trifascicular block. When left anterior and left posterior fascicular blocks occur together, the term left bundle branch block (LBBB) is used and is analogous to RBBB on the right side of the heart. RBBB may occur in normal hearts; LBBB is a serious finding.

First-degree heart block exists when the PR interval is greater than 0.21 sec. Second-degree heart block exists when some P waves are not followed by a QRS complex. Mobitz has subdivided 2nd-degree heart block into types I and II. Type I is characterized by a progressive lengthening of the PR interval prior to the dropping of the QRS complex. This is the classic Wenckebach phenomenon, where the block usually originates in the AV node conducting system and is reversible.

Mobitz type II heart block is characterized by a sudden dropping of a QRS complex, there having been no progressive lengthening in the PR interval. It is seen only when the block occurs in the His system and has a serious prognosis in that it frequently progresses to complete, or 3rd-degree, block. Third-degree block in the AV node is usually reversible whereas Mobitz type II block and 3rd-degree block of the His system are irreversible.

The QRS complex with 3rd-degree infranodal block is frequently wide and the ventricular rate is slow, averaging 40 bpm, although rates as slow as 15 bpm are encountered. Third-degree block of the AV node has a QRS complex of normal width and a faster rate (junctional rhythm). Complete infranodal heart block frequently results in a cardiac output which is not adequate for normal organ function. Congenital 3rd-degree heart block, because it is invariably high infranodal, is associated with a faster ventricular rate (50 bpm) which does not produce symptoms.[1,5-8]

The terms "sick sinus syndrome" and "brady-tachy" (bradycardia-tachycardia) syndrome refer to a group of rhythm disturbances resulting from failure of normal impulse formation in the SA node.[9-11] Rhythm disturbances may include (1) persistent severe sinus bradycardia; (2) intervals of sinus arrest as evidenced by absent P waves in which no escape rhythm arises or a lower ectopic pacemaker eventually takes over after several seconds; (3) paroxysmal or chronic atrial fibrillation due to temporary or permanent suppression of the sinus node; and (4) tachycardia alternating with bradycardia.[5]

K^+

Causes of Heart Block (table 1).—Heart block may occur at any age but is most commonly encountered in the 6th and 7th decades of life.[8,12] The commonest cause of heart block is a primary organic disruption of the His conduction system by Lenègre's or Lev's disease. The former is a sclerodegenerative process of the terminal portions of the fascicles and the latter is a fibrous encroachment of the proximal His conduction pathway from the fibrous structures surrounding it. These are the annuli of the mitral and tricuspid valves, the right fibrous trigone and the membranous portion of the interventricular septum. Similar primary degenerative changes may also involve the intra-atrial conduction system, producing a sick sinus syndrome.

The next commonest cause of heart block is coronary artery disease. The interruption of conduction may be due to a myocardial infarction or ischemia. The area and severity of heart block will depend upon the vessel affected. Involvement of the right coronary artery, which supplies the SA node in 55 percent of hearts, may temporarily produce SA node dysfunction on the basis of autonomic imbalance. A posteroinferior myocardial infarction will interfere with the blood supply to the AV node and frequently produce heart block which is usually transient.

TABLE 2
Indications for Pacing

LBBB and 1° heart block
↓ ↓
Stokes-Adams attacks
Angina
Heart failure
Ventricular irritability

It is not uncommon to find RBBB plus left anterior fascicular block with occlusion of the left anterior descending coronary artery. Trifascicular block on the basis of coronary artery occlusion implies massive muscle involvement which is usually not compatible with life.

Heart block is also frequently encountered with cardiomyopathies and myocarditis, and is well known in association with the surgical correction of congenital heart disease. These causes of heart block are organic in nature and generally permanent.

Other causes of heart block are functional and reversible. These include increased vagal tone and drug therapy with digitalis, quinidine, procainamide, propranolol and potassium. The vagus nerve has no effect on the infranodal conducting system whereas quinidine, procainamide, and propranolol depress conduction in the bundle of His.

Indications for Pacing (table 2).—Artificial pacemaker insertion is indicated when the patient has an impulse formation or conduction defect resulting in a heart rate and cardiac output that do not give adequate organ perfusion.[5,7,8,13,14] The reduction in heart rate is compensated for by an increase in stroke volume up to a maximum which will depend upon the state of health of the myocardium. In the face of a severely decreased cardiac output, blood pressure will be maintained by increasing peripheral resistance. When blood pressure falls, a point will be reached where organ failure will produce symptoms.

Heart block patients who have a history of Stokes-Adams attacks, angina, heart failure, or ventricular irritability are at great risk if subjected to general anesthesia,[15,16] which may precipitate heart block. General anesthesia also depresses myocardial function and peripheral resistance and, therefore, may cause organ failure in a patient who is barely compensating for his heart block.

Patients with bilateral fascicular block and a high degree of heart block who do not have symptoms are controversial.[5,7,14] The heart block, if originating in the AV node, may respond to atropine. Kastor[7] believes that patients with a type II 2nd-degree block should have a demand pacemaker even though they are asymptomatic.

Types of Pacemakers (table 3).—Fixed-rate pacemakers are ideal for patients with chronic complete heart block and a slow ventricular rate. Otherwise, a demand pacemaker should be employed; the ventricular-inhibited model is the most popular of these. The fixed-rate and the ventricular-inhibited demand pacemaker can be used with unipolar or bipolar leads via a transvenous or transthoracic approach. The most popular approach currently employed is transvenously through the cephalic vein in the deltopectoral groove.

Factors Affecting Pacing (table 4).—Alterations in the pacing threshold may markedly affect the performance of the pacing system. An increase in threshold may lead to intermittent or permanent failure of pacing. A decrease in threshold may induce ventricular fibrillation during the vulnerable period of the cardiac cycle. Normally, 30 ma current is required, and the standard pacemaker develops 10 ma. The threshold may be lowered to the point where the 10 ma current delivered by the battery is sufficient to induce ventricular fibrillation. Succinylcholine,[17] hyperkalemia,[17] and acid-base disturbances will raise the threshold. Hughes and coworkers[18] have reported an

Low threshold—Ventricular fibrillation	

increase in voltage requirements from 71 to 82 percent when the base excess was minus 15 and plus 15, respectively. Exercise, catecholamines, hypoxia, ischemia, and myocardial infarction reduce the pacing threshold.

Anesthesia for Pacemaker Implantation.—With this background, it is now appropriate to consider anesthesia for the implantation of a pacemaker, the change of a pacemaker battery, and for patients who have a pacemaker in place and are to undergo a surgical operation. It has been stated that heart block typically occurs in the 6th and 7th decades of life and the need for a pacemaker is dictated by symptom-producing heart block. These patients, because of their age, may have many associated diseases demanding specific considerations if morbidity and mortality are to be minimal. Their myocardial function may vary from bordering on normal to being barely compatible with life. The problems of assessing and anesthetizing a patient with severe heart disease will have been considered by other members of the panel.

A complete array of drugs and equipment must be at hand for cardiopulmonary resuscitation. The minimum requirements are a finger on the pulse, the ECG display on the oscilloscope, a DC cardiac defibrillator, and the usual drugs necessary for cardiac resuscitation.

Transvenous endocardial electrodes are most commonly employed with the implantation of a pacemaker. We, as others,[8,19] are firmly convinced that the electrodes should be inserted under local anesthesia. Patients who have heart block with symptoms and are submitted to general anesthesia are likely to develop cardiac standstill, ventricular tachycardia, or ventricular fibrillation.[15] Local anesthesia may be supplemented with light sedation. We use diazepam, finding that as little as 2.5 to 5 mg IV may be all that is required to calm the apprehensive patient.

It has been our experience that if the patient begins to object, the remedial action is not to increase sedation and thus verge on general anesthesia, but rather for the anesthesiologist to reassure the patient and have the surgeon stop the surgical procedure until adequate anesthesia at the operative site has been secured with the infiltration of additional local analgesic agent. We have found 0.5 percent lidocaine with epinephrine 1:200,000 ideal for this purpose.

This technic also makes possible creation of a pocket for the battery. The alternative is to secure pacing and then induce general anesthesia for the implantation of the battery, using a temporary external battery until the pocket is created and the implantable battery can be quickly secured to the leads and slipped into the pocket.

A thoracotomy is required for epicardial leads, which have been successfully implanted under local anesthesia and sedation.[20] We believe that such patients should have a temporary transvenous pacemaker inserted under local anesthesia, pacing secured, and the epicardial electrodes implanted under general anesthesia[21] appropriate for patients with cardiac disease, as discussed by other members of the panel.

Anesthesia for Battery Change.—A battery change is indicated when there is evidence of battery failure. In most instances, this is indicated by a slowing of the heart rate, which will signal complete failure of the battery in 7 to 20 days. Batteries may be elective ly changed just prior to the manufacturer's stated life expectancy of the battery. If the pacing system is functioning, the battery can be changed under general

anesthesia, recognizing that there is a critical point when the functioning battery is removed and the new battery secured to the leads and implanted into the pocket.

During this period the patient may revert to the rhythm for which he originally had the pacemaker inserted or cardiac standstill may occur. If the procedure is not quick and smooth, the heart, particularly in the presence of general anesthesia, may go into ventricular tachycardia or fibrillation. For these reasons, we believe batteries should be changed under local anesthesia with 0.5 percent lidocaine with epinephrine, 1:200,000, plus light sedation.

Anesthesia for Patients with Pacemakers. —Williams[5] stated that in 1974, 1/5000 North Americans were living with an implanted pacemaker. Johansson reports that in Sweden there are 63 new cases of complete heart block per million population per year.[17] It is obvious from these data that anesthesiologists will be increasingly faced by patients with pacemakers, and, from what has been said above, that the patient with heart block and symptoms is at much greater risk without a pacemaker than with one.

When the anesthesiologist is faced with a patient who has a pacemaker, we believe the procedure to be carried out should be as follows:

The reason for the implantation of the pacemaker should be known, as well as the type of pacemaker and its manufacturer's specifications.

It should be established that the pacemaker is functioning. This is achieved by monitoring the ECG, observing the pacemaker artifact, and assuring effective pacing. Failure of pacing may be due to battery failure, disruption of electrodes or failure of capture at a myocardial level (fig 2). A problem arises in a patient with a demand pacemaker of the ventricular-inhibited type when the patient's rhythm is such that the pacemaker is sensing the R wave but not having to initiate an impulse. The pacemaker should be converted with a magnet to a fixed-rate type and effective pacing assured.

Care must be taken to avoid trauma to the battery or damage to the leads. Transvenous pacemakers may be dislodged by placing the patient into an unusual position —for instance, hyperextending the arm of a patient with a temporary transvenous pacemaker placed through the brachial vein. This is also more likely to occur when the endocardial electrode has been in place for only a short time. The electrodes eventually become securely attached to the heart by endocardial reaction, but we have had patients whose electrodes became displaced as late as 2 weeks after implantation.

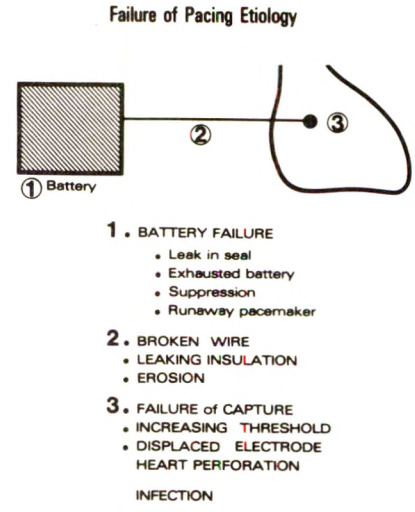

FIG 2. Failure of Pacing Etiology.

Factors which alter the pacing threshold, as described above, must be avoided. It must be emphasized that sudden reductions in cardiac output, as may occur with a massive hemorrhage or by suddenly taking the legs out of the lithotomy position, may result in myocardial ischemia and a lowered threshold. The adequacy of venous filling of the heart should be guaranteed.

Electrical Interference with Pacemakers. —Pacemakers may be adversely affected by electromagnetic fields.[17] These include cautery, diathermy, and radar impulses within physiologic range. In general, bipolar electrodes and fixed-rate pacemakers are less susceptible to electrical interference than unipolar leads and demand units.

Although there have been great technologic advances in the insulation of pacemakers, the grounding plate of the cautery should be placed as close to the operative site as possible and as far from the battery as possible. The cautery should not be used within 15 cm of the battery, not only because it may interfere with the battery circuitry, but also because if the cautery should come in contact with a break in the insulation of the electrode, the high-frequency current may cauterize the myocardium at the tip of the electrode, rendering it insensitive to pacing impulses.

When a situation exists that an electromagnetic field may be interfering with pacemaker function, the patient's hemodynamic stability must be monitored by following the pulse rate and blood pressure. If electrical interference occurs, the offending field must be turned off. If this is disadvantageous, as during a transurethral prostatic resection, the demand pacemaker should be converted to a fixed-rate unit, which may obviate the electrical interference from the cautery.

Inapparent signals from shortcircuits in the battery, from skeletal muscle, and from concealed premature ventricular contractions have been reported to interfere with demand pacemakers.[22] Outside the operating room, even microwave ovens and electric shavers may interfere with battery function.

The anesthesiologist with the above guarantees should then proceed to give an anesthetic best suited for the surgical requirements in view of the patient's medical status, knowing that the presence of the pacemaker is another factor adding to the safety of the patient with heart block during his operative and anesthetic experience.

CONCLUSIONS

A cardiac pacemaker is indicated when heart block results in Stokes-Adams attacks, heart failure, angina, or life-threatening ventricular arrhythmias. Heart block of this magnitude usually occurs in the 6th and 7th decades of life and is due to a degenerative process of the conducting system of the heart, although it is also seen earlier in life following myocardial infarction, myocardial inflammatory processes, and certain drug intoxications.

Because we are dealing with a geriatric population who may have associated diseases or with patients in a lower age group with severe myocardial disease, it is safest that temporary and permanent transvenous pacemakers be inserted under local anesthesia with appropriate sedation. A temporary transvenous pacemaker should be installed under local anesthesia prior to the implantation of a permanent transthoracic pacemaker under general anesthesia. When a pacemaker battery is to be changed, it can be safely and easily done under local anesthesia, again with appropriate sedation.

A patient with a pacemaker undergoing a surgical procedure is subject to various risks inherent to having a pacemaker. Patients with a fixed-rate pacemaker run the risk of sudden ventricular fibrillation if the pacemaker impulse falls in the vulnerable period of the cardiac cycle which corresponds to the upstroke of the T wave. Normally, 30 ma current is required to induce fibrillation during this period. This threshold will be markedly reduced by cardiac ischemia.

Patients with demand pacemakers may have their pacemakers suppressed by electromagnetic fields, the commonest cause being the cautery. This event can only be detected by monitoring the pulse, and fortunately the pacemaker usually resumes normal function as soon as the offending electromagnetic field is turned off.

Pacemaker failure may result in cardiac standstill, ventricular tachycardia, or ventricular fibrillation. In some instances, the pacemaker having been suppressed, the patient will revert to the heart rate for which the pacemaker therapy was instituted. In any event, all patients must be carefully monitored and all resuscitative drugs and procedures held in readiness should cardiovascular collapse be encountered following pacemaker failure.

ROUTINE PHENOBARBITAL. Phenobarbital may increase the activity of glucuronyl transferase and facilitate the production of water-soluble bilirubin. Administration of this drug prenatally may reduce the incidence of neonatal hyperbilirubinemia. Starting at 36 weeks gestation, 221 prenatal patients received oral phenobarbital 16 mg 4 times daily. Serum bilirubin levels exceeded 10 mg/dl in 4.1 percent of infants exposed to phenobarbital before birth. In contrast, serum bilirubin exceeded this level in 16.3 percent of infants not exposed to phenobarbital. Routine phenobarbital therapy may be a safe and effective method of preventing neonatal hyperbilirubinemia. *(Thomas CR: Routine phenobarbital for prevention of neonatal hyperbilirubinemia. Obst Gyn 47:304-308, 1976)*

Drugs in Cardiac Supportive Care

ROGER D. WHITE, MD*

IT IS essential to consider several basic principles of drug therapy when one elects to use drugs in any situation. This has critical implications in patients with cardiac disease. Some of the questions to be answered are: What is the precise indication for drug intervention? Which drug is most appropriate? What are the possible or likely side effects? Does drug therapy carry a risk of adverse effect that might, in fact, worsen the situation?

This presentation is directed at emergencies, or potential emergencies, for which drug treatment might be considered life-saving. As such, it falls within the province of resuscitation and emergency cardiac care. Objectives of intervention with drugs in this context include: to slow or to accelerate cardiac rate; to suppress ventricular ectopic activity; to stimulate spontaneous or more forceful myocardial contractions; to increase perfusion pressure; to correct metabolic acidosis.

The use of drugs in emergency cardiac care is discussed within the framework of several clinical situations in which urgent drug therapy is indicated. Specific drugs that are useful, and even essential, in emergency management include digoxin (or other rapid-acting digitalis glycosides), propranolol, atropine, lidocaine, procainamide, isoproterenol, epinephrine, calcium chloride ($CaCl_2$), and sodium bicarbonate ($NaHCO_3$).

The Need for a Planned Approach.—Unfortunately, in the presence of life-threatening crises, it is almost never possible to take time to ask and to answer all questions. Physicians involved in the management of patients with life-threatening crises, therefore, must have a well-planned and organized approach to such events in advance of their occurrence. This discussion will attempt to develop such an approach to several potentially life-threatening problems in patients with cardiac disease. The orientation is deliberately practical, without details of the theoretic considerations that underlie both the problems and their management. Furthermore, since "cardiac disease" encompasses a whole spectrum of lesions and related complications, primary consideration will be directed toward patients with coronary artery disease.

It must be emphasized that before the approach outlined herein is applied, all other factors in the anesthetic circumstance which might be causing or contributing to the apparent complication must be ruled out. These include, among others, inadequate ventilation, too light or too deep anesthesia, and electrolyte imbalance. The assumption that these have been considered will be made throughout this discussion.

Some of the questions to be reviewed are these: What circumstances might necessitate prompt drug intervention? In those circumstances, what specific indicators are there for drug treatment? What are the appropriate drugs and doses? What side-effects might be anticipated? These questions will be considered in the context of some of the potentially life-threatening conditions that may suddenly develop in patients with cardiac disease under anesthesia, particularly in patients with coronary artery disease.

The following outline will be used to identify conditions that might necessitate rapid intervention with drug therapy:

I. Cardiac dysrhythmias
   - A. Supraventricular
     1. Bradydysrhythmias—sinus or junctional
     2. Tachydysrhythmias — atrial flutter, atrial fibrillation, paroxysmal atrial tachycardia
   - B. Ventricular
     1. Ventricular premature beats (VPBs)
     2. Ventricular tachycardia
     3. Ventricular fibrillation

*Assistant Professor of Anesthesiology, Mayo Medical School, Rochester, Minnesota 55901.

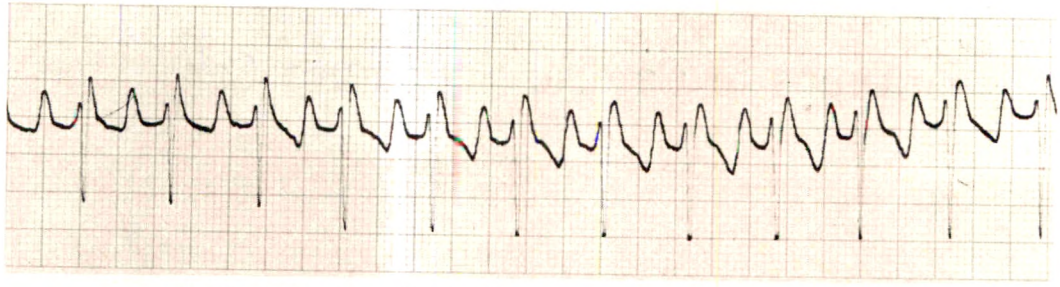

FIG 1. Atrial flutter with 2:1 A-V conduction. Ventricular rate 130 bpm.

FIG 2. Atrial fibrillation with rapid ventricular response. Ventricular rate approximately 160 bpm.

C. Atrioventricular (A-V) block
   1. Second-degree (Mobitz I and II)
   2. Third-degree (complete heart block)

II. Acute hypotension or hypertension

III. Cardiopulmonary arrest

I. Cardiac Dysrhythmias.

A. Supraventricular. 1. Bradydysrhythmias—Sinus or Junctional.—Slowing of the heart rate as an apparent result of reflex vagal activity during a surgical procedure is well known to anesthesiologists. The cardiac vagolytic action of atropine predictably produces an increase in the rate. Because heart rate is a major determinant of myocardial O_2 requirement,[1] acceleration of the rate in patients with coronary artery disease may disturb the relationship between myocardial O_2 supply and demand, leading to acute myocardial ischemia.[2]

Supraventricular bradycardia that does not compromise cardiac output or permit ventricular escape ectopy usually does not require treatment. If, however, bradycardia is accompanied by hypotension or frequent ventricular ectopic escape beats, treatment is necessary. Atropine can be given IV in increments of 0.3 to 0.5 mg until the desired rate is attained (usually around 60 to 70 bpm).

2. Tachydysrhythmias. — Atrial flutter (fig 1) may become life-threatening if the ventricular response is rapid enough to produce an acute fall in cardiac output and is accompanied by hypotension. In addition to the rapid ventricular rate, the myocardial O_2 requirement is increased and the coronary flow is compromised by the abbreviated diastolic time. This applies to rapid ventricular rates in all tachydysrhythmias and is a major reason why tachydysrhythmias may be poorly tolerated in the presence of coronary artery disease.

Atrial flutter is usually sensitive to direct-current (DC) cardioversion, which is the treatment of choice when possible. If impossible, and if hemodynamic deterioration is present, rapid digitalization should be carried out. Digoxin (0.5 to 0.75 mg) should be given IV, then 0.25 mg every 4 to 6 hours until the ventricular rate is controlled. If the ventricular rate is poorly controlled by digitalis, propranolol in 0.5-mg increments up to 3 mg can be given IV, slowly and cautiously. Congestive cardiac failure and pulmonary disease with a bronchospastic component are contraindications to propranolol. It must be kept in mind that acute congestive failure may be *precipitated* by the rapid ventricular rate.

In general, the same principles apply to the acute management of atrial fibrillation with a rapid ventricular rate (fig 2) and paroxysmal atrial tachycardia (fig 3). If hemodynamic deterioration develops rapidly after onset of these dysrhythmias, DC cardioversion should be employed when

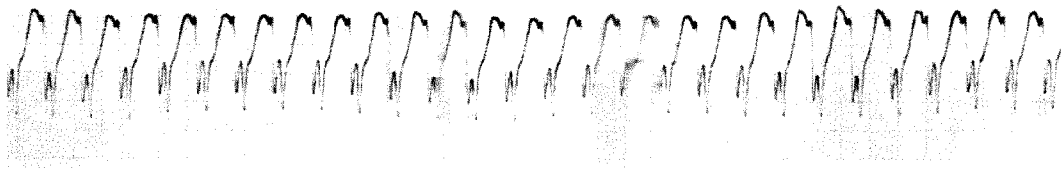

FIG 3. Paroxysmal atrial tachycardia in patient with known Wolff-Parkinson-White syndrome. Ventricular rate 220 bpm. Hemodynamic deterioration necessitated immediate DC cardioversion.

available. Otherwise, rapid digitalization is necessary to control the ventricular rate.

B. Ventricular. 1. Ventricular Premature Beats.—Ventricular ectopic activity, whether due to enhanced automaticity or reentry,[3] may be electric evidence of acute myocardial ischemia.[4] The probable role of the slow response action potential (the slow inward current) in the genesis and maintenance of reentrant dysrhythmias has recently been reviewed.[5] It is likely that the slow response action potential accounts for much of the ectopy seen in the early phase of acute myocardial ischemia.[6]

When ischemia is likely to be the cause of dysrhythmias, prompt pharmacologic suppression is usually necessary, since ventricular ectopic activity may progress rapidly to ventricular tachycardia or ventricular fibrillation (VF) or both. VPBs that are frequent (>5/min), multiform, close coupled (near the apex of the preceding T wave), or recurring in bursts or salvos of two or more in succession generally are considered specific indications for drug suppression[7] (fig 4). The drug of choice in such circumstances is lidocaine. A bolus of 75 to 100 mg (1 mg/kg) can be given IV and repeated PRN every 3 to 5 minutes up to a total of about 300 mg.[8] In order to sustain the plasma level of lidocaine in a suppressive range (1.5 to 5.5 μg/ml) it is necessary to follow the bolus with a continuous infusion of lidocaine at 1 to 4 mg/min.[9] This can be done by adding 1 gm of lidocaine to 250 ml of 5 percent dextrose in water (D/W) (4 mg/ml lidocaine) and infusing the solution via a

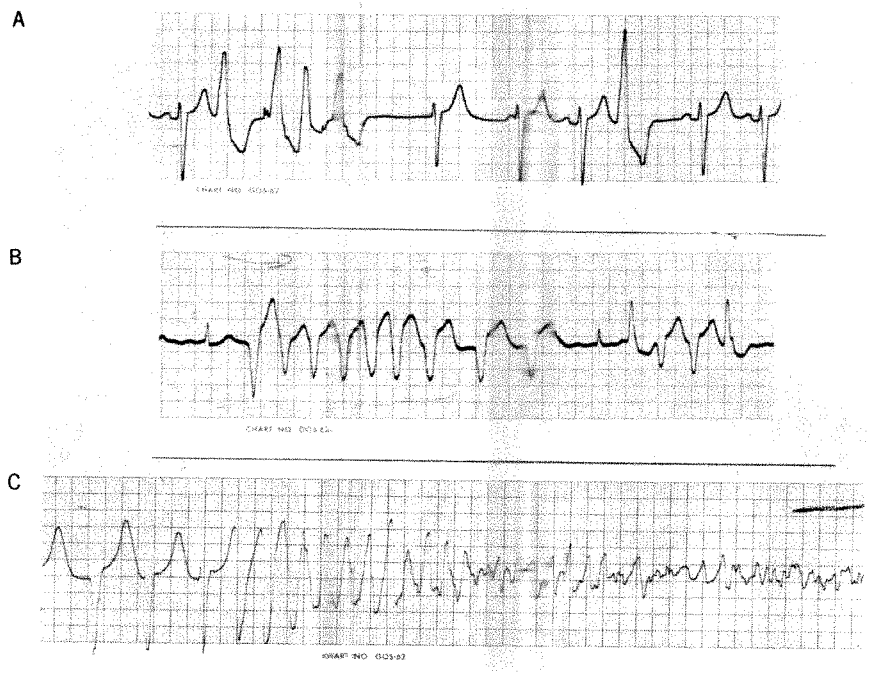

FIG 4. A. Ventricular ectopy, with run of 4 successive VPBs on left, followed by junctional escape beat. B. Burst of ventricular tachycardia. C. Brief burst of ventricular tachycardia initiated by close-coupled VPB (4th beat from left) with rapid degeneration into VF.

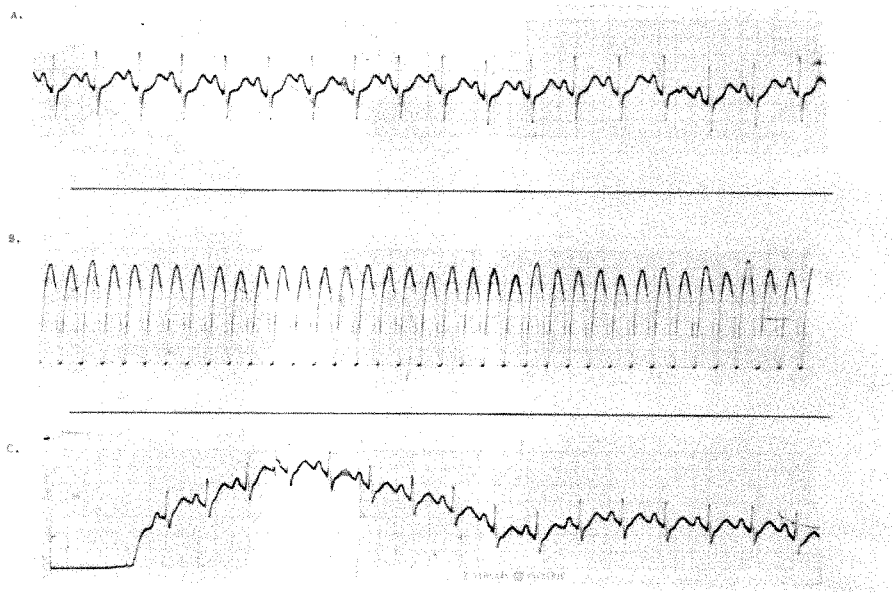

FIG 5. Sequential tracings in 50-year-old man with triple-vessel coronary artery disease undergoing anesthesia and surgery. A. Before induction: sinus tachycardia, 115 bpm. B. Prior to draping, while receiving halothane-N_2O-O_2: ventricular tachycardia, 250 bpm. Systolic pressure 50 torr. C. Immediately after 100 mg lidocaine IV and 200 watt-seconds DC countershock: sinus tachycardia, 120 bpm.

microdrip apparatus, initially at 60 microdrops/min (4 mg/min).

Lidocaine undergoes hepatic degradation. If cardiac output and hepatic blood flow are impaired or if hepatic disease is present, lidocaine toxicity will develop if the dose is not reduced. Plasma levels of lidocaine in excess of 6 μg/ml are likely to be associated with toxicity, usually related to the central nervous system.[7]

If lidocaine is ineffective in suppressing the ectopy, as may infrequently be the case,[10] procainamide can be used. It is given IV at a rate of 25 to 50 mg/min until adverse reactions occur, the dysrhythmia is terminated, or a total dose of 1 gm is given.[11] The ECG and the blood pressure must be observed closely, since procainamide may produce hypotension and ECG changes indicative of toxicity, usually widening of the QRS interval. Given in this manner, it can be used safely and effectively to suppress lidocaine-resistant ventricular ectopy.

2. Ventricular tachycardia (fig 5) can produce a precipitous decrease in cardiac output and blood pressure—even frank cardiopulmonary arrest. In such cases, *immediate* DC cardioversion is the treatment of choice, followed by injection of lidocaine as a bolus and by infusion as just described. If hemodynamic deterioration is not present, lidocaine as a bolus and an immediate infusion can be given. If this treatment does not cause the rhythm to improve promptly, DC cardioversion should be used, since ventricular tachycardia may rapidly degenerate into VF.

3. Ventricular fibrillation is a lethal dysrhythmia. Immediate treatment is DC defibrillation, followed by an injection of lidocaine as a bolus of 75 to 100 mg and an infusion at 1 to 4 mg/min. It must be emphasized that in the presence of myocardial ischemia, both ventricular tachycardia and VF, if terminated by DC countershock, must be followed by lidocaine therapy in order to maintain suppression of the ventricular ectopy and to prevent recurrence of the dysrhythmias.[7]

C. Atrioventricular Block.—As first-degree A-V block is not a life-threatening disorder, it will not be discussed here.

1. Second-degree block is classified as Mobitz I and Mobitz II. Mobitz I block is of the Wenckebach type, in which there is progressive lengthening of the P-R interval before the dropped ventricular response. This form of block, which is almost always at the junctional level, may accompany acute myocardial infarction of the inferior wall.[12] No treatment is usually required, since the ventricular rate is adequate, even if complete block should develop (the A-V

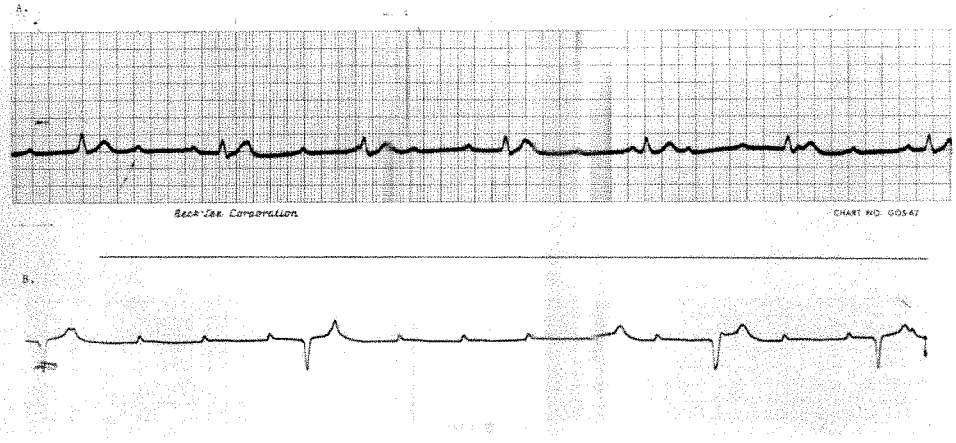

FIG 6. Complete A-V block. A. Atrial rate 90 bpm; ventricular rate 36 bpm. B. Atrial rate 77 bpm; ventricular rate variable, 25 to 30 bpm.

junction is usually the escape pacemaker in such cases). If the ventricular rate is associated with hypotension, atropine can be used in increments of 0.3 to 0.5 mg.

In Mobitz II A-V block, dropped beats occur, but the P-R interval of all conducted beats is constant. The conduction defect is below the A-V node, and in most cases there is some degree of bilateral bundle branch block.[12] Should this form of block develop, transvenous pacing is indicated, since progression to complete heart block will be accompanied by unusually slow ventricular rates of 30 to 40 bpm. Attempting to accelerate the ventricular rate with atropine or isoproterenol may slow the ventricular rate by increasing the degree of block.[13]

2. Third-degree A-V block (complete heart block) (fig 6) is usually accompanied by idioventricular escape rates of 30 to 40 bpm. Definitive treatment is cardiac pacing; this should be accomplished as soon as possible. It may be necessary to sustain the ventricular rate while preparations for pacing are made; atropine in increments up to a total of 2 mg can be tried. An infusion of isoproterenol is more likely to be effective. For this, 1 mg of isoproterenol can be added to 250 ml of 5 percent D/W, and this solution can be infused via microdrip until a sufficient ventricular rate is attained, usually 50 to 60 bpm.

II. Acute Hypotension or Hypertension.— The fundamental problem developing from either hypotension or hypertension in patients with coronary artery disease relates to an acute imbalance between myocardial O_2 supply and demand. Hypotension, by reducing pressure-dependent coronary blood flow, can produce acute myocardial ischemia, and the patient must be treated promptly. Hypertension, by increasing left ventricular wall tension, a major determinant of O_2 requirement, can increase myocardial O_2 demand. In the anesthetized patient, the initial evidence of acute myocardial ischemia produced by either hypotension or hypertension is S-T-T wave displacement or inversion on the ECG. Almost always the cause can be identified and appropriate treatment can be instigated. For example, acute and severe hypertension and tachycardia may accompany and follow laryngoscopy and intubation if anesthetic depth is insufficient. If this occurs, prompt control usually can be achieved by administration of anesthetic agents.

If hypotension is a manifestation of acute pump failure, vasoactive drug support may be necessary. Dopamine is useful in this circumstance,[14] and 200 mg is added to 250 ml of 5 percent D/W. Initially 2.5 μg/kg/min can be infused via microdrip and increased or decreased according to response.

Sodium nitroprusside is a relatively recent addition to drug alternatives in supportive cardiac care.[15] It is useful in the control of hypertensive crises, but it may also be employed in acute left ventricular failure accompanying myocardial infarction, because of its systolic unloading effect (a reduction in left ventricular afterload).[15,16] It is given as a constant IV infusion from a dilution of 50 mg in 500 ml of 5 percent D/W. The infusion can be started at 0.5 μg/kg/min and adjusted according to response.

These are only two of the pharmacologic options available in the presence of hypotension or hypertension. It is apparent that the cardiac origin of the crisis needs to be clearly established before such therapy is employed. If acute cardiac failure is present, hemodynamic monitoring should include direct arterial and pulmonary capillary wedge pressure as soon as feasible.

III. Cardiopulmonary Arrest. — Cardiopulmonary arrest may result from VF (or pulseless ventricular tachycardia), ventricular asystole (standstill), or cardiovascular collapse (electromechanical dissociation). Proper management of cardiopulmonary arrest necessitates a knowledge of, and performance ability in, both basic and advanced cardiac life support.[17] The specifics of advanced treatment modalities are reported by the American Heart Association.[18]

Ventilation with 100 percent O_2 must be instituted as soon as possible, for reasons well known to anesthesiologists. They include low cardiac output during cardiopulmonary resuscitation and intrapulmonary shunting, both major causes of hypoxemia.

Metabolic acidosis, the inevitable accompaniment of the arrested state, is treated with $NaHCO_3$, ideally with measurement of arterial blood-gas tension and pH as guides to therapy. Empirically, 1 mEq/kg can be given initially and repeated once if necessary. Thereafter, one-half the initial dose is given. Metabolic alkalosis, hyperosmolality, and retention of Na^+ and H_2O are possible consequences of administration of excessive $NaHCO_3$.

Ventricular fibrillation, as already pointed out, is best treated promptly by DC defibrillation, followed by lidocaine. If the fibrillation is fine, it can be converted to a coarse fibrillation more responsive to countershock by giving IV 0.5 mg (5 ml 1:10,000) of epinephrine. This can be repeated every 5 minutes, if needed. The patient with coarse VF that is unresponsive to defibrillation or that reverts repeatedly after temporary conversion should be treated with lidocaine as both bolus and infusion. If refractory VF persists, propranolol in 1-mg increments, along with 1.2 to 2.4 mg of atropine, can be given.[19] The total dose of propranolol probably should not exceed 3 to 5 mg. Hypoxemia and metabolic acidosis must be corrected before defibrillation can be expected.

Ventricular standstill is the most ominous form of arrest. After oxygenation and treatment for metabolic acidosis, 0.5 mg of epinephrine or 250 to 500 mg (10% solution) of $CaCl_2$, or both, can be tried. These can be repeated, or isoproterenol as an infusion can be begun.

Electromechanical dissociation is best treated with $CaCl_2$ in the foregoing doses to improve the cardiac inotropic state and, hence, cardiac output. If calcium is ineffective, epinephrine can be added. Hypoxemia and metabolic acidosis must be corrected before results can be expected in any of these causes of arrest.

RATE-PRESSURE PRODUCT. The product of heart rate and systolic blood pressure correlates with myocardial oxygen requirements. The constancy of this product during right atrial pacing induced anginal pain with or without angiotension produced hypertension was studied in 12 patients. Without angiotension produced elevations in blood pressure angina occurred at a heart rate of 100 beats/min and a systolic blood pressure of 139 torr. When systolic blood pressure was increased to 176 torr angina occurred when the cardiac rate was 131 beats/min. Despite the differences in rate and pressure the resulting rate-pressure product at which angina occurred was similar with or without hypertension. These data support the hypothesis that there is a constant myocardial oxygen consumption for each patient at which angina develops regardless of whether there is a relatively greater increase in heart rate or blood pressure. In contrast, drugs may change the angina threshold. For example patients exercising after nitroglycerin develop angina at a higher rate-pressure product while after propranolol the product at the onset of angina may be reduced. *(Cokkinos DV, Voridis EM: Constancy of pressure-rate product in pacing-induced angina pectoris. Brit Ht J 38:39-42, 1976)*

Anesthesia for Patients Early After Infarction

EMERSON A. MOFFITT, MD*

FOR an elective operation, sound advice, from Tarhan's study,[1] is to wait at least 6 months after a myocardial infarction (table). Tarhan's group documented the incidence of reinfarction occurring within a week of operation as 37 percent for patients anesthetized within 3 months of infarction. Waiting 3 to 6 months after infarction before operation reduced the incidence to 16 percent. The incidence of postoperative reinfarction stabilized at 5 percent after a 6-month interval from the previous infarction. The period of highest risk of anesthesia and operation is the first 15 days after infarction, with the new segment of dead and ischemic muscle present.

Everyone practicing clinical anesthesia has been, or sometime will be, faced with the necessity of anesthetizing a patient within 6 months of infarction. While only life-threatening emergencies should be operated upon early after infarction, they do occur and operation must be done. Other than the rare occurrence of appendicitis or a strangulated hernia, the most likely true emergency early after infarction is embolectomy. A pulmonary embolus may require whole body perfusion for removal: an anesthetic challenge of great magnitude. More likely is a clot from the left atrium, occluding a regional artery. An embolus to a femoral or brachial artery can be quite simply removed, but if infarction of bowel occurs from a mesenteric arterial embolus, a more major anesthetic procedure is required, with a much higher risk.

A. *Preoperative Assessment.*

The major areas for assessment include:

(a) *Circulatory.* Here is the site of the problem: the weakened myocardium. How reduced is peripheral blood flow? Are the limbs dusky and cool? Is there frank congestive failure? Is there hypotension, with or without vasoconstriction? Is there a slow or fast pulse rate or arrhythmias? Is urinary output adequate?

(b) *Respiratory.* Has the patient dyspnea or hypoxemia, with or without an increased inspired O_2 concentration? Does he need assistance with ventilation?

(c) *Laboratory work.* Are hematocrit,

TABLE

Myocardial Infarction After General Anesthesia: Relation to Interval from Previous MI to Surgery, by Sex[1]

Months	MI in men (M)		MI in women (W)		Percent MI again (M + W)
	Previously	Again postop	Previously	Again postop	
0-3	8	3			37
4-6	15	3	4		16
7-12	31	2	11		5
13-18	26	1	1		4
19-24	19	1	2		5
25+	186	10	46	1	5
Old MI, age not recorded	64	7	9		10
Total	349	27	73	1	6.6

*Professor and Head, Department of Anaesthesia, Faculty of Medicine, Dalhousie University, Halifax, Canada.

clotting factors, and electrolytes normal? Has he been taking anticoagulants? Is whole blood available and cross-matched?

(d) *Drugs.* These patients may be on a variety of cardiosupportive drugs, from digitalis, diuretics, propranolol and lidocaine to the catecholamines by drip.

One can readily see that the more affirmative answers there are to the above questions, the greater the risk of anesthesia and operation.

B. *Electrocardiographic Picture of Acute Infarction.*

Three zones in the region of an infarct are involved:

(a) A peripheral zone of ischemia causes inversion of the T wave due to altered repolarization.

(b) Next, a zone of muscle injury causes elevation of the S-T segment.

(c) The central zone of infarction, or death of muscle, causes Q or Q-S waves, due to absence of a depolarizing current from the dead tissue, plus opposing currents from other parts of the heart.

During recovery from the infarct (the subacute and chronic stages), the S-T segment is often the first to return to normal, then the T wave, due to disappearance of the zones of injury and ischemia.

C. *Basic Rules for Anesthetic Management.*

The paramount necessity is to maintain the already precarious circulation. The principles are:

(a) Use as light a level as is possible for the particular operation. Often, only analgesia and amnesia are needed, or regional anesthesia.

(b) Many combinations of drugs are possible, and can be used safely in small, careful doses.

(c) Assure an elevated inspired O_2 concentration and adequate ventilation.

(d) Keep the blood volume optimal: replace losses early.

(e) Treat abnormalities of rate and rhythm vigorously.

(f) Monitor closely.

D. *Effects of Anesthetic Drugs.*

All the potent agents depress myocardial contractility and dilate the peripheral vascular bed in direct relation to their concentration in arterial blood. The inhaled gases do this in the decreasing order of: halothane, methoxyflurane, enflurane, and N_2O. However, the risk of hypoxemia is incurred in using N_2O in the patient with a precarious circulation.

The opiates and Innovar® do not depress the myocardium particularly, but by arteriolar dilation they can produce hypotension in a vasoconstricted patient. Several drugs often given to these patients, such as lidocaine, quinidine, and diphenylhydantoin, can prolong the action of tubocurarine.

E. *Anesthetic Technics.*

The best approach depends on the site and kind of operation, as well as the length of time after the infarction.

The myocardium is most easily depressed during the first 30 postinfarction days. This early period also has the greatest likelihood of thrombus formation in the left atrium, requiring peripheral embolectomy. For the latter, local infiltration, small doses of diazepam and opiates, plus O_2 by mask, usually suffice.

The circulation is more stable after the 1st month. Then more safe choices are available:

(a) Careful induction with diazepam or thiopental.

(b) N_2O and O_2 plus opiate or small amounts of enflurane.

(c) Spontaneous or controlled breathing, as required.

F. *Potential Problems.*

The circulatory problems encountered during anesthesia are generally of 3 kinds:

(a) Abnormal rate, usually bradycardia.

(b) Abnormal rhythm; may be due to: damage to the conduction system; ectopic beats; effect of anesthetic agents.

(c) Decreased left ventricular function.

G. *Bradycardia.*

A heart rate below 60 bpm in origin may be:

(a) Extracardiac: due to vagal reflex.

(b) Intracardiac: in a posterior infarction, vagal reflex or damage to the conducting system.

(c) Iatrogenic: (1) From drugs such as digitalis and propranolol; (2) From anesthetic agents, the most potent of which slow the heart rate.

The hazard of bradycardia is that cardiac output further decreases. Due to the area of injured myocardium, the heart cannot increase its stroke volume to make up for fewer strokes. Also, during the long diastole, ectopic foci fire off from the area of the infarct. With these ectopic foci and the regular pacemaker both firing, there is the risk of ventricular fibrillation, due to an ectopic contraction hitting a T wave.

Sinus bradycardia may be abolished by small, repeated doses of atropine. Blocking vagal depression of contractility allows increase of sympathetic tone to the heart and greater cardiac output by this second mechanism, along with increase in rate.

With severe bradycardia or heart block present before anesthesia, the best approach is to have a transvenous pacemaker inserted for control of the rate.

During anesthesia, maintain normocardia and an elevated inspired O_2 concentration. Both gallamine and pancuronium tend to increase heart rate.

H. *Arrhythmias.*

The potential causes of, and contributors to, ectopic activity early after an infarction are many. Several are often present together:

(a) Reduced Pao_2 from respiratory or circulatory causes.

(b) Ectopic foci in ischemic and dead tissue areas, engendered by altered electrical activity.

(c) Hyper- and hypocapnea.

(d) Hyper- and hypokalemia.

(e) Catecholamine increase, either endogenous or exogenous.

(f) Digitalis toxicity and high doses of quinidine.

Digitalis is required for rapid atrial fibrillation, while both ventricular tachycardia and fibrillation require cardioversion.

The ventricular-hyperirritability rhythms (ectopic beats and bigemini) should be treated early and vigorously. Eliminate the possibilities of high or low $Paco_2$ and low Pao_2. If total body K^+ is reduced, 2 to 4 mEq boluses of KCl usually abolish premature ventricular contractions. Follow with KCl by drip. Lidocaine (in the doses mentioned by Dr. White[2]) is the traditional agent. These patients, already anesthetized and probably with a reduced cardiac output, are poor candidates for propranolol. Pace the heart at a faster rate if a pacemaker catheter is in place.

I. *Decreased Ventricular Function.*

Arterial hypotension is the most dreaded happening during anesthesia early after infarction, since above all, coronary perfusion must be maintained in the presence of a damaged myocardium. One must decide upon the causes of the reduced ventricular function. Has the pump failed or are other factors contributing to the inadequate circulation? Is congestive failure present, with high central venous, pulmonary arterial, and left ventricular end-diastolic pressure (LVEDP)? Are there signs of pulmonary edema, hypoxemia, or severe peripheral vasoconstriction?

The key to successful treatment of low cardiac output is to decide whether left atrial pressure and LVEDP are low, normal, or high. If they are low or normal, increasing the blood volume will raise these pressures and increase stroke volume and cardiac output. Starling's law works, with an increase of LVEDP improving cardiac output by sarcomere stretching, up to an LVEDP of 20 to 22 torr. Above that pressure, the sarcomeres are overstretched and the ventricle begins to dilate and fail. Since central venous pressure is an imprecise indicator of LVEDP, one must either measure pulmonary wedge pressure by Swan-Ganz catheter or estimate LVEDP from other signs of myocardial failure.

When hypotension is present with high atrial pressures, positive inotropic drugs are needed. For rapid action, calcium chloride (100 to 200-mg doses, to a total of 2 to 3 gm) often is effective. A catecholamine by microdrip (isoproterenol, epinephrine, dopamine) provides smoother action for long-term support. Small doses of lanoxin often will increase contractility. In addition, the surgeon must finish his operation quickly, acidosis and hypoxemia must be abolished, and arrhythmias and rate problems treated with KCl, lidocaine, or atropine.

If the precarious circulation can be at least minimally maintained until anesthesia and the surgical procedure are ended, many of these high-risk patients will survive the postoperative period.

Preanesthetic Evaluation and Management of Malignant Hyperthermia in the Pig Experimental Model

CHARLES E. SHORT, DVM, MS*
ROBERT R. PADDLEFORD, DVM†
CHARLES J. McGRATH, DVM‡
CHARLES H. WILLIAMS, PhD§
Columbia, Missouri‖

Fifty-three swine from the University of Missouri Sinclair Medical Research Farm were used in experimentation to determine their susceptibility to malignant hyperthermia, to determine appropriate anesthetic agents for susceptible swine and to investigate appropriate pharmaceutical agents which could protect against the development of malignant hyperthermia.

The screening technics used were successful in determining susceptible animals to MH and the anesthesia studies indicated that dissociative anesthetics had less tendency to trigger MH than did halothane and pancuronium was shown to have greater safety as a muscle relaxant than succinylcholine in this group of pigs. Pigs pretreated with reserpine had less tendency to develop symptoms of MH and some were completely protected. The principle undesirable effect was the development of hypotension if sufficient reserpine was used to provide total protection.

MALIGNANT hyperthermia (MH), a heritable disease which becomes of primary concern when a susceptible individual is exposed to anesthesia,[1] has caused widespread concern in man and is now being found with increasing alarm in swine.[2,3] MH has been reported in the dog[4] and cat,[5] and a suspected episode has occurred in the horse.[5a] The characteristics of the disease appear quite similar in animals[2-5] and in man,[6] and the hereditary predisposition is present in both, as is the higher incidence of the disease at younger age levels.[7,8]

Review of known cases of MH indicates that the development of symptoms may follow the administration of a large group of potent anesthetics and related agents, including halothane, methoxyflurane, ether, cyclopropane, succinylcholine chloride, d-tubocurarine chloride, gallamine, and multiple combinations of agents,[9] although it has been believed that local anesthesia, regional blocks, barbiturates, narcotics, neuroleptanalgesia, N_2O, and ketamine may be safely used in susceptible individuals.[8,10]

Individuals, animal or man, developing MH show an increase in body temperature (often progressing rapidly and uncontrollably), skeletal muscle rigidity, arrhythmias, hyperpnea, cyanosis, arterial O_2 desaturation, respiratory and metabolic acidosis, hyperphosphatemia, glucosemia, and, after initial hyperkalemia and hypercalcemia, possible hypokalemia and hypocalcemia.[11] As

Paper received: 3/17/75
Accepted for publication: 2/3/76

the condition progresses, there is an increase in serum levels of muscle enzymes. If the patient survives, muscle tenderness, weakness, and swelling are observed during the postanesthetic period. Serum creatine phosphokinase (CPK) levels are usually elevated before symptoms appear and increase further after the development of MH.[12] Serum aldolase, glutamic oxalic transaminase, hydroxybutyric dehydrogenase, and lactic dehydrogenase appear to be elevated after the disease.[13]

In man, preanesthetic histories and determination of CPK levels,[8] and when possible, muscle-tissue biopsies,[14] are of value in determining individual susceptibility.[15-17] In the experimental animal, an anesthetic challenge can be used as a screening test, with withdrawal of the agents immediately upon observation of symptoms. Determination of CPK values is probably the most widely used chemical test at present in man but is not absolute, since myocardial infarction, muscular disease, burns, and CO inhalation also can produce high levels of CPK.[18]

The etiology of MH is still debatable; studies have been made relative to the role of insufficient body adenosine triphosphate,[2,18] intracellular calcium metabolism,[2,19] uncoupling of oxidative phosphorylation, and reduction of muscle phosphorylase. The roles of single muscle cells versus muscle fiber responses and central action mediators versus peripheral have been studied,[6] as have the role of the sympathetic nervous system and of catecholamines before, during, or after the development of symptoms.[20]

The purpose of the present experiments was threefold:

1. To establish a protocol for more accurate screening of experimental animals.

2. To supply additional information for the safe selection of agents to be used for anesthesia where susceptibility to MH is known or suspected.

3. To test the hypothesis that MH relates to neurohumoral transmission of the adrenergic nervous system.

MATERIALS AND METHODS

Fifty-three swine were divided into 4 groups according to the phase of the research to be completed. Group I consisted of 34 pigs of similar age and size, averaging ± 9 kg each at the beginning of the study, and all with known hereditary probability for MH susceptibility.

Group II consisted of 10 pigs in the 7.5 to 10-week-old age range, averaging ± 9 kg each. These pigs were the offspring of MH-susceptible parents.

Group III (3 pigs, ± 46 kg each) served as controls, since there was no history of MH in their breeding stock.

Group IV (6 pigs) were unsusceptible subjects, used to ascertain whether the anesthetic technics and agents employed in this study could cause MH in unsusceptible subjects.

Halothane was administered by one of 3 standard anesthetic units: a Foregger Foretrend® 100; a North American Drager; or a Foregger Eiffel® model. When N_2O was used in conjunction with halothane, it was usually given at the ratio of 1:1 v/v with O_2. N_2O flows never exceeded 80 percent of total volume when used as the primary agent. O_2 flow rates were never allowed to drop below 1 L/min, usually ranging from 2 to 4 L/min. Whenever there was respiratory depression or arrest, adequate ventilation was provided by immediate manual or mechanical respiration, usually with a bird® Mark 7 respirator operated at 30 cm of H_2O, unless otherwise specified.

Cardiac electrophysiology was monitored by a Tektronix® model 410 oscilloscopic ECG monitor, and blood pressure by an indirect ultrasonic monitor. An Instrumentation Laboratories micro-blood-gas analysis system was used for blood gases and pH measurement; and for more detailed physiologic studies, a Hewlett-Packard multichannel oscilloscopic monitor with hot stylus printout for recording data.

Agents used, in addition to halothane, N_2O, and O_2, included sodium thiamylal, for ultrashort barbiturate inductions; ketamine, or a tiletamine-zolazepam combination,* for dissociative anesthesia; Innovar® for neuroleptanalgesia; succinylcholine or pancuronium for muscle relaxation; and methyldopa or reserpine for autonomic nervous system effects.

Methodology.—The method of identifying pigs susceptible to the MH syndrome was as follows:

*Tiletamine-zolazepam: CI-744, anesthetic under development, Parke, Davis & Company, Ann Arbor, Michigan.

Halothane (4%) in 2 L/min O_2 was administered for 60 seconds, after which the concentration was reduced to 2 percent. After the development of relaxation and the induction of anesthesia, halothane levels were adjusted for the maintenance of a surgical plane of anesthesia. While this initial concentration exceeds normal MAC values for induction, it was important in these experiments to create the availability of a high concentration of halothane to initiate responses indicative of MH, if possible. Animals were considered "susceptible" to MH when 2/3 of the following characteristics were seen with halothane within 20 minutes, and considered "normal" if such response did not follow:

a. A heart rate exceeding 200 bpm.

b. An increase in rectal temperature of 1° F.

c. Development of muscle rigor.

Normal in this context does not imply that the animals would not be susceptible to the development of MH with a similar challenge at a later date or to a challenge from another product.

Since one of our objectives was to find additional ways to anesthetize swine and reduce the risk of MH, ketamine was administered at the rate of 11 mg/kg body weight. Since ketamine leaves some muscle resistance in the pig, the tiletamine-zolazepam combination was administered at the rate of 6.6 mg/kg body weight, for comparison.

As part of the experimentation, effects of those methods of administering anesthesia which had tended to develop symptoms of MH in man were studied in these animals, to learn if similar responses could be expected. This included induction and maintenance by barbiturates, induction by Innovar, maintenance by N_2O-O_2, by halothane, and the use of succinylcholine (1.1 mg/kg) for muscle relaxation. Since succinylcholine and pancuronium have both been incriminated in producing MH in humans, these were also used as test agents. Pancuronium was administered at 2 levels in a 2-part trial, giving 0.11 mg/kg IV in the 1st portion and 0.22 mg/kg IV in the second.

Prophylaxis.—Studies included administration of methyldopa or reserpine to susceptible individuals, to determine whether these might prevent the developmnt of MH. There has been considerable attention to the effect of the monamine oxidase inhibitors and to the role of beta-adrenergic blockers, and whether these effects are created relative to central or to peripherally acting causes. To test the hypothesis that MH could be an autonomic nervous system response, 5 animals were given 5 mg of methyldopa twice daily. After 3 days, they were exposed to halothane anesthesia, using methods similar to those described.

Ten pigs of group II were similarly tested with reserpine. In the 1st trial, using reserpine only, 1 animal was given 0.22 mg/kg, administered for 2 days prior to challenge with halothane anesthesia. Five other reserpine-treated pigs, weighing from 20.8 to 34 kg, were given 0.5 mg/pig IM, 24 hours before halothane challenge, to determine a more specific effective dosage range. An additional 9 pigs each received 0.0275 mg/kg IM daily for 2 treatments prior to halothane. The last reserpine experiment was divided into 3 components, consisting of group A, 3 pigs given 0.045 mg/kg for 2 days prior to anesthesia; group B, 3 pigs given the same dose but for 3 days; and group C, 2 pigs receiving 0.045 mg/kg of reserpine IM for 4 days prior to anesthesia.

Supported in part by the Department of Medicine, University of Missouri College of Medicine and the Department of Veterinary Medicine and Surgery, College of Veterinary Medicine.

RESULTS AND DISCUSSION

Susceptibility Studies.—Even though it has been reported that MH has hereditary linkage, and although the animals used in this study were the offspring of known carriers of this hereditary potential, it was essential to experimental design that each animal be subjected to anesthetic challenge to determine the extent of its MH susceptibility (table 1).

The anesthesia record (fig 1) exemplifies a susceptible animal receiving an ultrashort barbiturate (thiamylal) induction with a preanesthetic administration of atropine and maintained on N_2O and O_2 for 1.5 hours before administration of halothane. It was maintained at a satisfactory plane of anesthesia and did not develop any symptoms of MH until after the initiation of halothane anesthesia.

These animals maintained adequate blood pressure and cardiovascular responses and showed little evidence of cardiac dysrhythmias. Their blood pH and blood-gas values

TABLE 1

Responses of Swine to Halothane Challenge for Determination of MH Susceptibility

	Heart rate at onset of rigor	Respiratory rate at onset of rigor
Group I, 34 pigs		
29 reactors to halothane*	227 ± 40 beats/min	59 ± 22 breaths/min
5 reactors to halothane (in later test, positive to succinylcholine challenge)	151 ± 16 beats/min	29 ± 7 breaths/min
Survival rate: 100%		
Reaction time: 2-16 min		
Group II, 10 pigs		
10 reactors to halothane*	212 ± 33 beats/min	29 ± 6 breaths/min
Survival rate: 100%		
Reaction time: 113 ± 60 sec		
Group III, 3 pigs		
3 reactors—halothane continued 5 min after beginning of rigor		
Survival rate: 0%		
Time from start of response until death: average 27 min		

*Halothane started via mask at 4% concentration for 60 sec, then reducing to 2% and then to maintenance of surgical plane anesthesia. Anesthesia stopped for groups I and II when rigor started.

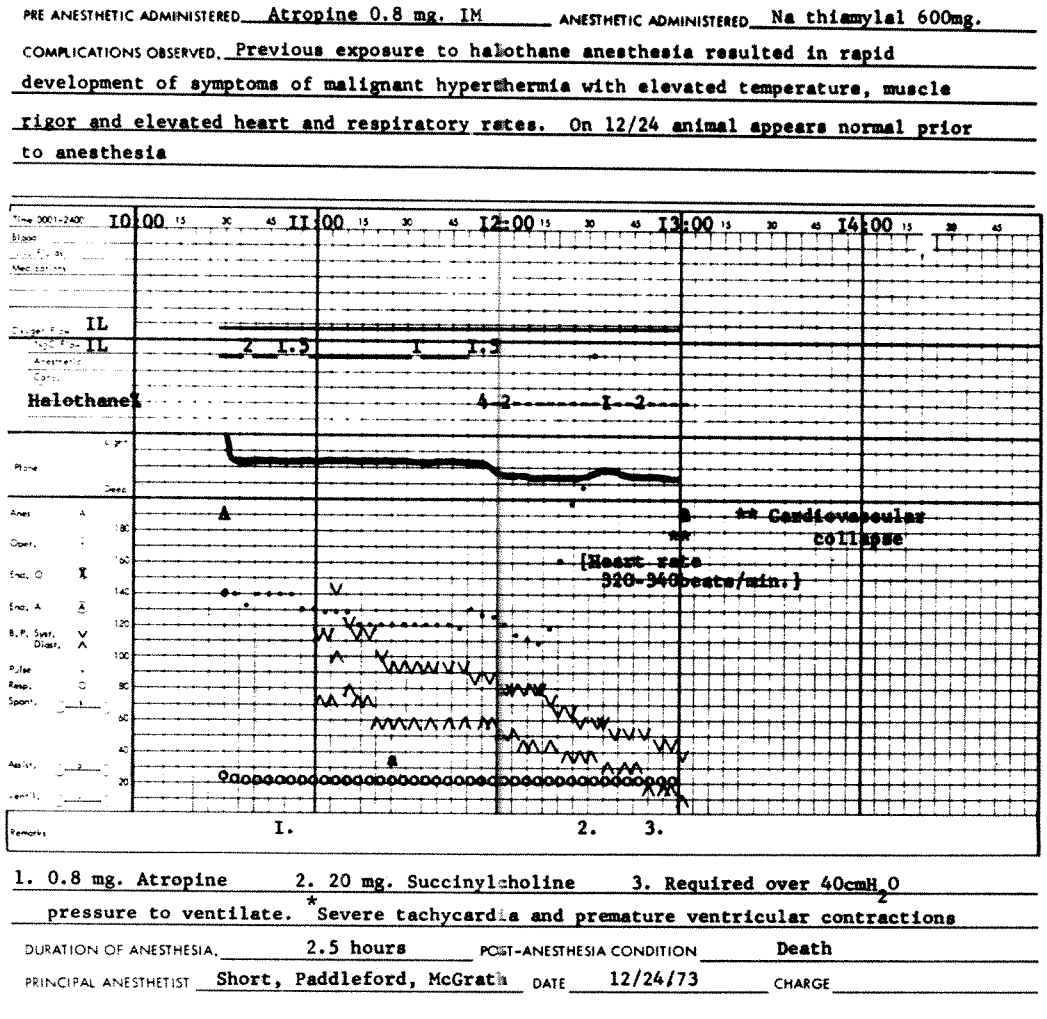

FIG 1. Anesthesia record for pig showing typical symptoms of malignant hyperthermia.

were within normal limits, with the exception of an elevated CO_2. This was compensated by added ventilation. After the initiation of halothane anesthesia, there was a drop in blood pressure, associated premature ventricular contractions, and these problems were exaggerated further after the administration of succinylcholine.

At this time, heart rate increased drastically, producing a severe tachycardia with inadequate blood pressure and difficulty in maintaining positive-pressure breathing, due to intracostal muscle rigidity. Even with halothane anesthesia in the presence of succinylcholine, there was extreme muscle rigidity, and after 2.5 hours of anesthetic management, the animal succumbed to cardiopulmonary collapse. This example of the typical responses seen in the experimental pig susceptible to MH when subjected to anesthetic management demonstrates the similarities to human patient responses.

Another pig (fig 2) demonstrated that the use of Innovar as an inducing agent to be followed by N_2O-O_2 does not always prevent MH symptoms in susceptible animals. This is somewhat in contrast to the concept that, for individuals susceptible to MH, narcotic or neuroleptanalgesia administration may be considered safe.

Use of Pancuronium.—After it was determined that susceptible animals might be expected to react to the administration of succinylcholine with a high degree of regularity, the possibilities of the administration of pancuronium as a muscle relaxant that might have some protective qualities were evaluated. In the animal (fig 3) to which 1.6 mg (0.22 mg/kg) of pancuronium was administered on 2 occasions, followed by 20 mg (2.1 mg/kg) of succinylcholine IV, no MH symptoms developed, in contrast to cases where succinylcholine was administered without pancuronium. This was later to be of significance, since it indicated the potential use of pancuronium as a muscle

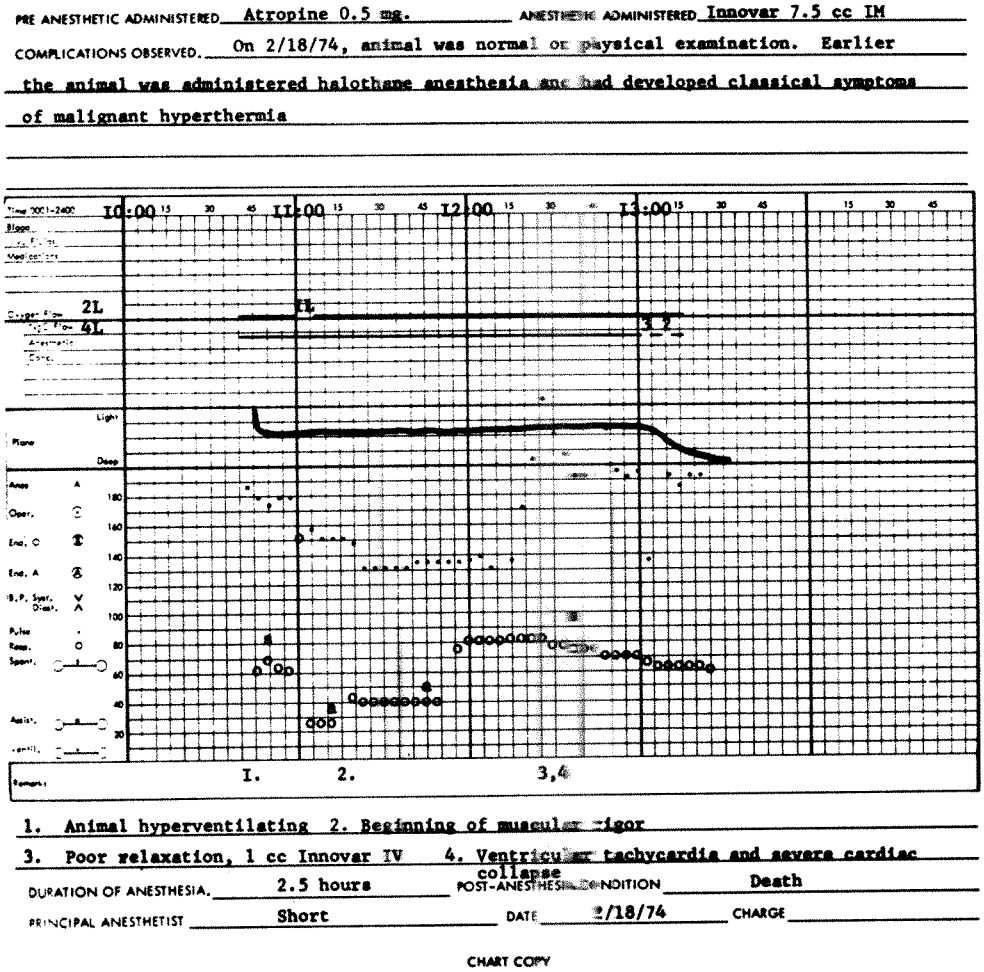

FIG 2. Anesthesia record for pig developing malignant hyperthermia with Innovar and N_2O.

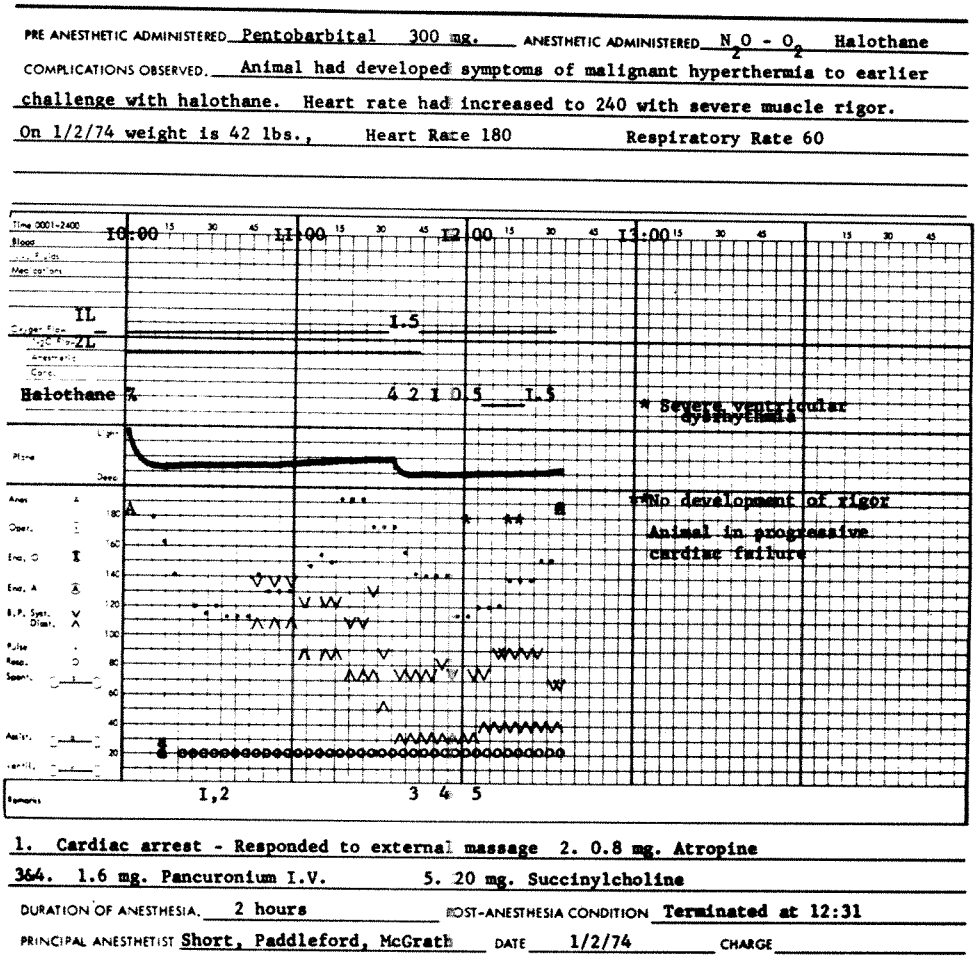

FIG 3. Anesthesia record illustrating lack of development of malignant hyperthermia to succinylcholine following pancuronium.

relaxant in animals susceptible to MH. Heart rates remained stable and adequate in all animals (table 2) and cardiac dysrhythmias did not appear. Respiration was maintained with a bird® mechanical ventilator and a 30 cm H_2O pressure/breath and maintaining the animals at 16 to 29 breaths/min.

Blood pressure in pancuronium-treated animals remained stable, although somewhat elevated, in pigs given the smaller dose. Relaxation followed in each individual pig within 1 minute after injection, lasting 6.5 minutes after the low dose and 14 minutes after the higher dose. Body temperature did not significantly change from pretreatment values.

Injectable Anesthetics (table 3).—Induction time was 3 minutes for both ketamine and tiletamine-zolazepam, and duration of anesthesia was 10.5 minutes for ketamine and 14 minutes for tiletamine-zolazepam. Heart rates remained stable for ketamine; with tiletamine-zolazepam, there was a drop in heart rate but it stabilized at an adequate level after 5 minutes. Respiratory rates were elevated with ketamine but remained at normal levels with the drug combination. It was not possible to accurately record blood pressures in the ketamine-treated pigs because of slight muscle tremors, but stable blood-pressure levels were observed in all animals anesthetized with the combination. Body temperatures remained stable with the ketamine-anesthetized pigs in spite of muscle tremors, and body temperature dropped during the maintenance of anesthesia with tiletamine-zolazepam.

Failure to develop MH symptoms with ketamine in spite of the degree of muscle activity during the anesthetic period is of

interest, since it was postulated that one of the reasons for the development of MH after succinylcholine administration is the severity of muscle rigidity and fasciculations shortly after administration. However, the degree of muscular activity after ketamine was mild compared with fasciculations after succinylcholine administration; perhaps herein lies the difference in effect.

Methyldopa and Reserpine Tests.—An initial trial of methyldopa in 5 animals known to be susceptible to MH showed a marked degree of protection against the development of MH symptoms from halothane exposure. However, although methyldopa blocks the synthesis of the mediator of adrenergic transmission, thus providing protection against development of MH, severe hypotension was an undesirable side effect.

As a result, the next step of the study involved chemical transmission and storage of a mediator; for this, the drug selected was reserpine (fig 4). In the animal whose chart is shown, body temperature dropped below control values during anesthesia. The animal was hypotensive, and even though it showed no MH symptoms and made an uneventful recovery after 45 minutes of anesthesia, the outcome was progressive cardiovascular collapse ending in death 3 days after the trial. Because of this undesirable result, a subsequent trial used 5 pigs, varying in weight from 20.8 to 34 kg, and given a single dose of 0.5 mg/pig IM 24 hours before halothane challenge. In these pigs, protection increased from 1.9 ± 1 minute to 6.4 ± 4 minutes after the administration of the reserpine (table 4). Protection was dose

Reactions

2 reacted to halothane within 2 min.

1 reacted to halothane within 15 min.

6 were protected throughout halothane challenge of 30-min duration.

4 were protected to succinylcholine challenge.

1 was not protected to succinylcholine and died with MH.

*Dosage: 0.0275 mg/kg IM daily for 2 treatments prior to halothane in 9 animals. 1.1 mg/kg succinylcholine administered IV in 5 animals. Five of these were given succinylcholine.

related in linear fashion. All animals survived.

With reserpine (0.0275 mg/kg) given IM for 2 daily treatments before halothane anesthesia (table 5), 2/9 pigs reacted to halothane administration within 2 minutes and a third reacted with muscle rigor after 15 minutes. Halothane challenge in 3 pigs was discontinued immediately upon the development of muscle rigidity, and all survived. Six pigs were protected throughout the halothane challenge of 30-minute duration. Five of the 6 protected to halothane challenge were subsequently challenged with succinylcholine at 1.1 mg/kg. Four of the five did not show the typical symptoms of MH. Body temperatures were maintained at acceptable levels throughout the procedure in the 4 protected animals, and cardiopulmonary responses were within normal limits with the exception of blood pressure, which dropped at times to levels unacceptable for safe anesthetic management.

*Dosage: A. 0.045 mg/kg per day for 2 days.
B. 0.045 mg/kg per day for 3 days.
C. 0.045 mg/kg per day for 4 days.

Since complete protection was not obtained at the 0.0275 mg/kg drug level, reserpine was given to 4 pigs at 0.045 mg/kg for 2 days, in a 2nd trial for 3 days, and in a 3rd trial for 4 days (table 6). Heart rates were elevated in group A and there was no marked degree of hypotension. These animals, however, reacted to halothane challenge with the development of rigor within 3 minutes. Pigs in group B had a slower heart rate and normal respiratory rate. Blood pressure was depressed, with a noticeable degree of hypotension. Rigor did not develop from the halothane challenge until 18 minutes after the onset of anesthesia. All these animals survived after the discontinuance of anesthesia with the exception of 1 animal whose temperature continued to rise, with other symptoms of MH. It died 2 hours later with a temperature of 111.9° F.

In group C, normal heart and respiratory rates were found, with a marked degree of hypotension; body temperatures were normal; none of the animals in this trial reacted to over 30 minutes of halothane anesthesia; and all survived to the challenge for development of MH. However, half of the animals died later with cardiovascular collapse from the reserpine.

CONCLUSIONS

Our method of challenge for the determination of MH-susceptible animals studied relative to the MH syndrome is effective and reproducible.

Six animals given succinylcholine developed MH, while animals given only pancuronium did not develop MH at either of 2 dosage levels, nor did the animals receiving succinylcholine after they were relaxed with pancuronium. Thus pancuronium may be a safer muscle relaxant than succinylcholine for use in MH-susceptible animals. Since animals treated with methyldopa did

not develop MH, as they had under control conditions, there is evidence that blocking of the transmission of adrenergic mediators, for example norepinephrine, lends itself to provide protection of susceptible animals to agents known to produce MH.

Reserpine studies indicate that this drug can be as effective as methyldopa in protecting susceptible animals and is more controllable, as methyldopa dosage levels which will afford protection against MH development also cause severe hypotension.

Sodium Nitroprusside-Induced Hypotension for Supine Total Hip Replacement

NOEL W. LAWSON, MD*
DOLA S. THOMPSON, MD†
CARL L. NELSON, MD‡
JOAN W. FLACKE, MD§
EDWARD R. NORTH, MD‖
Little Rock, Arkansas**

Deliberate hypotension was produced during general anesthesia by the infusion of sodium nitroprusside in 13 patients undergoing total hip replacement. Hemodynamic data from these patients were compared with those obtained from 5 patients under normotensive anesthesia for the same procedure. During the hypotensive period, which averaged 1.5 hours, the cardiac index rose 20 percent compared with controls. No acidotic tendency was seen. Blood loss in the study group averaged 475 ml, compared with 1475 ml in controls. From these data, a dose-response curve was derived which may allow the accurate prediction of the minute dosage of sodium nitroprusside required to safely induce hypotension during anesthesia.

TECHNICS to recover or reduce blood loss during surgical procedures in current use include deliberate hypotension during anesthesia, hemodilution, and several variations of autologous blood transfusion. Deliberate hypotension during anesthesia to reduce intraoperative blood loss was first used over 25 years ago.[1] Although introduced during an era when the risk of homologous blood transfusion was prodigious, this concept was controversial. As transfusion became safer during the 1950s, the popularity of hypotensive anesthesia waned. The risks of transfusion could no longer be equated with those of deliberate hypotension; nevertheless, in a 1969 report,[2] more than 5 percent of all patients receiving blood transfusions showed unfavorable reaction.

Today, induced hypotension is enjoying a revival, not only as a means to reduce the risks of and need for transfusion but also as a means of conserving a scarce national resource. Of the technics used to produce deliberate hypotension during anesthesia, none have proven ideal.[1] Of these, sodium nitroprusside, a potent but evanescent antihypertensive drug, has been used in some centers since 1962.[3] Scant data are available, but nitroprusside, in contrast to other technics, reportedly enhances cardio-circulatory dynamics,[4-7] producing arteriolar vasodilation independent of the autonomic nervous system. It was first used by Johnson[8] in 1929 for the treatment of hypertensive crisis and only recently became available commercially in the United States.

Several reports indicate that the inherent properties of nitroprusside are useful in a variety of unrelated clinical situations. Specifically, cardiologists[9] report improved cardiac output and tissue perfusion with the infusion of nitroprusside in patients with failing hearts and cardiogenic shock—a situation analogous to the myocardial depression produced by general anesthesia. This paper reports the results of a study in which cardiac output and other physiologic parameters were measured in 13 selected patients during halothane-N_2O-O_2 anesthesia and sodium nitroprusside-induced hypotension for total hip replacement.

METHODS

Thirteen patients of the Jehovah's Witness faith, ranging in age from 9 to 78 years, made up the study population. Patients with cerebrovascular disease, clinical or electrocardiographic evidence of ischemic heart disease, renal hypertension, serious peripheral vascular disease, or severe obstructive lung disease were excluded from the study. Extreme age was not considered a contraindication. Various hemodynamic measurements from this group were compared with data obtained from 5 patients, also undergoing total hip replacement, using the same but normotensive anesthesia.

Premedication consisted of morphine, diazepam, and scopolamine, except in patients over age 60, in whom the morphine was omitted. Anesthesia was induced in both groups with 2 percent thiamylal IV and maintained with halothane-N_2O-O_2 (50:50). Stable surgical anesthesia was maintained in all cases with an inspired halothane concentration of between 0.5 to 0.75 percent. Succinylcholine was used to facilitate endotracheal intubation. Five percent dextrose in lactated Ringer's solution was administered to both study groups at a rate of 12 to 15 ml/kg body weight the 1st hour and 6 to 10 ml/kg/hr thereafter. Homologous blood was not given to the control patients unless more than 500 ml of blood loss was anticipated. Positive-pressure ventilation was not used as a deliberate aid in producing hypotension; however, ventilation was assisted as needed to produce a $Paco_2$ between 37 and 41 torr. Nondepolarizing muscle relaxants were purposely omitted to avoid additional hemodynamic effects. In both study and control groups, the operation was performed with the patient supine, with slight hip elevation.

Arterial hypotension was induced in the study group by the continuous infusion of a 0.01 percent solution (100 μg/ml) of sodium nitroprusside in 5 percent dextrose in water just before the skin incision. The drug was delivered by a constant-infusion pump,* allowing accurate control of the dosage. The initial dose was 100 μg/min; this was adjusted later in order to produce the desired degree of hypotension, which was determined by bleeding from the operative site rather than by an arbitrary level of blood pressure. Infusion of nitroprusside was discontinued, and blood pressure allowed to return to normal before wound closure so that hemostasis could be assessed.

Arterial blood pressure, pulse rate, ECG, central venous pressure (CVP), urine output, and tympanic temperature were monitored continuously. The arterial blood pressure was monitored electronically through a cannula inserted percutaneously into the radial artery before the induction of anesthesia. A CVP cannula was inserted also at this time through a convenient vein. Its position was ascertained clinically by advancing the catheter within the thorax until oscillation in manometric pressure was noted with the respiratory cycle and heart beat. Proper positioning was confirmed postoperatively by x-ray. An indwelling urinary catheter was inserted after induction of anesthesia into all patients of both study groups. The ECG (lead II) was monitored by oscilloscope.

Cardiac output and arterial blood gases were measured 6 times during the perioperative period. In both study and control patients, measurements were made before induction of anesthesia and after 30 minutes of stable normotensive anesthesia. In the hypotensive study group, cardiac output was measured again 20 minutes after achieving stable hypotension and 3 minutes after acrylic cement was inserted into the femoral shaft. In the normotensive group, the measurements were made at corresponding times.

Finally, cardiac output was determined in both groups in the normotensive stage during wound closure and in the recovery room. Indocyanine green was injected rapidly into the CVP cannula and blood was withdrawn at a constant rate from the radial artery through a densitometer connected to a Lexington Instruments Model COC-SD cardiac output computer system. Dye curves and

*Harvard Apparatus Company, Millis, Massachusetts.

the computer analog output were recorded simultaneously on the previously calibrated dual-channel Linear Instruments chart recorder. Duplicate cardiac output was measured at each study interval and the data accepted when sequential determinations differed by less than 0.3 L/min. Total peripheral resistance (TPR), cardiac index (CI), and stroke volume (SV) were calculated from the above data.*

Blood loss was estimated by the amount in suction bottles and by weighing sponges. Irrigation fluid was collected by a separate suction system.

RESULTS

Hemodynamics.—The anesthetic management and hemodynamics of both study and control patients were essentially the same up to the point when hypotension was induced in the study group. The mean combined preinduction CI for both groups was above normal (4.25 L/min/m) with a wide spread of values ranging from a normal of 3.0 L/min/m to a high of 5.5 L/min/m. This elevation and spread of values was expected and thought to reflect various degrees of preoperative anxiety.

The statistical mean of the mean preinduction arterial blood pressure was 112 ± 5 torr. Following induction and after 30 minutes of stable, normotensive anesthesia, the mean CI of both groups fell to 2.32 L/min/m, representing a much narrower range of values. The decrease in CI was statistically significant ($p<0.01$, paired t-test). During this transition from awake to asleep, there was a moderate reduction in heart rate and the blood pressure returned to a normal mean value of 98 torr in both groups.† No significant CVP change was noted.

Hypotension was induced in the 13 study patients with nitroprusside and the dosage adjusted to obtain a blood pressure compatible with a dry surgical field. The statistical MAP achieving this condition was 64 ± 4 torr,† a 43 percent decrease from a mean preinduction blood pressure of 112 torr. The CI, measured after 20 minutes of stable hypotension, rose 20 percent from normotensive levels to a nearly normal CI of 2.95 L/min/m (fig 1). This parameter remained stable throughout the hypotensive period. However, the CI returned to the lower prehypotensive level when the nitroprusside infusion was discontinued. The difference in mean increase in CI during hypotension was statistically significant compared with that of normotensive controls, which remained depressed throughout the procedure ($p<0.01$, paired t-test) (fig 2).

Compensatory alterations in heart rate and CVP during induced hypotension were unpredictable. The heart rate either remained the same or rose slightly upon initiation of hypotension. Similarly, there was either no change or a slight fall in CVP. In those instances (3 patients) where heart rate rose and CVP fell, infusion of additional fluid restored these values toward normal without affecting the level of hypotension.

The mean calculated SV during normotensive anesthesia was 59 ± 7 ml for both study and control patients, increasing to a mean of 71 ± 5 ml during nitroprusside infusion, whereas no significant change was noted in the control patients. This 17 percent rise in SV during nitroprusside hypotension paralleled but did not match the rise in CI. These data were influenced by the 3 patients who developed an increase in heart rate and a fall in CVP at the initiation of deliberate hypotension. However, SV increased in these patients when the CVP and heart rate returned to normal with the infusion of fluid. The increase was noted when the 2nd set of cardiac output determinations were made following the insertion of the acrylic cement into the femoral shaft.

The mean preinduction TPR for both groups was 1373 dynes/sec/cm^{-5}. Mean TPR rose during normotensive anesthesia in both groups to 1691 dynes/sec/cm^{-5} (fig 1 and 2) ($p<0.01$, paired t-test). The rise in TPR accompanied the fall in cardiac index. Likewise, the rise in cardiac index and stroke volume with nitroprusside hypotension, paralleled the fall in the TPR to a mean of 743 dynes/sec/cm^{-5} ($p<0.01$, paired t-test) (fig 1). The TPR, cardiac index, and stroke volume returned to prehypotensive levels upon ending nitroprusside infusion. Thus, the rise in cardiac index encountered during nitroprusside-induced hypotension was accounted for solely

*Calculations were made on a Hewlett-Packard programmed computer Model 9810 A Cardiac-pulmonary PAC from the formula:

$$TPR = \frac{79.9 \times \text{mean blood pressure}}{\text{cardiac output}}$$

$$CI = \frac{\text{cardiac output}}{\text{body surface area}}$$

$$SV = \frac{\text{cardiac output}}{\text{heart rate}} \times 1000$$

†Mean value refers to the statistical MAP mean.

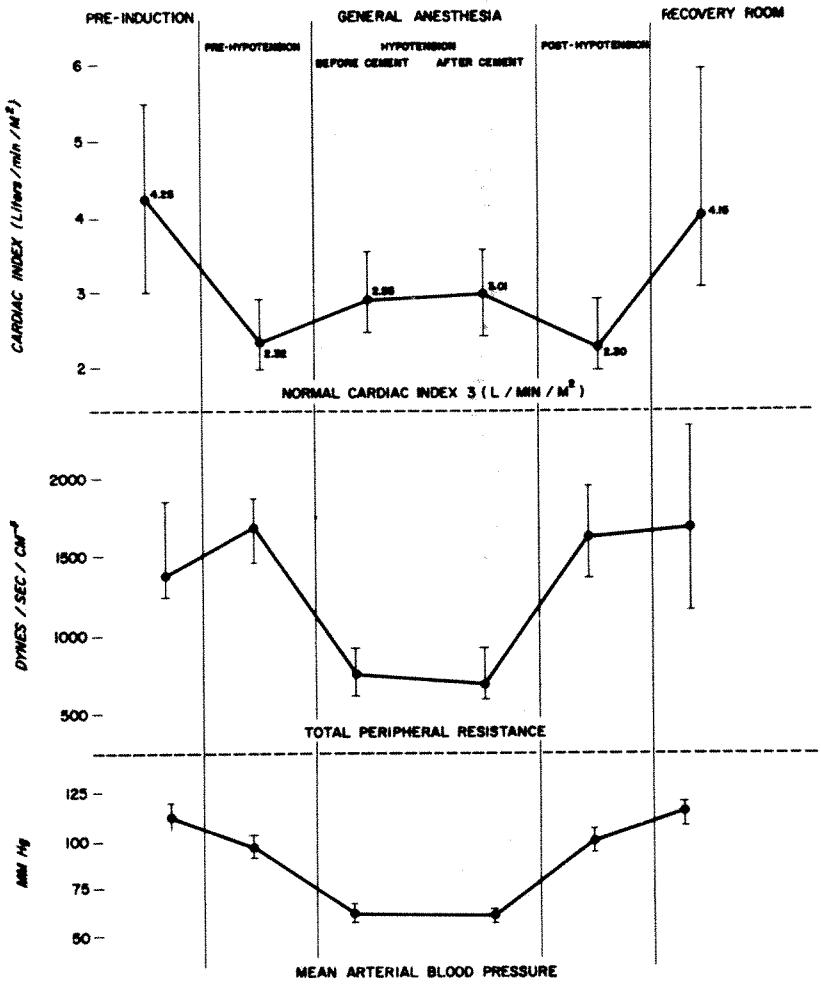

FIG 1. Cardiac index rose toward normal in all patients during nitroprusside administration under anesthesia ($p<0.01$). The mean TPR was markedly reduced during nitroprusside hypotension. The MAP achieving a dry surgical field was 64 mmHg. Isobars represent range of measured values.

by a marked decrease in the TPR. In contrast, there was little change in the cardiac index, stroke volume, or TPR (fig 2) in normotensive control patients. No significant change was noted in CI, TPR, or blood pressure in either group upon insertion of the acrylic cement into the femoral shaft.

Blood Gases and Tissue Perfusion.—A marked increase in A-aDo_2 was noted during hypotension in 8 patients but the Pao_2 was never less than 100 torr when an FIo_2 of 0.5 was maintained. However, arterial oxygenation returned to prehypotensive levels within minutes after resumption of normotension. Acid-base balance remained normal throughout the hypotensive period and no acidosis was noted. The urine output in both study groups remained normal. Enhanced tissue perfusion was further evident during hypotension in that the patients' skin became flushed and warmer to touch under the influence of nitroprusside. As a result, temperature loss was significant and troublesome during hypotension in the laminar airflow operating room. Hypotensive patients lost an average of 2.1° C temperature as compared with 0.5° C for controls ($p<$ 0.01, paired t-test).

Blood Loss.—The actual operating time averaged 105 ± 15 minutes for both groups. The duration of hypotension averaged 90 ± 15 minutes. The average blood loss in the 13 study patients was 475 (± 100) ml compared to 1475 (± 200) ml for controls (fig 5). The average preoperative hemoglobin in the hypotensive patients was 13.5 (range 10.8 to 15.8) gm/100 ml. The lowest postoperative hemoglobin in this group, usually

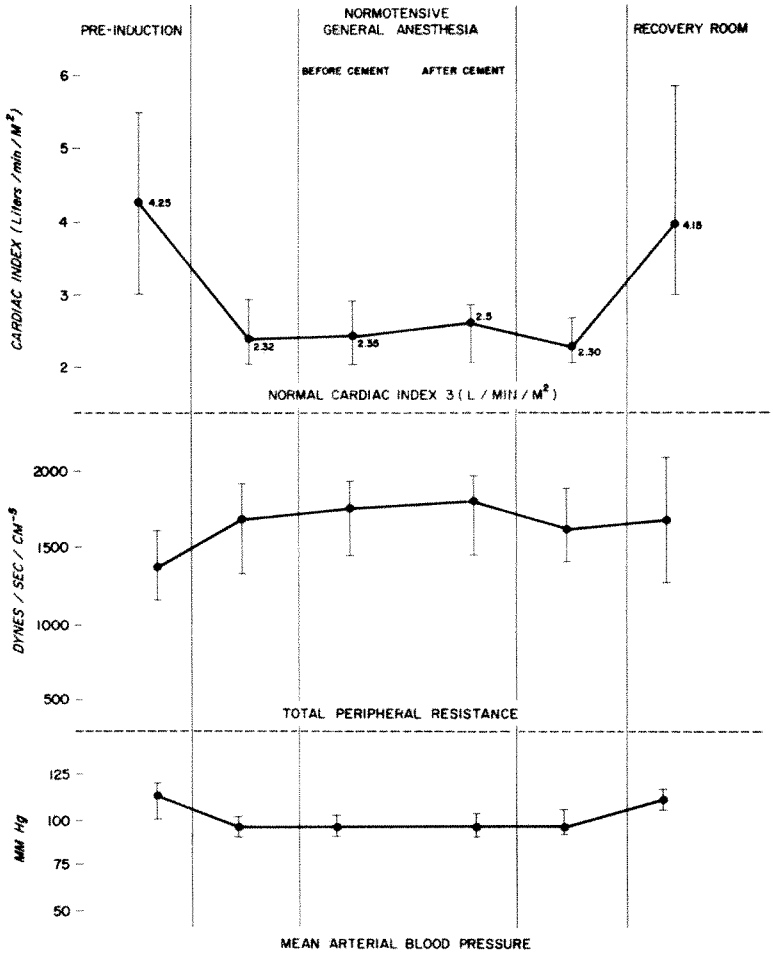

FIG 2. Cardiac index remained depressed in patients during normotensive halothane anesthesia. The mean TPR did not change significantly. The MAP was 98 torr. Isobars represent range of values measured.

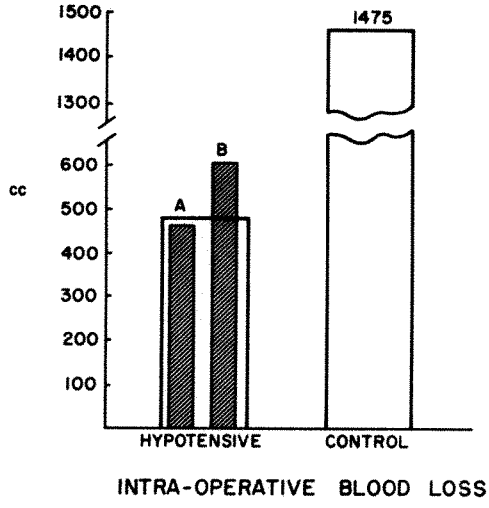

FIG 3. Surgical blood loss was significantly reduced with hypotensive anesthesia. Within the hypotensive group, patients without previous hip surgery (group A) lost less blood than those who had had previous hip surgery (group B).

found on the 3rd postoperative day, was 10.2 gm/100 ml.

Further, the amount of blood loss noted in the hypotensive study was divided into 2 distinct groups. Patients who had previous hip surgery lost significantly more blood than those without previous hip surgery. Nine patients who had no previous hip surgery lost an average of 460 ml of blood—31 percent of the expected blood loss. Four patients with previous hip surgery lost an average of 600 ml during hypotensive operation—45 percent of the expected loss. An extended surgical procedure was not a factor. The 5 control patients received a total of 14 units of homologous blood. Although homologous blood could not be given to the study patients, none was physiologically required.

Dosage of Nitroprusside.—The onset of action of nitroprusside began within 60 to 90 seconds after starting the infusion. The

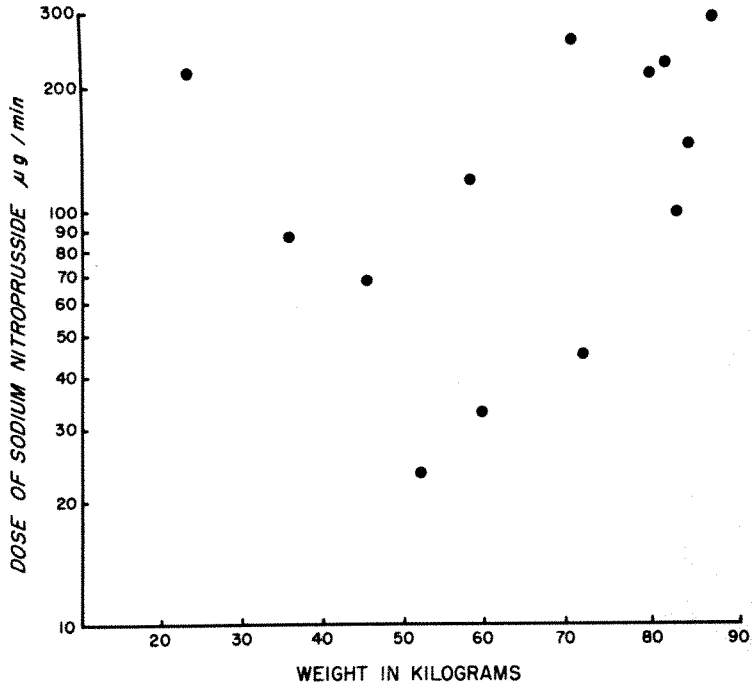

FIG 4. No correlation appears between patient weight and nitroprusside minute dosage needed for comparable levels of hypotension.

duration of action was equally evanescent, necessitating a controllable means of constant rate infusion to maintain stable hypotensive levels, blood pressure varying directly with the amount of nitroprusside infused. However, no consistent correlation could be found between dosage of nitroprusside and patient weight (fig 4), larger patients sometimes requiring the least drug. There was a noticeable inverse relationship between age

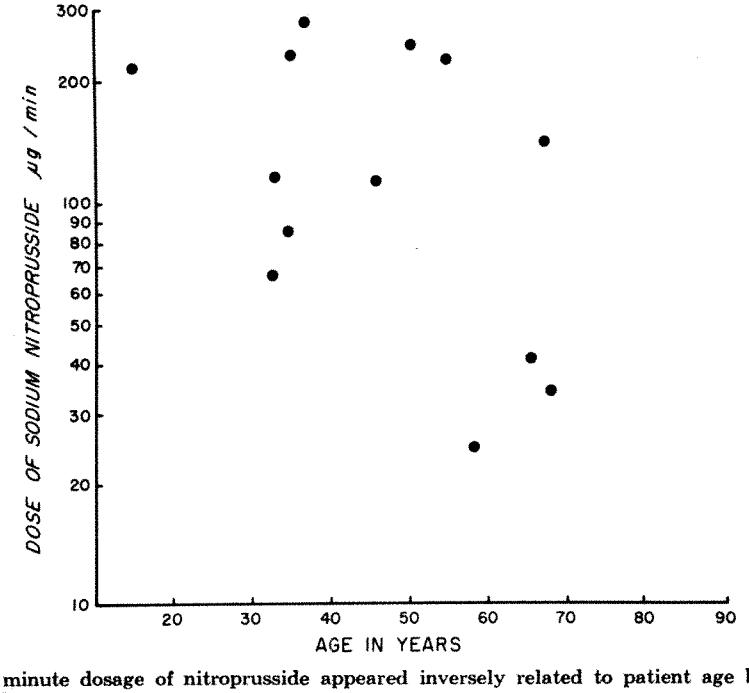

FIG 5. The minute dosage of nitroprusside appeared inversely related to patient age but was not statistically significant.

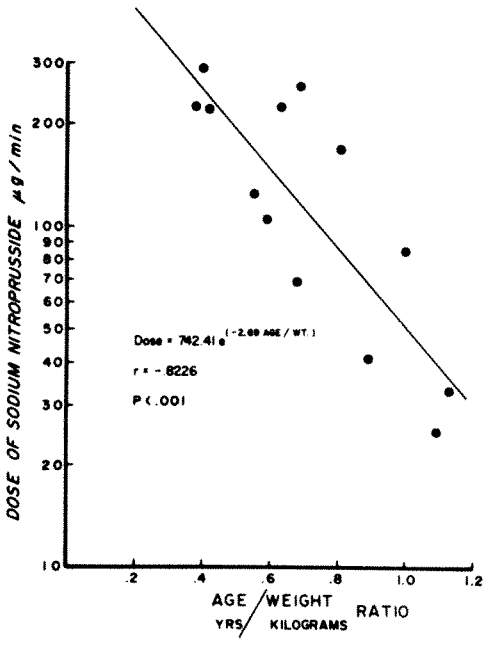

FIG 6. Age/weight ratios (yr/kg) produced a highly significant dose-response curve to maintain comparable levels of hypotension.

and the amount of the drug required but the correlation was not statistically significant (fig 5). There was, however, a highly significant correlation between the age/weight ratio of a given patient and the dose of nitroprusside required to maintain comparable levels of constant hypotension in another patient. Age/weight ratio (yr/kg) plotted against the required minute dosage of nitroprusside produced a highly significant ($p < 0.001$, $r = -0.822$) curve (fig 6). No nitroprusside tachyphylaxis was noted throughout the series. Once the desired level of blood pressure was attained and the minute dosage adjusted, only minor changes in the rate of infusion were required to maintain constant levels of hypotension. No adverse effects occurred as a result of sodium nitroprusside-induced hypotension.

DISCUSSION

To date, all methods of producing deliberate hypotension during anesthesia have caused a reduction in cardiac output in proportion to the degree of hypotension.[1] These methods include the popular combination and sequence of deep halothane anesthesia, positioning, positive-pressure ventilation, and ganglion blockers. Prys-Roberts and associates[10] presented convincing evidence that hypotension produced by halothane, whether deliberate or unintentional, is due to a dose-dependent impairment of myocardial contractility and not the result of vasodilatation, as popularly believed. Although vasodilatation may occur in selective vascular beds, the overall peripheral vascular resistance remains unchanged.

Admittedly, calculated values for TPR may not be meaningful when both pressure and cardiac output change in the same direction. However, our results confirmed those of Prys-Roberts. The calculated TPR remained essentially unchanged, if not slightly increased, throughout normotensive halothane anesthesia as compared with *awake* control measurements (fig 2). Simultaneously, the decreased cardiac output seen with halothane anesthesia is caused not only by a decrease in myocardial contractility but also is aggravated by a relative increase in workload, vascular resistance remaining unchanged.[11]

During nitroprusside-induced hypotension, the cardiac output increased toward normal from the depressed levels measured during normotensive anesthesia. The improvement in cardiac output and tissue perfusion was reflected entirely in decreased TPR. The reduction in myocardial afterload allowed the halothane-depressed myocardium to function at a more efficient level. Additionally, cardiac output returned to the lower prehypotensive levels following the end of nitroprusside infusion and return to normal vascular resistance (fig 1). Changes in heart rate and CVP were unrelated to changes in cardiac output. When such changes occurred, they were related more to the patient's state of hydration, a rise in heart rate or fall in CVP at the start of induced hypotension responding to fluid infusion without affecting the level of hypotension or cardiac output.

These conclusions are at variance with those of Wildsmith's group,[6] who also reported a 20 percent increase in cardiac output during nitroprusside hypotension but attributed the rise to a reflex and consistent increase in heart rate. The CVP fell significantly and the SV remained unchanged in their study. Rushmer[12] has demonstrated that tachycardia alone is not an efficient mechanism for increasing cardiac output unless such other mechanisms as increasing circulatory volume act to maintain or increase stroke volume.

Our fluid regimen followed that recommended by Jenkins and Giesecke[13] for hip operations. Therefore our patients received

substantial volume loading during the hour preceding deliberate hypotension. The British study, conducted on patients for middle-ear surgery, did not describe intraoperative fluid management. Perhaps differences in intraoperative fluid management account for the apparent discrepancy between this report and that of Wildsmith.

Like others,[4-7] our study indicates that use of sodium nitroprusside produces a hypotensive state clinically superior to other technics. The patient's skin became flushed and warm; urine output was not compromised; and no arterial or venous acidosis was noted during the hypotensive period. Nitroprusside hypotension significantly reduced surgical blood loss by reducing arterial blood pressure without apparent jeopardy to tissue blood flow. It acts directly on the arterioles, producing vasodilation and a hypotensive state unlike that produced by ganglion blockade.

Ganglion blockers have a highly specific action on synaptic transmission in autonomic ganglia which produces a number of troublesome side effects during induced hypotension. These effects include tachycardia, histamine release, cycloplegia, myoneural blockade, and tachyphylaxis,[1] although ganglion blockers differ in degree and type of side effects. Nitroprusside, in contrast, has no action on the heart or sympathetic ganglia.

The safety of nitroprusside-induced hypotension has been ascribed not only to improvement in tissue perfusion during hypotension but also to its evanescent action.[6,7] The speed of onset and the duration of action of nitroprusside is between 60 and 120 seconds, necessitating a continuous infusion to maintain steady hypotension. The degree to which nitroprusside lowers blood pressure is dose dependent, and pressure levels can be changed within seconds by altering the infusion rate, yet just such variability has constituted one of the main difficulties in its administration, dosage during anesthesia having usually been adjusted empirically according to response. The recommended dosage producing the desired pressure levels, around 70 to 75 torr systolic, has ranged from 0.5 to 30 μg/kg/min.[5]

As shown above, when both age *and* weight were considered, a highly significant dose-response curve relating the dose of nitroprusside to blood pressure decrease resulted (fig 6). Studies are in progress to further verify the relationship between age and weight to the predicted minute dosage of nitroprusside. Present findings suggest that perhaps age is the more important consideration.

Taylor[7] and Davies[14] have noted that young patients require larger doses of nitroprusside than adults to produce the same degree of hypotension. Our tentative dose-response curve confirms that observation. The age/weight ratio of a normally developing child from age 2 until maturity remains constant at around 0.3 to 0.5. A ratio of 0.35 (fig 6) on the curve would indicate that the needed dose of nitroprusside under halothane anesthesia would be in the range of 250 to 300 μg/min throughout childhood and adolescence.

Side Effects.—Doubts have been expressed about the safety of nitroprusside because its immediate metabolic products are cyanide and thiocyanate. Vesey's group[15] reported a significant rise in plasma cyanide following infusion of nitroprusside for hypotensive anesthesia. They concluded, however, that those levels encountered did not produce toxic effects. Certainly, nitroprusside has been safely used for extended periods in treating hypertensive crises, without a dangerous buildup of toxic products.[16] Recently, several anesthetic deaths[17-19] were reported in which nitroprusside was implicated, but most of these occurred under extraordinary circumstances in which the evidence against nitroprusside may be spurious.

Only Davies and coworkers[17] clearly documented a death due to nitroprusside overdose. Johnson[8] stated the therapeutic index of nitroprusside to be around 10:1, but McDowell and colleagues,[20] working with primates, suggested that the toxic:therapeutic dose ratio might be closer to 6:1. Too, the accumulation of toxic byproducts is related not only to total dosage but also to the time over which it is administered. Seifen* reported the successful use of nitroprusside for prolonged hypotensive anesthesia for the excision of a massive cerebral arteriovenous fistula. Mean blood pressure was kept at 65 torr for over 8 hours using 57,000 μg (119 μg/min) without clinical evidence of toxicity. The patient in the fatality reported by Davies, on the other hand, received 120 μg/kg/min (4800 μg/min) over 80 minutes. This patient, whose age/weight ratio was

*Seifen A: Prolonged deliberate hypotension with sodium nitroprusside: a case report. Presented at the 69th Annual Meeting of the Southern Medical Association, Miami Beach, Florida, November 16, 1975.

0.35, received 20 times the dose of nitroprusside our data would have predicted.

The goal of hypotensive anesthesia is the safe reduction of intraoperative blood loss, thus reducing transfusion risks. Previous hypotensive technics had a narrow margin of safety in that cardiac output was usually reduced in proportion to the degree of induced hypotension. This is in contrast to the results of our study, in which sodium nitroprusside was used as the sole hypotensive agent. Nitroprusside, a potent direct vasodilator, reduces the afterload on the anesthesia-depressed heart. The improvement in cardiac output plus better tissue perfusion appears to widen the margin of safety over that of earlier technics. We found not only that sodium nitroprusside dosage is predictable but also that this agent is effective and safe in reducing blood loss in selected patients undergoing total hip replacement in the supine position.

Train-of-Four Fade and Edrophonium Antagonism of Neuromuscular Block by Succinylcholine in Man

CHINGMUH LEE, MD*

Thumb twitch in response to train-of-four stimulation (2 Hz for 2 sec) of the ulnar nerve was measured in 36 patients anesthetized with halothane and N_2O and paralyzed with succinylcholine chloride (SCC). Train-of-four fade was detected whenever a block was produced. The train-of-four ratio decreased with continued exposure to SCC. Edrophonium effect was predictable by the train-of-four ratio in a semiquantitative manner, a high ratio predicting block enhancement and a low ratio, antagonism. When calculated at 30 to 50 percent recovery (from complete block), a train-of-four ratio of 0.4 or less reliably predicts antagonism. The magnitude of antagonism is also predictable in a semiquantitative manner, although complete antagonism cannot be ascertained. The lower the ratio, the more effective the antagonism becomes. Train-of-four fade, therefore, appears to be a consistent and sensitive quantitative sign of phase II neuromuscular block by SCC in man.

SENSITIVITY of neuromuscular transmission to nondepolarizing block is closely dependent on the rate of nerve stimulation. After establishment of a partial block, a train of indirectly-elicited twitches fade initially, reaching a new lower steady level at the 4th to 6th twitch.[1-3] The limit of fading corresponding to the frequency of stimulation is therefore well approximated by the train-of-four ratio, the ratio of 4th:1st twitch in each train. Train-of-four fade appears to be a consistent and sensitive quantitative sign of nondepolarizing block.[1-3]

Originally, train-of-four twitches at 2 Hz were observed to fade significantly under nondepolarizing block but not under depolarizing block.[1-3] Subsequently, fading was seen also after prolonged exposure to succinylcholine chloride (SCC).[4] Demonstration of phase II neuromuscular block, however, does not necessarily predict the antagonistic effect of anticholinesterases on the block. This report concerns the predictability, by the train-of-four ratio, of the effect of edrophonium, an anticholinesterase, on SCC-induced neuromuscular block.

METHODS

Thirty-six adult patients, 19 to 77 years old (ASA I or II) undergoing general surgical, gynecologic, and orthopedic operations, were studied. All had normal blood chemistries and were not receiving antibiotics, anticholinesterases, or other drugs known to affect neuromuscular transmission. Premedication consisted of 100 mg of pentobarbital, 75 mg of meperidine, and 0.6 mg of atropine IM at ½ to 1 hour before induction. Anesthesia was induced with 100 to 500 mg of thiopental IV (in increments) and maintained with halothane (0.3 to 1%, inspired) and N_2O-O_2 (60:40). All patients were intubated. Ventilation was controlled with a ventilator delivering tidal volumes of

Part of the material in this report was presented as an abstract at the 1974 ASA meeting, Washington, DC, and appeared in the Proceedings (pp 137-138) as "Quantitative assessment of dual block using train-of-four stimulation." That portion of this investigation was carried out at the Department of Anesthesiology, Duke University Medical Center, Durham, North Carolina.

Paper received: 8/11/75

Accepted for publication: 1/27/76

12 ml/kg at the rate of 10 breaths/min. Body temperature was 36 to 37.5° C esophageally.

The procedure was that of stimulating the ulnar nerve and recording the thumb twitch.[4] Trains of 4 supramaximal square pulses of 0.1 ms duration (0.5 sec apart) were repeated every 12 seconds. The stimuli were derived from a Grass S88 stimulator, passed through a Grass SIU5 stimulus isolation unit and delivered close to the ulnar nerve via a pair of stainless needles placed subcutaneously at the wrist. Thumb twitch was recorded on a Grass Model 7 polygraph via a Grass FT.03 or FT 10C force-displacement transducer. The thumb was uniformly abducted. When an FT.03 was employed, tetanic force was not measured.

The initial dose of SCC, given IV, varied from 2 mg (as a test observation) to 90 mg as a bolus. Paralysis was maintained by IV drip of a 0.2 percent SCC solution, interrupted from time to time to assess the spontaneous recovery, the train-of-four ratio, and, occasionally, the effect of 10 or 15 mg of edrophonium IV.

Atropine (0.6 to 1 mg) routinely preceded edrophonium test. Train-of-four ratio was calculated at approximately 30 to 50 percent recovery from complete block and correlated with the effect of edrophonium. Since spontaneous recovery rate ranged from near nil to double the twitch tension within 30 seconds, the edrophonium effect was evaluated 30 to 40 seconds after injection. Invariably, the peak effect of edrophonium was obtained within this period.

RESULTS

The train-of-four ratio varied with the degree of block, the time course of each dose, and the total dose as well as the total duration of SCC exposure. The effect of edrophonium varied accordingly.

A high train-of-four ratio predicted block enhancement, while a low train-of-four ratio predicted antagonism (fig 1). If the 4th twitch was similar to the first in strength, block was enhanced; if much weaker than the first, block was antagonized. If the train-of-four ratio before the test was 0.3 to 0.4 or less, block was not enhanced but consistently antagonized.

Marked antagonism, equivocal effect, and block enhancement by edrophonium, was seen with various train-of-four ratios (fig 2). Such antagonizing effects were observed both in the train-of-four ratio, selectively improving the 4th twitch, and in the percentage of block, improving all twitches (fig 2, C). A slight antagonism might improve only the 4th and 3rd twitches of the train.

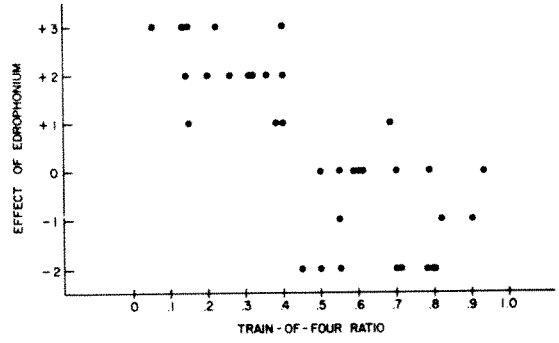

FIG 1. Relations between effect of edrophonium and the train-of-four fade in humans partially recovering from SCC neuromuscular block. Each dot represents 1 of the 35 observations made on 23 patients after SCC administration. Ordinate: −2, enhancement of block; −1, decrease in rate of recovery, without enhancement of block; 0, no apparent effect; +1, slight antagonism, or antagonism observable only in 4th and 3rd twitches of the train-of-four; +2, moderate antagonism, more than tripling 1st twitch of train-of-four in 30 to 40 seconds (converting 1st twitch from 20% to 70% of control); +3, marked antagonism, with complete reversal of 1st twitch of train-of-four. Note that no deepening of block occurred when train-of-four ratio was less than 0.4.

In some patients in whom both tetanic fade and post-tetanic twitch facilitation were clearly demonstrated, the block was not antagonized in the presence of a train-of-four ratio of 0.5, as illustrated in figure 3.

The total amount of SCC administered at the time of edrophonium tests averaged 6.06 ± 2.8 mg/kg, 3.18 ± 1.45 mg/kg, and 1.22 ± 0.72 mg/kg in the antagonized (16 observations), the unaffected (8 observations), and the enhanced (11 observations) occasions, respectively. These data do not represent the minimal dose requirement for each category.

DISCUSSION

Previously recognized clinical signs of phase II SCC block include lack of fasciculation, fade of tetanic contraction, and post-tetanic twitch facilitation. These signs do not emerge simultaneously;[5-10] they suggest changes in the nature of the block but, with probable exception of a marked post-tetanic

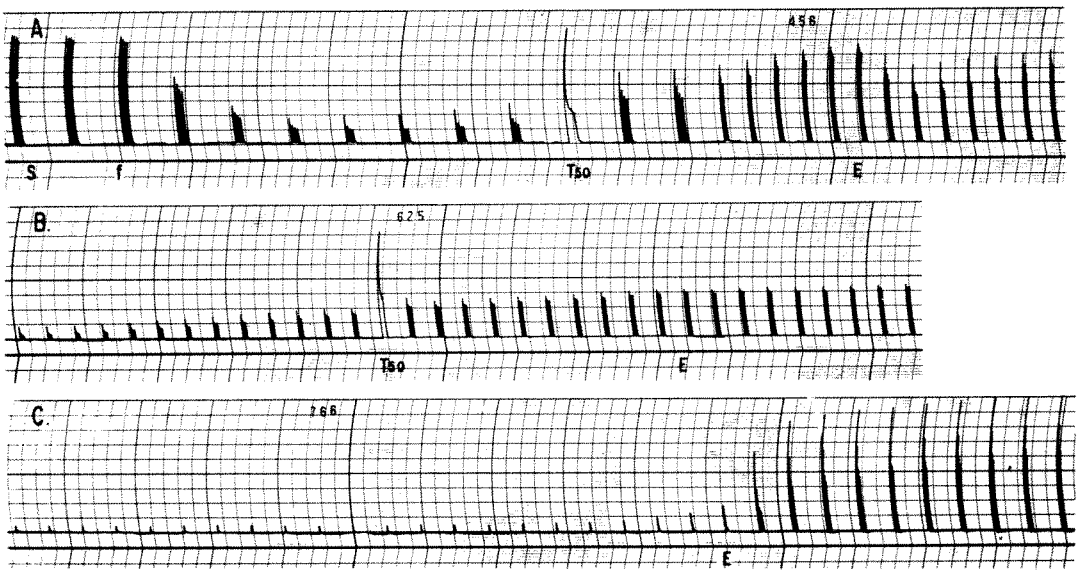

FIG 2. Three cases illustrating relationships among train-of-four fade, effects of edrophonium on block, and total quantity of SCC administered. Total SCC given was (A) 1.5 mg/kg, (B) 3 mg/kg; (C) 5 mg/kg. The train-of-four ratio (4th:1st twitch ratio in each train) measures train-of-four fade. In A and B, edrophonium (E, 10 mg IV) enhanced the block (A), or slowed down recovery (B) despite marked tetanic fade (T 50) and post-tetanic twitch facilitation. Train-of-four ratios before tetanic stimulations were 0.5 and 0.8, respectively. In (C), marked antagonism by edrophonium is seen in the presence of marked train-of-four fade. In A, "f" indicates fasciculations.

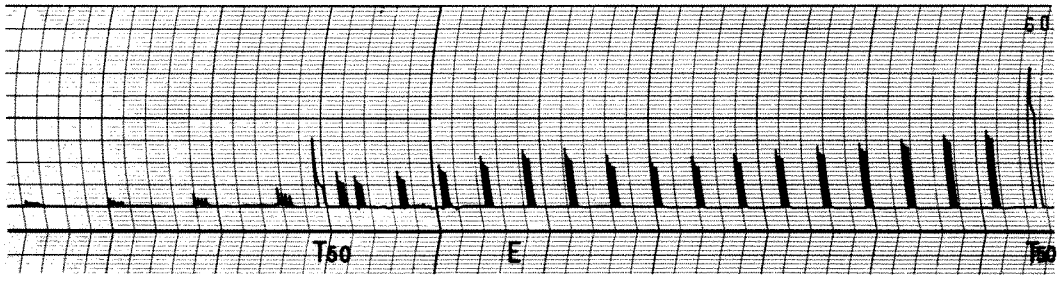

FIG 3. Block enhancement by edrophonium (E, 10 mg IV) despite faded tetanus (T 50) and marked post-tetanic twitch facilitation. Chart speed was varied before T 50 to permit clear tracing. Patient given an SCC total of 50 mg (0.6 mg/kg). The train-of-four ratio was 0.5 or more.

facilitation,[7] do not reliably predict antagonism by anticholinesterases. Difficulties have resulted from attempts to antagonize the block.[11-13]

Theoretically, an anticholinesterase can antagonize a curariform nondepolarizing block, produce neuromuscular block of its own, and prolong and/or enhance an SCC-induced depolarizing block.[14-17] Antagonism results when the overall antagonizing effect outweighs the enhancing effect, as often seen in phase II.

Our study demonstrated that train-of-four fade reliably predicts, in a semiquantitative manner, the overall effect of edrophonium on SCC-induced neuromuscular block. A slight train-of-four fade predicts block enhancement, a marked train-of-four fade, antagonism. The effect is unpredictable when the train-of-four ratio approximates 0.5. Until supported by further investigations, however, use of anticholinesterases cannot be routinely advocated for treatment of prolonged neuromuscular block after administration of large doses of SCC in clinical

practice, since the magnitude of antagonism may vary and may not be clinically satisfactory. Similar observation on prolonged neuromuscular block after SCC administration to patients with atypical plasma cholinesterase has been described.[18] Effects of other anticholinesterases have not been reported.

Whether train-of-four fade is manifestation of an underlying change in mechanism of neuromuscular block is not known. It is possible that each of the clinical signs of block (including train-of-four fade and tetanic fade), endplate polarization, and the sensitivity of the endplate to the transmitter may each change from the 1st to the 2nd phase with a different time course and dose relationship.

The existence of definite train-of-four fade following the 1st effective SCC dose was not seen by Ali's group,[1-3] who reported no train-of-four fade in the absence of halothane. A slight fade, however, may be suggestive of the beginning of a 2nd mechanism of block, ultimately characterized by marked train-of-four fade. My recent report[4] that train-of-four ratio permits clinical delineation of phases I and II, and the present observation that train-of-four ratio predicts edrophonium antagonism of SCC, support the speculation that train-of-four ratio reflects the moment-to-moment relative proportions of 2 mechanisms of SCC block operating simultaneously. The edrophonium-antagonizable block, characterized by marked train-of-four fade, becomes more observable as exposure continues.

During continuous SCC administration, train-of-four fade as a monitor of neuromuscular block has several potential advantages. It permits delineation of phases I and II.[4] Provided that 10 seconds are allowed between applications, the stimulation itself leaves no residual effect on the block or the fade and permits immediate reevaluation for dynamic studies. The ability to follow both the block and the fade simultaneously without artificially changing either (as does a tetanic stimulation) is a definite advantage in dealing with a short-acting neuromuscular blocker because the magnitude of fade, besides other factors, is dependent on the degree of block[19] (fig 2) which changes rapidly. Compared with tetanic stimulation, it is less painful and less likely to deplete the transmitter, thus introducing yet another factor in fade.

It is possibly more reliable than tetanic fade and post-tetanic facilitation in prediction of antagonism by edrophonium, although in the present study reliability of train-of-four and tetanus in prediction of edrophonium effect cannot be compared statistically because tetanic stimulation was purposely avoided in most cases.

ACKNOWLEDGMENT

LEFT VENTRICULAR FUNCTION. Simultaneous comparisons of left atrial, pulmonary capillary wedge, pulmonary artery end-diastolic and central venous pressure were obtained in patients undergoing cardiac operations. Left atrial pressure was identical to pulmonary capillary wedge pressure and pulmonary artery end-diastolic pressure in 24 percent and 18.5 percent of the measurements, respectively. It was within ± 4 torr of the pulmonary capillary wedge pressure and end-diastolic pressure in 94.6 percent and 89 percent respectively. Technical problems with the Swan-Ganz catheter occurred in over 25 percent of patients. The authors conclude that wedge pressure is a more reliable indirect measurement of left atrial pressure than is the pulmonary artery end-diastolic pressure. There was no consistent correlation between central venous pressure and either indirect or direct indicators of left ventricular function. *(Humphrey CB, Oury JH, Virgilio RW et al: An analysis of direct and indirect measurements of left atrial filling pressure. Neutrophil Chemotaxis During and After General Anesthesia and Operation

THEODORE H. STANLEY, MD*
GARY E. HILL, MD†
MARY R. PORTAS, MTASCP‡
NANCY A. HOGAN, BA§
HARRY R. HILL, MD‖
Salt Lake City, Utah**

The neutrophil granulocytes of 43 patients undergoing general anesthesia and operation were examined to determine if altered function occurs during these procedures. Neutrophil chemotaxis, random migration, and total and differential leukocyte counts were determined immediately before anesthesia; after 35 to 60 minutes of anesthesia but before operation; 60 minutes after initiation of operation; and 60 minutes after operation. Anesthetic agents included 1 to 3.5% enflurane, 0.5 to 2% halothane, or 0.5 to 1.1 mg/kg of morphine plus N_2O-O_2 (60:40).

Neutrophil and total white blood cell counts were uninfluenced by any of the anesthetics; however, marked rises in both occurred during operation and persisted postoperatively after each of the anesthetic technics. Neutrophil chemotaxis was reduced an average of 36, 32, and 21%, respectively, by halothane, enflurane, and morphine before operation and 20, 10, and 5% intraoperatively. Preoperative reductions in chemotaxis were statistically significant after all anesthetics. However, only halothane produced a significant intraoperative reduction in chemotaxis. Postoperative neutrophil chemotaxis did not differ from control (preanesthesia) values after any of the anesthetics. Halothane and enflurane reduced leukocytic random migration before but not after operation. Morphine had no effect on random migration at any time. These data demonstrate that anesthesia impairs neutrophil function in man but that operation appears to reverse this depression.

EARLY polymorphonuclear responses to bacterial invasion in the body are critical in determining the outcome of an infection. It has been shown[1] that prompt infiltration of phagocytic cells into an area of bacterial invasion is essential if multiplication of the organisms is to be prevented. Unidirectional movement of leukocytes toward a chemotactic stimulus, neutrophil chemotaxis, is one of the mechanisms by which phagocytic cells are attracted to an area of bacterial invasion.[2,3] The influence of anesthesia and operation on leukocyte motility has not been adequately studied.

Paper received: 2/19/76
Accepted for publication: 3/26/76

This investigation was undertaken to determine the effects of general anesthesia and operation on neutrophil chemotaxis in man.

METHODS

After giving informed consent, 43 adult patients about to undergo elective orthopedic, gynecologic, plastic, or neurosurgical operations served as experimental subjects. Patients who had infection, extensive tumors, required a blood transfusion, or sustained significant hypotension during or immediately after the operation were excluded from the study.

Premedication, at 1.5 hours before operation, included a barbiturate (1 mg/kg) or diazepam (1 mg/10 kg), morphine (1 mg/10 kg), and atropine (0.05 mg/10 kg). Blood (9.5 ml) from a peripheral vein was obtained before anesthesia and added to 0.5 ml of a solution of beef lung heparin (1000 u/ml). Following this, an infusion of lactated Ringer's solution was started in an arm vein and standard blood pressure and precordial pulse rate monitoring initiated. Anesthesia was induced with a sleep dose of sodium thiopental (200 to 300 mg) IV and maintained with enflurane (1 to 3.5%), halothane (0.5 to 2%) or morphine (0.5 to 1.1 mg/kg), plus N_2O-O_2 (60:40). All patients were intubated after 15 to 19 minutes of anesthesia.

Twenty patients were given succinylcholine (1.5 mg/kg) for intubation; the remainder required no muscle relaxant. Some patients needed pancuronium (2 to 7 mg) for muscle relaxation intraoperatively, but this was not administered until a 2nd blood specimen was obtained and the operation had begun. Muscle relaxation was reversed postoperatively with atropine (1 to 1.5 mg) and neostigmine (3 to 6 mg), and patients were extubated and returned to the recovery room.

Additional blood specimens for neutrophil chemotaxis examination were obtained after 35 to 60 minutes of anesthesia (after a minimum of 20 minutes following intubation) and before operation; following 60 minutes of operation; and 60 minutes after operation. All blood specimens were also examined for leukocyte random migration and total and differential white blood cell (WBC) counts.

Leukocyte-Function Tests.

Chemotaxis.—Hill and coworkers' *in-vitro* method[2,4] was used for studying chemotaxis. Leukocyte-rich plasma was obtained by allowing the erythrocytes in the 10-ml heparinized blood specimens to settle over a 1-hour period. After determination of the number of polymorphonuclear leukocytes (PMNs) in the leukocyte-rich plasma, 0.1 ml of the suspension was diluted to 0.4 ml with tissue-culture medium 199, and the cells were deposited on 1 side of a 5-μ millipore filter using a Shandon cytocentrifuge.* The filters were immediately placed in a modified Boyden chamber† and a chemotactic stimulus was added to the attractant side. After incubation for 3 hours at 37° C, the migrant PMNs within the reticule of 10 random fields were counted (using a 10x ocular, 45x objective, and 5x 5-mm photo reticule). A chemotactic index was calculated by dividing the number of migrant PMNs by the total number of PMNs ($x10^6$) delivered to the starting side of the filter. This method of calculating the chemotactic index takes into account only the number of PMNs delivered to the filter and the number moving completely through the filter. It, therefore, measures intrinsic neutrophil chemotactic activity. The percentage or total number of mononuclear cells in the suspension does not affect the leukotactic index, and there is no association between the number of PMNs delivered to the filter and the leukotactic index. Chemotactic assays were made in triplicate.

Chemotactic Factors.—A bacterial chemotactic factor was prepared from a culture filtrate of *Escherichia coli* grown in medium 199 for 24 hours at 37° C. After passage through a 0.2-μ millipore filter, this factor was frozen at −70° C in 1-ml ampules. For each experiment, an ampule was thawed and diluted in medium 199, so that each ml of the solution contained 50 μl of the factor. A volume of 2 ml of this solution was added to the bottom or attractant side of the chemotactic chamber for each analysis. The same lot of filtrate was used throughout the study.

Random Motion.—Random motion of leukocytes was measured by determining the chemotactic index when no chemotactic stimulus was added to the attractant side of the modified Boyden chamber.

RESULTS

The 3 groups of patients were comparable

*Shandon Scientific Company, Sewickley, Pennsylvania.

†Neuroprobe Corporation, Bethesda, Maryland.

with respect to age and weight and had operations of similar type and duration (table 1). Preanesthesia PMN chemotaxis, random migration and counts, and total WBC counts were also similar in the 3 groups (tables 2, 3). Neutrophil and total WBC counts were uninfluenced by any of the anesthetic agents; however, marked rises in both occurred during operation and persisted postoperatively after each of the anesthetic technics.

Neutrophil chemotaxis was reduced an average of 36, 32, and 21%, respectively, by halothane, enflurane, and morphine preoperatively and 20, 10, and 6% intraoperatively (table 3). Preoperative reductions in chemotaxis were statistically significant after all anesthetic agents (table 3). However, only halothane produced a significant intraoperative reduction in chemotaxis. Postoperative neutrophil chemotaxis was not significantly different from control values with any of the anesthetics.

Halothane and enflurane reduced preoperative but not intraoperative or postoperative random PMN migration (table 3).

Morphine did not change random PMN migration at any time.

DISCUSSION

The neutrophil response to bacterial invasion consists of an increased release of PMNs from bone-marrow reserves into the blood, margination of PMNs to the walls of blood vessels, diapedesis through blood vessel walls into infected tissues, movement of PMNs to the invading organisms, and phagocytosis.[3] Investigations of the influence of anesthesia on the total neutrophil granulocyte response to infection have been primarily concerned with phagocytosis.[5-8] These studies have demonstrated that general anesthesia has little effect on phagocytosis *in vitro*[5,7,8] but can depress leukocytic bacterial engulfment *in vivo*.[6]

Before phagocytosis can take place, PMNs are attracted by and migrate toward the infecting stimulus. This process of leukocyte chemotaxis is markedly stimulated during active bacterial infections but can be depressed by certain disease processes (diabetes mellitus, rheumatoid arthritis, and allergic diseases)[9-15] and by the administration of a number of pharmacologic agents (histamine, epinephrine, isoproterenol, and the prostaglandins).[16]

Because of the nonavailability of a good *in-vivo* model and the tediousness of *in-vitro* methods, the influence of anesthesia on leukocyte migration has not been intensively studied. Development of a technic employing a cytocentrifuge to sediment leukocytes directly on millipore filters appears to have eliminated some of the problems of previous *in-vitro* methods of measuring neutrophil chemotaxis.[4]

The present study demonstrates that clinical concentrations of halothane and enflurane plus N_2O, and anesthetic doses of morphine and N_2O impair neutrophil granulocyte chemotaxis in man, and that random motion is also depressed by these anesthetic agents. Interestingly, operation and the early postoperative period are associated with marked rises in PMNs and total WBC counts and a reversal of granulocyte function.

Why anesthesia with the above agents depresses PMN function, and operation reverses this depression, is not clear. However, the mechanism may be related to changes produced by these agents in intracellular concentrations of cyclic 3′,5′-adenosine monophosphate (cAMP), cyclic 3′,5′-guanosine monophosphate (cGMP), or both these nucleotides. Our recent work[16] has shown that intracellular cAMP and cGMP provide opposing regulatory influences on leukocyte chemotactic activity, and has demonstrated that incubation of PMNs with cAMP, or with agents that promote increased intracellular cAMP, inhibits leukocyte chemotaxis. In contrast, cGMP and compounds which promote increased intracellular cGMP concentration markedly enhance the leukotactic response.

The influence of anesthesia and of anesthesia and operation on intracellular cAMP and cGMP has not been extensively studied. However, Sprague's group[17] has shown that clinical concentrations of halothane and isoflurane (an isomer of enflurane) result in marked increases in intracellular cAMP in rat aortic-wall tissue. Similar changes in leukocyte cAMP would help explain the effects of anesthesia on leukocyte chemotaxis in this study. The effects of operation and early postoperative recovery on intracellular nucleotide concentrations are unknown. Such variables as type and depth of anesthesia, degree of trauma, and area and duration of operation markedly influence metabolic and endocrine responses intraoperatively and postoperatively and make study of intracellular nucleotide concentrations and leukotactic mechanisms extremely difficult.

Surgical stress, particularly postoperative stress, is associated with marked elevations in circulating catecholamines.[18] The alpha-adrenergic catecholamines markedly enhance PMN hemotaxis.[16] In contrast, beta-adrenergic stimulators produce a marked depression of the neutrophil response to the bacterial chemotactic factor.[16] Perhaps operation and the early postoperative recovery period in our patients were associated with a preponderance of alpha- rather than of beta-adrenergic stimulation.

The effects of anesthesia and of specific anesthetic agents on the incidence and magnitude of postoperative infections is unknown. Our findings, and those of others,[6] suggest that the anesthetic state should enhance the development of infections. Further studies are being conducted to determine the effect of various anesthetic and pharmacologic agents on neutrophil granulocyte chemotaxis. Such studies may lead to technics for pharmacologic modification of PMN function during anesthesia and surgical procedures.

Guest Discussion

DAVID L. BRUCE, MD
Department of Anesthesia
Northwestern University
Chicago, Illinois

Dr. Stanley and coworkers have tackled the question of anesthetic influence on chemotaxis and have come up with data that are most interesting. A possible role of anesthesia in promoting infections was postulated as long ago as 1903,[1] and this question is still prompted by studies up to and including the one under discussion. Since resistance to infection, the original definition of immunity, involves a number of events on both cellular and humoral levels, information about anesthetic effect on chemotaxis is important. Migration of neutrophils to a site of bacterial invasion is the body's first line of defense.

The results of this present study indicate a suppression of neutrophil chemotaxis by general anesthetics, an effect antagonized to an extent by operation. If the anesthetic effect had just involved the cellular events secondary to stimulation by a chemotactic factor, random migration would have been spared. However, if the data are arranged in terms of percent change from baseline values (table), we see that the volatile agents depressed chemotaxis and random migration of these cells to the same extent.

Previous studies by one of this paper's coauthors, Dr. H. R. Hill, failed to demonstrate a cyclic-GMP effect on random leukocyte motility at concentrations that markedly enhanced the neutrophil chemotactic response.[2] It thus seems likely that the volatile anesthetics produced fundamental changes in the intracellular contractile proteins that cause cellular locomotion and that the present authors' hypothesis of cyclic nucleotide modulation of these changes is only speculative. Lymphocytic contents of cyclic-AMP have been measured and found not to be altered by halothane,[3] but that does not prove that Dr. Stanley's hypothesis is incorrect. It does require its substantiation by measurements of cyclic nucleotides in these stimulated neutrophils.

TABLE

Anesthetic Effects on Chemotaxis and Random Migration

	Preanesthetic, %	Anesthesia, %	Anesthesia and operation, %	Postoperative, %
Halothane				
Chemotaxis	100	64	80	92
Random migration	100	59	84	87
Enflurane				
Chemotaxis	100	67	89	97
Random migration	100	63	82	103
Morphine				
Chemotaxis	100	78	94	107
Random migration	100	88	115	115

It is fascinating to see, in these data, yet another example of depression of a physiologic function by anesthesia and subsequent surgical stimulation of the same function. Again, the balance between anesthesia and operation is involved. Implicit in such a balance is the necessity for operation, and one wonders what hazard is associated with general anesthesia administered for relatively painless diagnostic or very minor surgical procedures. Most patients have sufficient functional reserves of heart, lungs, kidneys, liver, and hematopoietic tissues that modest reductions from anesthesia are unimportant. Gross surveys of infection rates among surgical patients would likely show nothing. Studies like that reported today carry the implication that the patient with marginal reserves, such as one with granulocytopenia, will be further compromised by general anesthesia.

We do not "put patients to sleep;" we give potentially fatal, toxic drugs that facilitate operation but compromise virtually every physiologic function that has been studied. General anesthesia carries with it this real, apparently irreducible risk, and this requires that it be treated as controlled toxicity rather than a harmless period of sleep.

DRUG INTERACTION. Methyldopa and haloperidol are both thought to prevent dopamine from reaching its central neurotransmitter effector site. As such, patients may become vulnerable to unwanted mental effects of methyldopa when it is combined with haloperidol. The authors describe two hypertensive patients treated with methyldopa who developed impaired mental and motor function when haloperidol was added to the regimen. Symptoms cleared within 48-72 hours after discontinuing haloperidol. *(Thornton WE: Dementia induced by methyldopa with haloperidol. N Engl J Med 294:1222, 1976)*

Hypertension and Decreased Renal Blood Flow Following Methylene Blue Injection

ALEXANDER A. BIRCH, MD*
WILLIAM H. BOYCE, MD†
Winston-Salem, North Carolina‡

Renal blood flow (RBF) and arterial blood pressure (BP) were monitored in 12 patients undergoing nephrolithotomy in the lateral flexed position. All patients were preoxygenated and were anesthetized with sodium thiopental, N_2O, O_2, and fentanyl. Maintenance relaxation was obtained with pancuronium bromide. Arterial pressure was monitored by percutaneous arterial catheter.

Following exposure of the kidney and renal pedicle, an electromagnetic flow probe was attached to the renal artery and baseline flows recorded. Following baseline measurements, 20 ml of 1 percent methylene blue was given intravenously. All patients studied showed an immediate rise in BP, and 11/12 showed a simultaneous decrease in RBF. The average fall in RBF was 35 percent at one minute. Both parameters returned to normal values on the average in 177 seconds. The decreased RBF appeared to be part of a generalized vasoconstriction caused either by sympathetic reflexes or by the direct action of methylene blue.

AT OUR institution, nephrolithotomies are frequently performed for removal of staghorn renal calculi. To facilitate entry into the kidney, a relatively avascular renal plane is located by the following procedure: The posterior segmental renal artery is located and clamped. Methylene blue (20 ml, 1% solution) is then given IV, the plane between the now blue kidney and the red distribution of the postsegmental artery is determined, and the kidney incision made along the intersection of the 2 colors.

While continuously monitoring arterial blood pressure (BP) and renal blood flow (RBF) for another project, we observed marked transient rises in BP and decreases in RBF after methylene blue injection. These observations prompted the following investigation.

METHODS AND MATERIALS

After informed consent, BP and RBF changes were studied in 12 adult male and female patients, aged 19 to 65 years. Premedication consisted of 10 mg of diazepam and 0.4 mg of atropine IM, 1 hour before induction of anesthesia. After preoxygenation (100% O_2), anesthesia was induced with sodium thiopental (3 to 4 mg/kg), N_2O, O_2, and fentanyl. Pancuronium or succinylcholine was used to facilitate intubation. Maintenance anesthesia was with N_2O, O_2, and fentanyl, and maintenance relaxation was with pancuronium.

A 20-gauge Teflon catheter was placed in either the right or left radial artery and attached to an arterial pressure transducer. All patients were intubated and turned to the flexed lateral position. Ventilation was controlled throughout the operation.

Blood loss during exposure of the kidney did not exceed 200 ml and was replaced with 5 percent dextrose in lactated Ringer's solution. Once the renal artery was exposed, a properly calibrated electromagnetic flow

probe* was placed around the artery and flow recorded. Signals from the flow probe and the transducer† were displayed on a Model-7 Grass Polygraph‡. After clamping the posterior segmental artery, baseline measurements were made; then 20 ml of 1 percent methylene blue was given over a 15-second period, the entire response period being recorded.

RESULTS

Thirty seconds after injection, the mean arterial pressure (MAP) of all patients had increased ($p<0.001$, sign test). At 1 minute, MAP was still significantly higher than baseline ($p<0.001$), as was the 2-minute value in 11/12 patients ($p<0.003$). At the 3-minute mark, MAP had returned to near baseline in all patients.

Following methylene blue injection, RBF fell in 11/12 patients at both the 30-second and 1-minute intervals ($p<0.01$). At one minute, the average RBF fell 35 percent. The RBF in 9/10 patients ($p<0.011$) was less than baseline at 2 minutes (fig 1), all patients tending to return toward baseline at 3 minutes.

Changes in renal vascular resistance at 30 seconds and 1 minute were also statistically significant ($p<0.001$, fig 2).

Five patients developed arrhythmias (either PACs or occasional PVCs) during the peak of the hypertensive response; these arrhythmias disappeared as the BP returned toward control values. Transient hypertension occurred in every patient studied and increases in BP were severe, with an average duration of 177 seconds (range 90 to 250). The range of peak values was from 185/105 to 260/155, one man showing a rise of 90 torr, from 170/110 to 260/155.

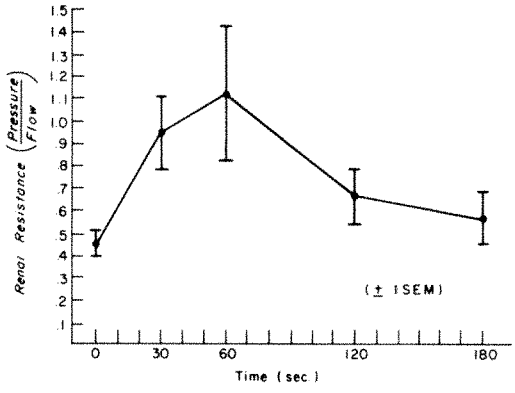

FIG 2. Changes in renal vascular resistance in 12 patients (± 1 SEM) following methylene blue injection.

DISCUSSION

Goodman and Gilman[1] mention a "moderate rise in blood pressure after methylene blue injection in animals," but we have found no prior report of this effect in man. In our study, MAP rose an average of 35 percent above baseline at 30 seconds and 29 percent at 1 minute. At the same time as hypertension occurred, a fall in RBF was seen, with an average decrease of 28 percent at 30 seconds and 35 percent at 1 minute, followed by a gradual return toward normal.

The acute onset of these changes along with a short duration (177 sec) suggests to us that methylene blue injection either causes a generalized reflex vasoconstriction or direct vascular effect. The hypertension evidently causes reflex slowing of the heart by stimulating sino-aortic baroreceptors.[2] We also feel that the arrhythmias were related to the hypertension.

The mechanism of action of methylene blue in causing vasoconstriction still remains [illegible]. The methylene blue used in [illegible] distilled-water solu-

takes 5 to 15 minutes before sizable amounts are released, which does not coincide with the time course seen in our study. The role of serotonin, speed of drug injection, as well as of dosage, in methylene blue-induced hypertension and decreased RBF, require further study. Meanwhile, it is clinically important for anesthesiologists to be aware of these responses in man, so that blood pressure readings during such procedures will not lead to the conclusion that the patient is "light" and to the administration of an inappropriate dose of anesthetic or analgesics.

CPK-MB ISOENZYME. The diagnosis of acute myocardial infarction postoperatively may be obscured by anesthetic or analgesic drugs and nonspecific serum enzyme changes after major surgery. The electrocardiogram may fail to diagnose acute myocardial infarctions in over 30 percent of patients. However, the MB isoenzyme of creatinine phosphokinase (CPK) is specific for myocardium and may serve as an indicator of injury in the early postoperative period. CPK-MB isoenzyme was present in the serum in 10 of 30 patients after cardiopulmonary bypass and in no patient after thoracotomy. In 6 of these patients the other enzyme tests were not suggestive of myocardial injury. Isoenzyme elevations correlated with the duration of cardiopulmonary bypass (over 90 minutes), aortic cross clamp time (over 75 minutes), interruption of coronary artery blood flow for more than 30 minutes and heart valve replacement rather than vein bypass grafts. CPK-MB isoenzyme proved to be a useful adjunct in the diagnosis of acute myocardial infarction in the early postoperative period. *(Pyle RB, Blomberg DJ, Burke MD et al: CPK-MB isoenzyme: Use in diagnosis of acute myocardial infarction in the early postoperative period. Halothane MAC in Dogs Unchanged by Phenobarbital

OSCAR VIEGAS, MD*
ROBERT K. STOELTING, MD†
Indianapolis, Indiana

Halothane MAC in dogs was not significantly changed by phenobarbital (PB) therapy. Following 10 consecutive days of oral PB (10 mg/kg), halothane MAC was 0.95 ± 0.05 vol/dl (mean ± SE) compared with a halothane MAC of 1.05 ± 0.03 vol/dl in another group not given PB. The absence of change in MAC may reflect either the development of tolerance to CNS sedative effects of PB or the masking of antanalgesia effects of the barbiturate by associated sedation and/or analgesia.

ACCELERATED anesthetic drug biotransformation could prolong establishment of the brain partial pressure required for anesthesia (prolonged induction) but should not change the brain partial pressure necessary to produce anesthesia. However, any associated CNS sedative effects produced by agents responsible for accelerated drug biotransformation could have additive anesthetic effects which would be reflected by a reduced MAC for an inhalation anesthetic.

For example, phenobarbital (PB) pretreatment in rats stimulates hepatic microsomal enzymes responsible for inhalation anesthetic biotransformation[1] and at the same time is a CNS depressant.[2] Therefore, we speculated PB might reduce anesthetic requirements. However, this study demonstrates that PB administration did not significantly alter halothane MAC in the dog.

METHODS

Anesthesia was achieved and maintained in 12 mongrel dogs (10 to 15 kg), using halothane in O_2. Endotracheal intubation was performed without neuromuscular blockers and ventilation was then mechanically controlled. Esophageal temperature was monitored and external heating or cooling applied to maintain body temperature near 37° C. End-tidal halothane was measured intermittently with a Beckman infrared analyzer and maintained constant for 15 minutes. After 15 minutes and just before the first 30-second tail-clamp stimulus, an arterial blood sample was drawn from a femoral artery catheter for determination of arterial blood gases and pH, halothane,[3] and PB concentrations.[4]

The arterial halothane concentration was converted to the equivalent alveolar concentration assuming a halothane blood/gas partition coefficient equal to 2.4 for the dog. Halothane MAC was calculated as that concentration midway between the highest halothane concentration just permitting movement and the lowest concentration preventing movement.[5]

Six dogs received PB (10 mg/kg) orally every afternoon (1600 to 1800 hours) for 10 consecutive days. Halothane MAC was determined about 16 hours after the last PB dose. The 6 remaining dogs did not receive PB but were anesthetized in an identical manner.

Paper received: 11/7/75
Accepted for publication: 1/28/76

Data were analyzed for statistical significance by paired analysis with Student's *t*-test, and $p<0.05$ considered significant.

RESULTS

The presence of serum PB levels of 24.9 ± 3.8 μg/ml (mean ± SE) was not associated with a significantly reduced halothane MAC as compared with dogs not given PB (table). MAC in the treated dogs was 0.95 ± 0.05 vol/dl and in the untreated dogs 1.05 ± 0.03 vol/dl.

DISCUSSION

Although sedation may limit initial therapy with PB, the usual response is the development of tolerance despite the presence of therapeutic blood levels.[2] Indeed, it was our impression that animals treated with PB were not sedated as compared with the untreated group. Nevertheless, it seemed possible that CNS depression produced by PB, even in the absence of apparent sedation, might have an additive anesthetic effect as reflected by decreased MAC for an inhalation anesthetic.

However, when the last PB dose was given about 16 hours before anesthesia (simulating the patient taking PB chronically but not receiving the last dose before an elective operation), halothane MAC was not altered despite the presence of a serum PB concentration averaging 24.9 μg/ml (therapeutic range for seizure control 20 to 30 μg/ml*).

TABLE

Halothane MAC and Serum Phenobarbital Concentrations

	Phenobarbital		No phenobarbital
	MAC, vol/dl	Serum PB, μg/ml	MAC, vol/dl
	0.92	18.2	1.01
	0.77	23.2	0.95
	0.90	40.4	0.98
	1.01	25.0	1.08
	0.92	29.0	1.05
	1.15	14.0	1.19
Mean	0.95	24.9	1.05
± SE	0.05	3.8	0.03
Pa_{O_2}, torr	289 ± 31		325 ± 28
Pa_{CO_2}, torr	34.4 ± 3.1		32.1 ± 2.5
pH	7.45 ± 0.1		7.41 ± 0.1

Drugs such as reserpine,[6] alpha-methyldopa,[6] and chronic dextroamphetamine[7] may decrease halothane MAC secondary to CNS catecholamine depletion. The effect of PB on CNS catecholamine levels is not known, but sedative doses do prevent the stress-induced release of norepinephrine in the brain stem of rats.[2]

The analgesic action of barbiturates is controversial. In 1 report,[8] pentobarbital was effective in reducing postoperative pain in 50 percent of patients. In contrast, Dundee[9] and Clutton-Brock,[10] independently, demonstrated that thiopental or pentobarbital reduced the pain threshold. If antanalgesia was indeed produced by PB, a greater halothane concentration would have been required to prevent movement in response to the painful tail-clamp stimulus. The fact that halothane MAC was not altered suggested that PB antanalgesia either did not occur or was offset by sedative and/or analgesic actions of the drug.

Anesthetic induction may be delayed in the presence of enzyme induction. Berman's group[11] reported that PB did not alter the arterial methoxyflurane concentration required to produce sleep, but the time required for establishment of this arterial concentration was delayed. In our study, the difficulty in maintaining an identical inspired anesthetic concentration, ventilation, and cardiac output, plus the inability to quantitate enzyme induction or demonstrate a clear endpoint for induction, made any attempt at measuring the time for anesthetic induction impractical.

If these data are applicable to man, we conclude that halothane anesthetic requirement will not be altered in the patient receiving PB.

ACKNOWLEDGMENT

The authors thank Elizabeth B. Solow, MS, for determining the serum phenobarbital levels.

INSULIN ABSORBANCE. Interest in low-dose constant intravenous insulin infusion for the management of ketoacidosis has raised questions as to the method of insulin administration. A recent study showed greater than 50 percent insulin absorption to glass or plastic intravenous infusion containers. The authors evaluated 500 ml of normal saline and lactated Ringers (with or without 1.25 grams/dl human serum albumin) for insulin infusion. An infusion system utilizing a 50 ml "washout" with 25 units regular insulin permits delivery of at least 75 percent of the expected insulin for the first 50 ml and 100 percent thereafter. After the first 20 ml insulin concentrations were identical with or without added albumin. The passage of 50 ml through the infusion apparatus probably saturates insulin binding sites such that further insulin loss is minimal. *(Peterson L, Caldwell J, Hoffman J: Insulin absorbance to polyvinylchloride surfaces with implications for constant-infusion therapy. Massive Myoglobinuria Precipitated by Halothane and Succinylcholine in a Member of a Family with Elevation of Serum Creatine Phosphokinase

WILLIAM E. MOORE, MD*
ROBERT L. WATSON, MD†
JAMES J. SUMMARY, PhD‡
Honolulu, Hawaii§

Massive myoglobinuria developed in a patient given halothane and IV succinylcholine. Marked elevations of serum CPK were found in the patient and several family members. Myopathic changes in electromyogram and lack of neuromuscular symptoms and physical findings prompted the diagnosis of familial nonprogressive muscular dystrophy. Other hereditary muscular diseases were eliminated by medical workup. It is recommended that patients with known myopathy or unexplained elevations of serum CPK not receive the combination of halothane and succinylcholine.

MYOGLOBIN, along with other contents of skeletal muscle, can be released into the circulation in response to hereditary muscle disorders, muscle ischemia, and, rarely, from drugs and other toxins.[1] Authors of isolated case reports[2,3] of massive myoglobinuria implicating general anesthesia have failed to fully evaluate their patients postoperatively for the various hereditary muscle disorders known to be associated with myoglobinuria.

The following case is unique in that massive myoglobinuria secondary to halothane-succinylcholine general anesthesia occurred in a patient who was later found to have a subclinical myopathy characterized by persistently elevated serum creatine phosphokinase (CPK).

CASE REPORT

The patient was a healthy, 13-year-old, 32-kg boy, admitted for a repeat tympanoplasty 2 years after his initial operation, which had been complicated by postoperative infection.

Premedication was with 30 mg of meperidine, 50 mg of pentobarbital, and 0.15 mg of glycopyrrolate. Curare (3 mg IV) preceded induction with 150 mg of thiopental and 60 mg of succinylcholine. Neither gross muscle fasciculations nor myotonic response was noted; however, muscle relaxation was judged inadequate and the patient received a second bolus of 60 mg of succinylcholine. He was then intubated and maintained on 1 percent halothane and 60 percent N_2O. The operative procedure was completed uneventfully 2 hours later with no elevation of rectal temperature.

No complications were noted until 4 hours postoperatively, when the first voided urine was dark brown. Benzidine test of urine was positive for occult blood but the

Paper received: 11/17/75
Accepted for publication: 1/29/76

urine contained no red blood cell forms. Spun serum was clear, so a presumptive diagnosis of myoglobinuria prompted treatment with IV fluid and furosemide diuresis. Hemoglobinuria was eliminated by ammonium sulfate precipitation. Diuresis was brisk but urine remained positive for myoglobin for 24 hours postoperatively. No renal failure resulted. The patient exhibited marked muscular weakness and required assistance in standing and walking for the first 2 postoperative days.

Clinical laboratory tests are summarized in the table. The extremely high levels of serum CPK were isoenzyme type III, characteristic of skeletal muscle.

Review of the patient's medical history revealed no prior episodes of dark urine and only minor complaints of calf muscle cramps with vigorous exercise. The previous anesthetic procedure had been by halothane mask induction with a single bolus of succinylcholine (1 mg/kg); the rectal temperature had been normal.

Family members, screened for CPK, showed abnormal elevations in the father and 3 of the 4 siblings. An 11-year-old brother had a serum CPK of 1000, with a repeat CPK 1 year later of 541; all CPK elevations were of the isoenzyme type III.

Because of the possibility of familial muscle disease, the propositus was reevaluated 4 months postoperatively for hereditary muscle diseases associated with myoglobinuria. Detailed neuromuscular examination showed no abnormalities. Blood lactic acid levels following ischemic forearm exercise were identical with those of a control volunteer. Gastrocnemius muscle biopsy specimens appeared normal to light and electron microscopy. Assay of muscle phosphorylase "b," using the method of Krebs and Fisher,[4] demonstrated 1.56 μ/mg protein in the patient and 0.31 μ/mg protein in control human volunteer muscle. Rowland's group[5] previously reported no detectable phosphorylase "b" activity in patients with McArdle's disease.

Serum triglycerides were normal. Electromyogram (EMG) showed decreased amplitude and duration compatible with a myopathic process. An EMG 1 year postoperatively gave the same results. An EMG on the brother with elevated CPK levels was also compatible with myopathy.

Lack of muscular symptoms and physical findings is strong evidence against periodic paralysis, myotonia dystrophica, and progressive Duchenne muscular dystrophy.[6] Although no hyperthermia developed with exposure to 2 general anesthetics, the possibility of malignant hyperthermia still exists. Normal blood lactic acid levels[7] and muscle phosphorylase "b" eliminate McArdle's type V glycogen storage disease. Elevations of serum triglycerides have been associated with the newly described[8] abnormality of fat metabolism in which the enzyme carnitine palmityl transferase is virtually absent from skeletal muscle.

The diagnosis of familial nonprogressive muscular dystrophy was made by neurologic consultation based on abnormalities of EMG, serum CPK in the family, and lack of progressive muscular findings.

Studies by Tammisto and Airaksinen[9,10] have shown that it is possible to induce mild amounts of myoglobinuria in children by the use of 4 intermittent boluses of succinylcholine when given with halothane general anesthesia. They have also indicated that a preinduction dose of curare is protective.[10,11] More recently, Ryan's group,[12] with the aid of a sensitive immune precipitin technic, was able to detect serum myoglobin in the range of 5 to 85 mcg/ml in 40 percent of

*Isoenzyme type III, characteristic of skeletal muscle.

children under general anesthesia following a single 1 mg/kg IV bolus of succinylcholine. This method was so sensitive that, of 16 patients with detectable myoglobinemia, 6 had completely cleared their serum 45 minutes later. Thus, it would appear possible to induce mild amounts of myoglobinuria with multiple doses of succinylcholine in children receiving general anesthesia.

In contrast to these series, Bennike and Jarnum[3] reported an adult patient who was given a single IV bolus of 100 mg of succinylcholine under general anesthesia and later developed massive myoglobinuria with resultant acute renal failure. This patient's serum CPK returned to normal 10 days postoperatively and remained normal. No ischemic exercise test or muscle assay of phosphorylase was reported; however, Bennike felt that the patient had some preexisting muscle disease, possibly McArdle's disease, on the basis of a strong history of intermittent painful swelling of the thighs.

The present case of massive myoglobinuria in a child receiving halothane anesthesia and 2 IV doses of succinylcholine is unusual in that the patient was pretreated with curare and that the proband and family members were found to have persistent elevations of serum CPK. Under normal circumstances, a patient with this form of hereditary muscle disease would not be detected by even the most detailed preoperative history and physical examination. For this reason, a new short-acting, nondepolarizing relaxant drug would be a useful alternative agent, particularly in children.

Since this case documents interaction of a genetic muscle disease with the popular agents, succinylcholine and halothane, any patient with known myopathy or known to have abnormal elevations of type III serum CPK should receive this combination of drugs with caution. Intubation of these patients may be safer without relaxant drugs, or, if relaxants are necessary, with carefully administered nondepolarizing relaxants.

The Effects of Heparin on Recovery from Ischemic Brain Injuries in Cats

EDWARD H. STULLKEN, JR., MD*
MARTIN D. SOKOLL, MD†
Iowa City, Iowa‡

Since ischemic anoxia in experimental animals has been reported to produce areas of cerebral postocclusive nonperfusion, the authors studied the effect of heparin on recovery from tourniquet-produced cerebrovascular injury in 41 barbiturate-anesthetized, ventilated cats ($Paco_2$ 30 ± 2.5 torr). Twenty-four control animals were subjected to 2-to-12-minute ischemic injuries without further treatment. Seven experimental animals were given heparin (1000 u/kg) 1 minute before 4-to-7-minute ischemic injuries, while 10 animals received heparin (1000 u/kg) immediately after 4-to-7-minute injuries. All animals were monitored with continuous arterial and intracranial pressure (ICP) recordings, EEG, and evoked cortical responses. Ischemia and evoked-response recovery times were linearly related in all groups ($r = 0.998$ control, $r = 0.936$ heparin preinjury, $r = 0.951$ heparin postinjury). Regression-line slope comparison indicated shorter evoked response and EEG recovery times in the heparin-treated groups than in the control group. Heparin administration did not effect elevations of ICP seen 6 and 12 hours postinjury in control versus experimental groups. In cats with injuries lasting 5 minutes or more, all control animals were decerebrate and apneic, while 5/12 heparin-treated animals had lesser neurologic deficits.

THOUGH some studies suggest that the brain is uniquely sensitive to hypoxic injury because of low anaerobic substrate levels,[1] this view is not universally held.[2] Other studies of the effects of total cerebral ischemia have identified areas of postocclusive nonperfusion ("no-reflow" phenomenon).[3-11] Langfitt[12] suggests 2 possibilities: intravascular sludging and red cell aggregation in small vessels during ischemic anoxia, or endothelial and periglial cell swelling with collapse of the cerebral capillary bed, both resulting in subsequent hindrance of reflow.

From direct observations of cerebral microvasculature in dogs during and after induced cardiac arrest, Hekmatpanah[13] believes that greater emphasis should be placed on intravascular obstruction by sludged red blood cells and thrombin microemboli as the etiologic agent in anoxic cerebrovascular (CV) injury. However, Cantu and Ames[8] have shown that increasing jugular venous osmolality with systemic hypertonic mannitol and glucose solutions prior to the ischemic anoxic insult decreases subsequent CV obstruction. Their data would indicate endothelial and periglial cell edema to be the cause of the obstruction.

More recently, Levy's group[14] presented convincing evidence that the no-reflow phenomenon may not occur at all if cerebral perfusion is maintained in the postischemic period. These and other authors[15] relate failure to recover neuronal function after ischemia to primary neuronal injury resulting in massive increases in perivascular potassium concentration released during the

ischemic period. Many authors[8,13,16] agree that systemic hypertension after ischemic anoxic injury improves recovery.

Sodium heparin, when used in doses larger than those employed in anticoagulant therapy, is known to have anti-inflammatory and antihistaminic properties.[17-20] Saliba and coworkers[21] found parenteral heparin useful in reducing tissue necrosis and loss in burned patients. On the basis of these reports, we studied the effects of parenteral heparin on recovery from ischemic anoxic brain injuries in cats.

METHODS AND MATERIALS

Forty-one adult cats were divided into 3 groups; (I) 24 control animals given 2-to-12-minute ischemic anoxic injuries without therapy; (II) 7 experimental animals given heparin (1000 u/kg) 1 minute before ischemic anoxic injuries lasting 4 to 7 minutes; (III) 10 experimental animals given heparin (1000 u/kg) immediately after injuries of 4 to 7 minutes duration.

The cats were anesthetized with intraperitoneal sodium pentobarbital (25 mg/kg), intubated, and ventilated with a Harvard pump and room air to maintain a $Paco_2$ of 30 ± 2.5 torr. Esophageal temperatures were maintained at 36 ± 0.5° C. Arterial and venous cannulae were inserted in femoral vessels and a Richmond ICP bolt was placed in the right parietal subarachnoid space.[22,23] Continuous arterial and intracranial pressures were recorded on a Beckman R 411 Dynograph® via Statham P23Db transducers and 5 percent dextrose in water was infused through the venous cannula at 5 ml/kg/hr.

A shielded silver-silver chloride electrode was inserted through the left frontal sinus onto the surface of the frontal cortex and sealed in place with Eastman 910 adhesive. Continuous unipolar EEG activity and cortical evoked responses to electrical stimulation of the right forepaw (10 v, 1 msec, 0.33 Hz) were recorded from the silver-silver chloride electrode with reference to an indifferent ear electrode. The EEG and evoked cortical responses were recorded on a Tektronix® 564 B storage oscilloscope after passage through a preamplifier and 60 Hz filter.

Ischemic anoxic injuries were produced by inflating a pneumatic cuff around the neck to 1200 torr. The adequacy of this method of interrupting cerebral blood flow was tested by injecting fluorescein dye IV in 5 cats immediately after cuff inflation, and, in another 5 cats, immediately after bilateral vertebral and carotid artery clamping. The appearance time for trace amounts of dye on the cerebral cortex was 2.5 ± 0.2 minutes postinjection in both groups.

Neither of these recognized methods produce complete cerebral ischemia. We could demonstrate no significant difference between the 2 methods and chose the less invasive. Minimal flow probably continued through the anterior spinal artery. Hossman and Kleihues[7] indicated that this remaining flow is not significant and may indeed interfere with recovery.

An evoked cortical somatic response was chosen as a sensitive monitor of multineural ischemic anoxic injury and subsequent recovery.[7] The preinjury appearance of the evoked response, its disappearance time after cuff inflation, and its reappearance time after cuff release were noted in all animals. The disappearance time of the evoked response was taken as the point of complete loss of wave-form. A response 10 percent of control amplitude was chosen as the reappearance point. Disappearance and reappearance times for EEG activity were also noted. Evoked response recovery times after cuff release were plotted as a function of cuff inflation time. Regression lines and correlation coefficients were calculated. Differences in line slopes were subjected to *Z* analysis.*

All animals were then observed for 24 hours. Mean arterial pressures (MAP) were maintained at 100 to 120 torr with norepinephrine during observation period. The development and intensity of cerebral edema was evaluated by continuous ICP recordings. The neurologic state of all cats was examined 24 hours postinjury.

RESULTS

EEG and evoked-response tracings were similar in all animals before cuff inflation (fig 1). Disappearance times of EEG and evoked response after cuff inflation did not vary between control or experimental groups. All animals responded to cuff inflation with tachycardia, hypertension, and arrhythmias. After cuff release, 11/24 control animals and 8/17 experimental animals required intermittent norepinephrine administration to maintain MAP greater than 100 torr (fig 2).

*Z analysis: a test that compares regression-line slopes for significance of variance. Steel and Torrie: Principles and Procedures of Statistics. New York, McGraw Hill & Company, 1960, pp 188-191.

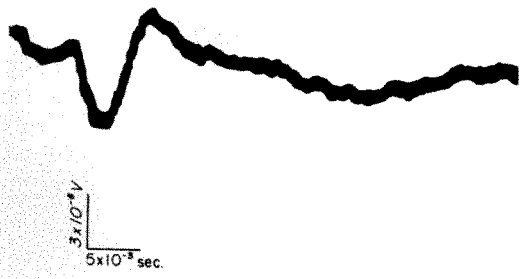

FIG 1. Example of control somatic cortical evoked response tracing.

The duration of ischemic injury was linearly related to evoked-response recovery times in all groups (fig 3). Regression lines for the 2 experimental groups (B, C, fig 3) differed significantly from that of the control group (A, fig 3). The Z factor between control and heparin preinjury regression-line slopes was 1.76 ($p<0.032$). Regression-line slopes for the 2 experimental groups were not significantly different ($Z=0.239$) ($p>0.05$).

Postinjury EEG recovery times were not as well related to the duration of ischemia as were those for evoked response, EEG activity consistently appearing after the evoked response. The difference between these recovery times was directly proportional to the duration of cuff inflation. Correlation coefficients for ischemia versus EEG recovery times were 0.791 for control animals, 0.818 for heparin preinjury treated animals, and 0.786 for heparin postinjury treated animals.

Control ICP was 6.1 ± 3.1 torr (SD) for all 41 cats studied. During cuff inflation, ICP decreased 2.9 ± 1.6 torr for all cats.

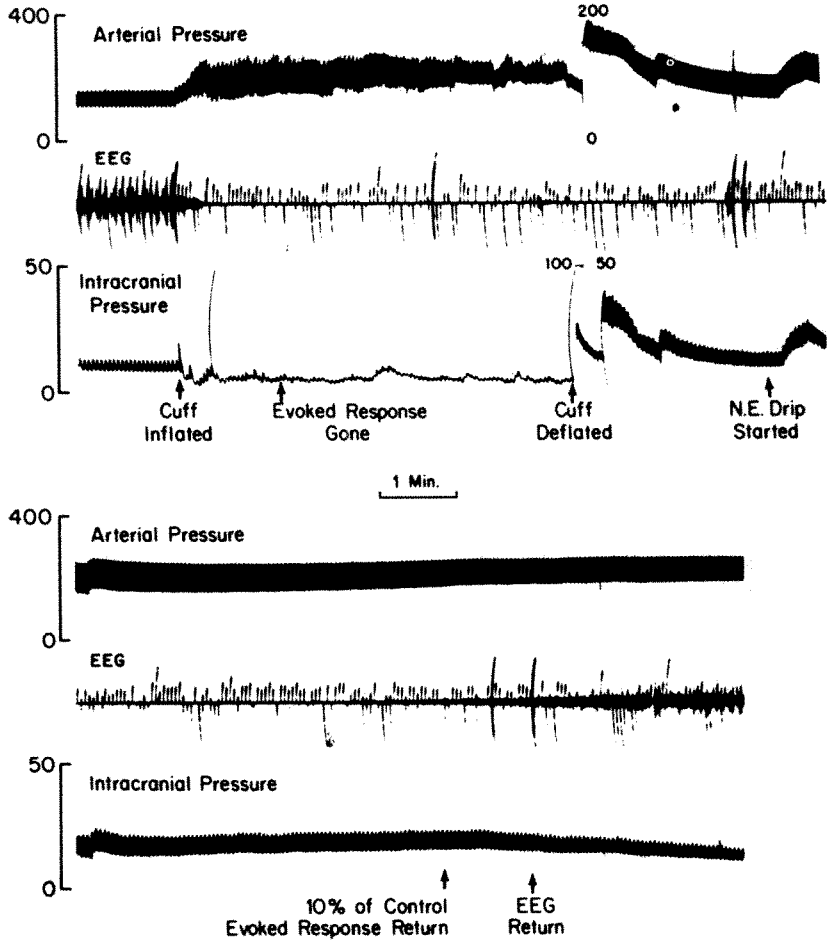

FIG 2. Effect of cuff inflation and release on arterial pressure (top line), EEG (middle lines), and ICP (bottom line). The figure is read from left to right and the 3 tracings are continued in the bottom half of the figure. The 0.33 Hz spikes in the EEG tracings are artifacts.

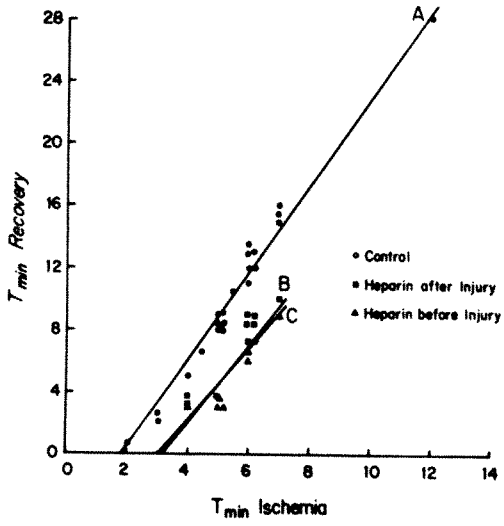

FIG 3. A. Regression line for control animals. B. Regression line for experimental animals given heparin before injury. C. Regression line for experimental animals given heparin after injury.

Immediately after cuff release, ICP increased to 32.3 ± 7.9 torr and then gradually returned to near control levels within 30 minutes (fig 2). A later sustained increase in ICP was noted beginning 3 to 4 hours postinjury. The degree of this late increase was variable for all cats studied and not related, at a confidence level of $p<0.05$, to either the duration of ischemic injury or the administration of heparin.

The neurologic status of cats 24 hours postinjury was dependent both on the duration of injury and the administration of heparin. Ten cats received ischemic injuries of less than 5 minutes duration. Five control cats manifested variable neurologic deficits 24 hours after injury. One was apneic and decerebrate while 4 were severely ataxic. Five of the 17 cats given heparin either immediately before or after injury were less severely impaired after 24 hours; 2 appeared neurologically intact while 3 manifested variable degrees of ataxia.

The 19 control cats given ischemic injuries of 5 minutes or more were all apneic and decerebrate after 24 hours. The 12 experimental cats that received ischemic injuries of 5 minutes or more manifested variable neurologic findings after 24 hours; 7 were apneic and decerebrate while 5 were breathing spontaneously and reacted to stimuli. Of these latter, 3 were ataxic and 2 were quadriparetic.

DISCUSSION

This study shows that heparin modifies the response of cats to ischemic anoxic CV injury. Regression-line slope comparison of control animals with heparin-treated animals indicated a more rapid return of evoked response activity in the heparin-treated groups after ischemic injuries of 4 to 7 minutes duration. There was no significant difference in recovery, whether heparin was administered before or after injury.

Fischer and Ames,[16] studying longer anoxic injuries in rabbits, did not find heparin beneficial for postischemic recirculation. This discrepancy may be due to heparin inactivation at low pH levels. Cats in our study had a blood pH of 7.45 ± 0.05 from controlled mild hyperventilation before ischemic injury. They sustained injuries of shorter duration than animals in Fischer's study and, therefore, probably had lesser degrees of intracerebral acidosis immediately after injury. Systemic pH in our cats was not significantly different before than after injury.

Many authors[3,8,10] state that microvascular obstruction from thrombotic debris is not a major factor in ischemic injuries of less than 5 minutes duration, yet our results reveal a beneficial effect of heparin on recovery from 4-to-7-minute ischemic anoxic injuries. This would indicate that heparin may reduce endothelial and periglial cell edema as well as prevent thrombotic accumulation in cerebral capillary beds.

The high correlation coefficients demonstrated for evoked-response regression lines in all 3 groups of cats support the assumption that evoked somatic cortical responses are sensitive reproducible indicators of recovery from ischemic injury. Regression lines for EEG recovery had lower correlation coefficients. The nature of the evoked-response recovery lines also indicates that the cuff-inflation method of causing ischemic anoxic injury is reproducible. Dye appearance on the cerebral cortex after both methods of occlusion indicates that neither method interrupts collateral flow (most likely through the anterior spinal artery).

Comparison of neurologic findings for control and experimental animals 24 hours postinjury also revealed heparin-induced differences. With injuries of 5 or more minutes duration, control animals were all decerebrate and apneic, while 5/12 heparin-treated animals had lesser neurologic impairment.

Our results failed to demonstrate parallel differences in postinjury intracranial hypertension between control and experimental groups. Failure to demonstrate this expected correlation might be attributed either to inaccuracies in long-term pressure recordings from the Richmond bolt in thin cat skulls or to the small size of the experimental-animal sample.

This study has, however, demonstrated the need for further detailed investigation of heparin use in decreasing the degree of CV injury after ischemic anoxia. It also describes a relatively simple and reproducible experimental design for studying drug effect on CV ischemic injury.

ACKNOWLEDGMENT

The authors wish to thank Mr. L. R. Davies for his expert technical assistance.

MICHAEL R. HODGES§
EDWIN S. MUNSON, MD‖

Pulmonary venous admixture ($\dot{Q}sp/\dot{Q}t$) was analyzed as a function of fractional concentration of inspired O_2 (F_{IO_2}) in 30 patients who required postoperative mechanical ventilation. Pulmonary and radial artery blood-gas tensions and pH were measured and $\dot{Q}sp/\dot{Q}t$ was calculated with F_{IO_2} ranging from 0.21 to 1. In all patients, $\dot{Q}sp/\dot{Q}t$ decreased when F_{IO_2} was increased from 0.21 to 0.4 and then stabilized to an F_{IO_2} of approximately 0.6. As the F_{IO_2} was increased to 1, $\dot{Q}sp/\dot{Q}t$ increased. Since the inhalation of gas mixture with $F_{IO_2} \geq 0.6$ increased right-to-left intrapulmonary shunting of blood, we recommend respiratory function be evaluated during inhalation of a clinically useful concentration of O_2 rather than at an F_{IO_2} of 1.

PULMONARY venous admixture ($\dot{Q}sp/\dot{Q}t$) may result from intrapulmonary arteriovenous shunting of blood, or from shunt-like effects produced by decreased O_2 diffusion through the alveolar capillary membrane, and perfusion of lung units with small but finite ventilation/perfusion ratios.[1] Determination of $\dot{Q}sp/\dot{Q}t$ by the equation derived from a 2-compartment model gives an estimation of the right-to-left intrapulmonary shunting of blood that would have to exist to explain the observed differences between pulmonary end-capillary and systemic Pao_2. However, the various causes of $\dot{Q}sp/\dot{Q}t$ cannot be distinguished by such a 2-compartment model.[2]

Pure O_2 inhalation will minimize both diffusion abnormalities and the effect of $\dot{Q}sp/\dot{Q}t$ on lung units with low $\dot{V}_A/\dot{Q}$.[3] However, recent evidence[4,5] suggests that overall $\dot{Q}sp/\dot{Q}t$ may not be minimized, and that intrapulmonary shunt may actually increase, even with short periods of O_2 inhalation. Our study was performed to quantitate the effect of elevated F_{IO_2} on $\dot{Q}sp/\dot{Q}t$ in patients requiring continuous mechanical respiratory support.

METHODS

Data were obtained from 30 surgical patients admitted to the intensive care unit during a 6-month period. All patients either had been unable to maintain arterial pH (pHa) ≥ 7.35 because of respiratory depression or had elevated $\dot{Q}sp/\dot{Q}t$. Pulmonary and radial artery catheters were inserted percutaneously. Each patient was intubated

This study was a part of Veterans Administration Project #573-1917-01.

orotracheally and mechanical ventilatory support was provided with an intermittent mandatory ventilation volume-cycled ventilator (J. H. Emerson Company). A mandatory tidal volume of 12 ml/kg was delivered with sufficient frequency to maintain a pHa $\geq$ 7.35. A precalibrated, high-flow, air-O_2 blender (bird Corporation) with verified accuracy of $\pm$ 1% of the indicated F_{IO_2} provided a continuously heated and humidified gas flow (20 to 30 L/min) which allowed patients to breathe spontaneously between mechanical breaths. A threshold-resistor valve (J. H. Emerson Company) provided PEEP when indicated.

No patient showed evidence of chronic obstructive lung disease and all had stable vital signs and a hemoglobin (hgb) concentration $\geq$ 11 gm/100 ml. In all patients, P_{aO_2} values were $\geq$50 torr (F_{IO_2} = 0.21) and the pHa was between 7.35 and 7.55. Proper orotracheal tube placement was confirmed by chest roentgenogram. Clinical data on individual patients are shown in table 1.

Each patient received an F_{IO_2} of 0.21 for 30 minutes before heparinized pulmonary and radial arterial blood samples were collected anaerobically. Blood-gas tension and pH were determined with standard electrode technics (Instrumentation Laboratories). F_{IO_2} was increased to 0.3 for 15 minutes and blood samples again were collected. This sequence was repeated at 15-minute intervals using F_{IO_2}'s of 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, and 1.

$\dot{Q}sp/\dot{Q}t$ was calculated at each F_{IO_2} using the equation:

$$\dot{Q}sp/\dot{Q}t = \frac{C\acute{c}o_2 - Cao_2}{C\acute{c}o_2 - C\bar{v}o_2}$$

where Cao_2 = 1.34 (hgb) (Sao_2) + 0.0031 Pao_2; $C\bar{v}o_2$ = 1.34 (hgb) ($S\bar{v}o_2$) + 0.0031 $P\bar{v}o_2$; $C\acute{c}o_2$ = 1.34 (hgb) ($S\acute{c}o_2$) + 0.0031 [($P_B - P_{H_2O}$) $F_{IO_2} - P_{ACO_2}$]; Sao_2, $S\bar{v}o_2$ and $S\acute{c}o_2$ are O_2 saturations of arterial, pulmonary artery, and pulmonary end-capillary hgb, respectively, and P_B is barometric pressure; the respiratory quotient was assumed equal to 1; 1.34 = O_2 capacity of hgb in ml O_2/gm hgb,[2] and 0.0031 = O_2 solubility coefficient in O_2 ml/torr. O_2 saturation was calculated by the method described by Severinghaus.[6] $P\acute{c}o_2$ was assumed equal to estimated P_{AO_2}.[2]

In 5 randomly selected patients, heart rate, mean pulmonary artery pressure, mean systemic blood pressure, pulmonary artery occlusion pressure, and cardiac output determined by thermodilution technic[7] were measured at each F_{IO_2}. An *in vivo* O_2 electrode (International Biophysics Corporation) was inserted in the radial artery so that Pao_2 response to changing F_{IO_2} could be measured continuously. To assess the possible influence of mechanical ventilation, PEEP, and cardiac output on the relationship between F_{IO_2} and $\dot{Q}sp/\dot{Q}t$, patients retrospectively were divided into subgroups as follows: group A (8 patients) had an IMV rate $\geq$ 6/min; group B (11 patients) received PEEP $\geq$ 10 torr; group C (19 patients) received PEEP $\geq$ 4 torr; group D (7 patients) had a $P\bar{v}o_2 \leq$ 30 torr (F_{IO_2} = 0.21); group E (9 patients) had a $P\bar{v}o_2 \leq$ 38 torr (F_{IO_2} = 0.7); group F (10 patients) had $P\bar{v}o_2 \leq$ 40 torr (F_{IO_2} = 1). Data were examined statistically using an analysis of variance (ANOV) and the paired 2-tailed Student's *t*-test when ANOV indicated significant differences.

RESULTS

When plotted as a function of F_{IO_2}, $\dot{Q}sp/\dot{Q}t$ formed a convex curve with a minimum value occurring between F_{IO_2} = 0.4 and 0.7 for each patient (figure). As F_{IO_2} was raised from 0.21 to 0.4, $\dot{Q}sp/\dot{Q}t$ decreased and then remained unchanged as F_{IO_2} was raised to 0.7. $\dot{Q}sp/\dot{Q}t$ increased as F_{IO_2} was raised to 1, but was less than when F_{IO_2} was 0.21 ($p<0.001$).

Patients in subgroups A, B, C, D, E, and F showed no significant change in trends of mean $\dot{Q}sp/\dot{Q}t$ when data from subgroups were compared with those of all other patients. *In vivo* Pa_{O_2} recordings revealed that 90% of the change in Pa_{O_2} occurred within 5 minutes of increasing F_{IO_2} by 0.1 and within 7 minutes of increasing F_{IO_2} by 0.79. Complete equilibration was reached by 15 minutes when F_{IO_2} was increased directly from 0.21 to 1. There were no differences in cardiac output, heart rate, mean pulmonary artery pressure, mean systemic blood pressure, pulmonary artery wedge pressure or $Ca\text{-}\bar{v}O_2$ as F_{IO_2} was increased in 5 patients (table 2).

DISCUSSION

Adequate pulmonary gas exchange is essential to the successful management of critically ill patients. Various methods have been advocated to evaluate pulmonary function and effectiveness of therapy. Pa_{O_2} and $P(A\text{-}a)O_2$ vary with F_{IO_2} and may be influenced significantly by O_2 consumption and cardiac output.[8,9] Therefore, estimating $\dot{Q}sp/\dot{Q}t$ with these measurements alone may be misleading.[9] When $\dot{Q}sp/\dot{Q}t$ is calculated directly from Ca_{O_2} and $C\bar{v}O_2$ measurements and calculated $C\acute{c}O_2$,[10] one can determine whether $\dot{Q}sp/\dot{Q}t$, cardiac output, or O_2 consumption is primarily responsible for arterial hypoxemia. It has been thought that establishing an F_{IO_2} of 1 will insure that

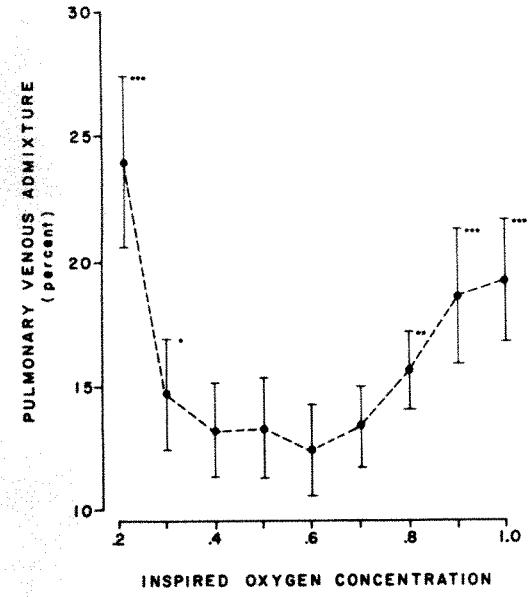

FIGURE. Calculated mean pulmonary venous admixture as a function of inspired O_2 concentration. Values represent mean ± 2 SE of 30 observations. (Asterisks indicate significant difference from value observed at F_{IO_2} = 0.6; *$p<0.05$, **$p<0.01$, ***$p<0.001$.)

calculated $\dot{Q}sp/\dot{Q}t$ is secondary only to direct intrapulmonary right-to-left shunting of blood[8] and will not produce detrimental side effects if confined to brief periods of exposure. For this reason, several authors have recommended that pulmonary gas exchange be evaluated during inhalation of 100% O_2.[11-14]

The significant decrease in $\dot{Q}sp/\dot{Q}t$ which occurred as F_{IO_2} was increased to 0.4 may have been the result of 2 factors. Interstitial pulmonary edema may have created a relative barrier to O_2 diffusion across the alveolar-capillary membrane. Additionally, areas with low $\dot{V}_A/\dot{Q}$ ratios will cause P_{AO_2} and $C\acute{c}O_2$ to be lower than estimated and, therefore, increase $\dot{Q}sp/\dot{Q}t$ during inhalation of room air. With increasing F_{IO_2}, the elevated P_{O_2} gradient across the alveolar-capillary junction may promote better O_2 diffusion. Increased F_{IO_2} also will increase P_{AO_2} and decrease P_{AN_2} in poorly ventilated lung units. In both instances, Ca_{O_2} will increase, lowering calculated $\dot{Q}sp/\dot{Q}t$. Since no significant change occurred in $\dot{Q}sp/\dot{Q}t$ as F_{IO_2} was increased from 0.4 to 0.6, effects of diffusion abnormalities and areas with low $\dot{V}_A/\dot{Q}$ on $\dot{Q}sp/\dot{Q}t$ may have been minimized.

(n) = number of patients studied.

Several factors may have influenced the increase in $\dot{Q}sp/\dot{Q}t$ when F_{IO_2} was raised from 0.7 to 1. Absorption atelectasis and decreased functional residual capacity (FRC) may occur during inhalation of 100% O_2.[4,15,16] However, decreased FRC has been shown to correlate poorly with $\dot{Q}sp/\dot{Q}t$ in some patients.[17] Therefore, even if absorption atelectasis caused increased $\dot{Q}sp/\dot{Q}t$ at elevated F_{IO_2}, it may not have been the only contributing factor. Ramachandran and Fairley[18] reported that 5% N_2 added to the inhaled gas mixture will prevent absorption atelectasis. One might also expect PEEP to minimize the effects of absorption atelectasis by increasing FRC.[4,17] The $\dot{Q}sp/\dot{Q}t$ of patients in groups B and C who were treated with PEEP increased by the same magnitude as that of the patients who did not receive PEEP. Therefore, increase in $\dot{Q}sp/\dot{Q}t$, particularly F_{IO_2}'s of 0.8 and 0.9 may have been caused by factors other than absorption atelectasis.

West[19] has suggested that there may be a greater increase in $\dot{Q}sp/\dot{Q}t$ in response to increased F_{IO_2} when $P\bar{v}O_2$ is low. In this situation, the increased $P(A\text{-}a)O_2$ gradient would cause a more rapid efflux of O_2 from alveoli to capillary blood. If net gas outflow from alveoli into capillaries exceeds gas inflow from the airways, alveolar collapse could occur. Comparison of the response of $\dot{Q}sp/\dot{Q}t$ to increased F_{IO_2} in patients with low $P\bar{v}O_2$ and in those with elevated $P\bar{v}O_2$ revealed no significant differences. Although $C\bar{v}O_2$ varied widely in our patients, $P\bar{v}O_2$ was relatively constant (range 25 to 53 torr). This suggests that the small differences observed in $P\bar{v}O_2$ of 20 to 30 torr may be insignificant in promoting alveolar collapse with increasing P_{AO_2}.

Hypoxic pulmonary vasoconstriction is thought to occur in areas with low $\dot{V}_A/\dot{Q}$.[20] Alveolar gas in such areas will not equilibrate completely with upper airway gas but will equilibrate with mixed-venous blood. Precapillary pulmonary vasoconstriction normally will shunt blood away from these units to areas with better ventilation, thus improving overall $\dot{V}_A/\dot{Q}$.[21,22] When F_{IO_2} is increased sufficiently, P_{AO_2} will rise, $P\bar{v}O_2$ will increase, and the degree of hypoxic vasoconstriction may decrease. The resulting increase in perfusion to areas with low $\dot{V}_A/\dot{Q}$ could cause $\dot{Q}sp/\dot{Q}t$ to increase. This mechanism may be responsible for the observed increase in $\dot{Q}sp/\dot{Q}t$ in response to elevated cardiac output,[22-24] since increased cardiac output will cause an increase in $C\bar{v}O_2$ and $P\bar{v}O_2$.[25] All our patients responded to increasing F_{IO_2} with an elevated $P\bar{v}O_2$; therefore, the increase in $\dot{Q}sp/\dot{Q}t$ also may have been caused by release of hypoxic pulmonary vasoconstriction.

A 3rd explanation for the increased $\dot{Q}sp/\dot{Q}t$ is extra alveolar intrapulmonary shunting of venous blood. Such anatomic shunting has been shown to occur with chronic obstructive pulmonary disease,[26] and following IV infusion of epinephrine,[27] both with radioactive tracer materials[28,29] and histologically.[30] Nomoto's group[27] has suggested that such shunts may be responsible for hypoxemia in some critically ill patients with respiratory failure.

As has been previously reported,[15] N_2 washout occurred within 15 minutes when F_{IO_2} was raised from 0.21 directly to 1, supporting the contention that P_{AO_2} was stable by 15 minutes when F_{IO_2} was increased by only 0.1. Therefore, a lack of equilibration of pulmonary capillary and alveolar gas tension was an unlikely source of variation in $\dot{Q}sp/\dot{Q}t$. There was no change in cardiac output, heart rate, systemic blood pressure, mean pulmonary artery pressure, or pulmonary artery occlusion pressure as F_{IO_2} was increased. Therefore, changes in $\dot{Q}sp/\dot{Q}t$ could not be explained by variation in overall pulmonary or systemic vascular resistance. Erroneous assumption of a respiratory quotient of 1 could have induced a maximum error of +3% in calculating $\dot{Q}sp/\dot{Q}t$ with $F_{IO_2} = 0.21$, and then only if $P_{aCO_2} \geq 50$ torr, which was not the case in any patient.

Several authors[11,13,14] have advocated therapeutic respiratory maneuvers directed toward minimization of calculated $\dot{Q}san/\dot{Q}t$ which requires $F_{IO_2} = 1$. However, regardless of etiology, $F_{IO_2} \geq 0.7$ caused significant increase in $\dot{Q}san/\dot{Q}t$ in every patient studied. Therefore, treatment based on measurement of $\dot{Q}san/\dot{Q}t$ may be directed at reversing a pathologic condition induced by measurement conditions and not necessarily by the patient's primary pathophysiologic process. For this reason, we recommend that evaluations of patients' respiratory status be conducted with a clinically useful F_{IO_2}, which, in most instances, will range from 0.4 to 0.6 and will minimize calculated $\dot{Q}sp/\dot{Q}t$.

ACKNOWLEDGMENT

DISCUSSION

E. SCOTT McCORD, M.D.
Department of Anesthesiology
University of Missouri Medical Center
Columbia, Missouri

Dr. Douglas and his group should be congratulated on this most interesting paper. It points out that we should never become too satisfied with what we think is the truth, for more than likely someone will eventually show us that it wasn't really a truth at all.

In order to evaluate the ability of the lungs to oxygenate the blood one of the first steps is to measure the arterial O_2 tension (Pa_{O_2}). However, for this to have any real significance, one also needs to know the alveolar O_2 tension (PA_{O_2}). From these two, one can calculate the alveolar-arterial O_2 tension difference $P(A\text{-}a)O_2$. Even this, however, is not enough for thorough understanding of the situation because it tells us only a problem with oxygenation exists but nothing of what the problem may be. Intrapulmonary causes for an increase in $P(A\text{-}a)O_2$ may stem from an intrapulmonary right-to-left shunt ($\dot{Q}sp/\dot{Q}t$), ventilation/perfusion maldistribution ($\dot{V}_A/\dot{Q}$) and/or diffusion abnormalities.

The authors undertook this study in an effort to either confirm or deny reports in the recent literature that suggest a high concentration of inspired O_2 (FIO_2) may in itself increase the intrapulmonary shunt. Their goal was to define in a stepwise manner the actual change in $\dot{Q}sp/\dot{Q}t$, if any, that takes place with a changing FIO_2.

I would like to commend Dr. Douglas for the basic simplicity of the study. Small but often compounding errors are easily introduced into such studies and simplicity becomes very desirable. Many of these potential problems and sources for error have either been explained or otherwise accounted for by the authors and need no further mention. A couple of points, however, may be made here for emphasis.

It was stated that standard electrode technics were used, yet one of the problems in comparing various investigations is the definition of standard technic. Calibration of O_2 electrodes, handling of blood samples, and corrections for temperature variations in blood-gas and pH measurements, among others, seem to vary from study to study. Methods used to determine O_2 saturation also are of importance because of possible pH-independent changes in the O_2 dissociation curves.[1] This might alter mixed venous O_2 saturations if calculated from pH and $P\bar{v}O_2$ determinations alone.

Several questions are raised by this study. One has to wonder what effect longer exposure to O_2 would have on pulmonary shunting. Wolff and associates[2] reported a greater increase in $\dot{Q}sp/\dot{Q}t$ in trauma patients exposed to an FIO_2 of 0.83 than in those exposed to only 0.4 at the end of 48-72 hours. There were, however, no data to show whether the shunt varied with time. Another study[3] revealed no change in the shunt after 6-12 hours on 100% O_2, but direct comparisons here are not possible because it dealt with spontaneously breathing normal volunteers.

Two additional questions to be answered include: (1) what effect the presence or absence of preexisting chronic pulmonary disease might have on FIO_2 and measured shunting, and (2) how spontaneous versus mechanical ventilation might affect the relationship. McAslan's group[4] reported results very similar to those in the present study for patients without preexisting disease but a decreased shunt for patients who had preexisting chronic lung disease. This present study was rather remarkable in revealing no significant differences between either age groups or the various acute disease processes. While studying the effect of increasing FIO_2 on $P(A\text{-}a)O_2$, Cole and Bishop[5] along with others, reported an increased $P(A\text{-}a)O_2$ with an FIO_2 up to about 0.4. This remained fairly constant until the FIO_2 was 0.8, at which point the $P(A\text{-}a)O_2$ decreased with further increases in FIO_2.

On the surface, these data would appear to conflict with those in the present study. It must be remembered, however, that $P(A\text{-}a)O_2$ and $\dot{Q}sp/\dot{Q}t$, while often taken to represent the same thing, particularly with the FIO_2 is 1, are in reality not the same at all. At any rate, these 2 studies should not be compared directly because Cole and Bishop used spontaneously breathing normal volunteers. Nevertheless, it would be interesting to know the $P(A\text{-}a)O_2$ for Dr. Douglas' 30 patients at each FIO_2.

Whether this present paper becomes a definitive study, accurately describing the relationship between various levels of FIO_2 and pulmonary shunting, or whether it only defines a relationship existing between the patients studied under the conditions available and the technics used, can only be answered when others attempt to duplicate the results and when additional populations are studied. The ideal will be to define that FIO_2 (or range of FIO_2) that will create the smallest shunt while at the same time eliminate as much as possible any $\dot{V}_A/\dot{Q}$ disturbances.

It would appear that Dr. Douglas has added significantly to our knowledge of this area and has pointed out quite correctly what probably is a multifaceted etiology of

the changes observed. Several unanswered questions remain, however, which must be answered before the full relationship between F_{IO_2}, pulmonary shunting, $\dot{V}_A/\dot{Q}$ and $P_{(A\text{-}a)O_2}$ are fully defined.

Absence of Recall After General Anesthesia: Implications for Theory and Practice

STEVEN L. DUBOVSKY, MD*
ROBERT TRUSTMAN, PhD†
Denver, Colorado‡

To investigate the possibility that recall of auditory information occurs following general anesthesia, letter-word pairs were presented to 36 patients receiving light planes of general anesthesia for short operations. Postoperative testing which tapped auditory and visual memory demonstrated no evidence of recall. In a subsequent study, a single word was repeated during brief obstetric procedures in 12 patients. Postoperative testing was designed to maximize apparent recall. The only patient able to remember the experimental word had awakened during anesthesia. Even without the use of more sophisticated physiologic and psychologic measures of recall, the data presented indicate that, for all practical purposes, an adequately anesthetized patient does not remember information presented during surgery. Apparent recall probably indicates inadequate or uneven anesthesia. Anesthetic agents may interfere with memory formation by altering brain RNA or protein synthesis or electrochemical activity, or they may produce retrograde amnesia.

EVER since Crile[1] reported a patient who could repeat a discussion that occurred while she was anesthetized, there has been considerable controversy regarding whether or not the anesthetized patient can be aware of events occurring during surgery. It has recently been suggested that the advent of newer muscle relaxants and lighter planes of anesthesia have increased the likelihood of awareness during anesthetic procedures.[2-4] Many physicians have both hoped that optimistic remarks made during operations might have beneficial effects and been concerned that pessimistic remarks might have adverse effects on the patient's postoperative course. Case reports of physical[4] and psychologic[5] distress experienced by patients who have apparently overheard discouraging remarks made during surgery have increased this concern.

Since the use of interview data alone in uncontrolled studies has failed to provide good evidence of recall of information presented during anesthesia,[6-9] attempts have been made to use hypnosis[4,10] and physiologic measures of recognition of familiar material[10,11] to provide evidence that memory following general anesthesia does occur, even though the patient is not consciously aware of it.

Wolfe and Millett[12] and Hutchings[13] suggested postoperative comfort to unselected surgical patients at the completion of their operation, but before they were "awake." They reported that many patients responded to these suggestions by demonstrating less postoperative pain, nausea, and vomiting. It is unlikely, however, that the patients were truly anesthetized when they received the suggestions. It is also not known if the patients actually experienced less postoperative discomfort or, if knowing that they were experimental subjects, they simply complained less. Nursing staff may also have been more solicitous of patients whom they knew to be experimental subjects.

Paper received: 12/1/75
Accepted for publication: 1/6/76

Pearson[14] attempted to deal with these questions with a double-blind placebo control design. Patients receiving, during surgical anesthesia, taped suggestions that they would be able to recover faster, were discharged 2.42 days sooner than placebo groups hearing music or nothing intraoperatively. A subsequent study of similar design, with the addition of electroencephalographic measurements to document depth of anesthesia while tapes were played, failed to confirm Pearson's findings.[15]

The present study applies a double-blind placebo-control design to the question of whether material presented during general anesthesia can be retrieved postoperatively. Simple, easy-to-learn experimental material is presented during light anesthesia, with tests of recall measuring subtle evidence of memory.

METHODS

After giving informed consent, patients aged 18 to 55, about to undergo elective surgery under general anesthesia, were told that the experimenters believed that auditory information could be learned during anesthesia, even though the patient remains asleep. It was suggested that the patients would be able to learn letter-word pairs presented during anesthesia, and recognize them on a postoperative test.

Eight letters chosen least frequently in a pilot study of letter guessing were selected as experimental letters. Two additional letters were arbitrarily chosen as "bogus" stimuli to be presented on a postoperative recognition test, but not presented experimentally. Nouns beginning with the letters chosen as stimulus letters were next paired with these letters. Subjects in a preliminary study were then asked to check from four choices the word that seemed to go best with each letter, e.g.,

"F" is for { Fire / Friend / Family / Food }

The 2 *least*-frequently checked words for each of the 8 stimulus letters (in this case, "Fire" and "Food") were paired with the letters in 2 experimental lists of alliterative letter-word pairs using Evans' method[16] of studying sleep learning. A placebo list of number-word pairs was prepared for the control group (table 1).

Cassette tapes of each list, lasting 15 minutes each, began with suggestions that although the patient was asleep, he would hear and remember the letter-word pairs on the tape. Repetitions of the stimuli followed, and the tape ended with repeated suggestions that the patient would remember the material presented. The tape for each subject was randomly selected and given to the anesthesiologist, who was unaware of its contents. The patient was anesthetized with a ± 1.3 MAC concentration of anesthetic. When the patient was judged clinically to be in a light plane of surgical anesthesia, the anesthesiologist began the tape, which was played in its entirety through earphones.

As soon after surgery as possible, recognition memory was tested by the experimenters, who were unaware of the contents of the tape to which the patient had been exposed. First, the patient was reminded that he had been exposed during anesthesia to letter-word combinations which he should be able to remember. Next, he was asked to look at a randomized alphabet and check any letters he thought he heard while anesthetized. At the same time, a tape recording of the same voice as that used during anesthesia read each letter in the sequence viewed by the patient, to aid auditory recognition.

Finally, the patient was presented with 10 separate pages, each containing a letter

Lists 1 and 2 were presented to Experimental Groups I and II.

List 3 was presented to Placebo Group III.

and 4 words, and was asked to check the word he thought was paired with the letter presented during anesthesia. Again, a recording of the same voice played each choice aloud as the subject viewed it on the checklist. After each response, the subject stated his degree of certainty regarding his response using a 1-to-4 scale.[16] Two letter-word combinations not presented during anesthesia ("bogus" letters and words) were included to correct for guessing.

If retention and recognition of these stimuli had occurred, patients in experimental groups I and II would check more of the 8 experimental letters than did subjects in group III (placebo-control group). Subjects in group I would select more words from list 1 than subjects in group II or III. Subjects in group II would select more words from list 2 than subjects in group I or III. And subjects in groups I and II would express less certainty in choosing "bogus" words than words from their respective lists.

RESULTS

Most of the 36 patients underwent brief obstetric procedures, carried out under light anesthesia (table 2). Preoperative medication was atropine with or without diazepam in all patients.

Mann-Whiteney U tests[17] were calculated to compare recognition of letters and words presented during anesthesia vis-a-vis type of anesthetic received. These yielded U values of 36 for letter recognition and 33 for word recognition (not statistically significant by 2-tailed test). Therefore, the type of anesthetic received did not significantly influence apparent postoperative recognition of material presented during anesthesia. There was also no relationship between time-until-testing and apparent postoperative recognition of letters ($r_s = +0.31$; p=ns) and words ($r_s = +0.42$ and 0.12 for groups I and II; p=ns) presented during anesthesia.

On postoperative testing of letter recognition, the experimental groups failed to surpass the control group in number of experimental letters checked ($H = 3.72$; p=ns) suggesting that they did not recognize letters presented during anesthesia. In the selection of words from lists 1 and 2 by each group, group I did not recognize words from list 1 more frequently than group II or III, and group II did not recognize words from list 2 more frequently than group I or III (table 3). This is confirmed by simple analysis of variance of these scores (table 4). Subjects in groups I and II were therefore unable to recognize words presented to them during anesthesia more frequently than subjects who did not hear these words.

Subjects in the experimental groups were then compared for the average certainty they expressed in choosing relevant experimental words (list 1 for group I; list 2 for group II) versus bogus words on the post-operative recognition test. They expressed significantly higher average certainty on bogus items, and were not more certain in

their choice of relevant experimental items (sign test [2-tailed] = 0.96 [negative comparisons] and 0.008 [positive comparisons]; $p = <.05$ for choice of bogus items). Groups I and II did not surpass controls in high-certainty selection (table 5).

Additional Study. — To investigate the possibility that too many stimuli were presented for anesthetized subjects to process, an additional study was devised presenting only 1 stimulus word. A tape beginning with the suggestion that the patient would remember the word that followed was presented to 12 patients undergoing D & C or tubal ligation. Next, the word "salami" was repeated every 5 seconds for 5 minutes, every 30 seconds for another 5 minutes, then again every 5 seconds for the remainder of the tape (total = 12 minutes). Postoperative recall was tested within 24 hours. Subjects were asked to choose the word they had heard during anesthesia as they looked at a list of 10 possible choices designed to maximize recognition of the experimental word and heard each word repeated on a tape recorder by the experimental voice.

Eleven subjects did not recognize the experimental word. The 12th subject said, "Don't even show me the choices: the word was *'salami.'* " She remembered awakening during anesthesia, and her anesthesiologist reported that in the middle of the procedure, she had opened her eys and winked at him. Our only evidence for postoperative recall occurred in a patient who was not fully anesthetized!

DISCUSSION

Although the patients were presented with simple stimuli, and strong suggestions were given that they would be able to remember the stimuli, they were not strongly motivated to do so. Learning under any circumstance is known to be facilitated by motivational factors[18] such as hunger.[19] It is also well known that information which is meaningful[2,9] and is associated with strong emotion[18,19] is easier to remember. Meaningful, emotionally laden words occurring in the context of a motivational state (the wish to get well) might well be more likely to be remembered. While the creation of bogus "crises" during operation in one study[20] satisfied these conditions, good controls are impossible to devise, and serious ethical difficulties are created.[2] Apparent recall of emotionally laden words or words of particular significance to the patient, such as names of family members, would be complicated by the probability that patients would be exposed to them perioperatively.

Our method of testing memory needs also to be carefully considered. Although recognition memory is a sensitive measure of recall,[10,16] auditory stimuli may influence a patient even though he does not remember them consciously.[3,4,9] It is possible that hypnosis, which is said to be a tool for recovering such unconscious memories[3,4,9,11,21] and has been used in studies of apparent recall following anesthesia,[2] would have provided evidence of recall. The use of hypnosis as an adjunctive investigative tool, however, raises the possibility that the hypnotist

is suggesting the correct answer to the subject subliminally, complicating interpretation of the data. Also, not all patients are equally hypnotizable and differences in apparent recall may reflect differences in depth of hypnosis during testing.

An even more elegant method of testing unconscious recognition of significant information employs the observation that heart rate decreases when attention is directed to a familiar or important stimulus, even when there is no verbal report of recognition of the stimulus.[10] Measuring heart rate or some other physiologic measure of attention[9] might have provided some evidence of postoperative recall. However, the interpretation of such measures would be complicated by the physiologic effects of the anxiety of hospitalization and surgery and of various medications.

A final possibility is that the anesthetized state has cueing properties which need to be reintroduced to truly test recall.[22] If such state-dependent learning[23] did occur, the patient would only recall stimuli presented during anesthesia while under repeated anesthesia. Even if this were possible, it would be difficult to demonstrate and would not be of clinical importance.

We used methods which maximize learning and recognition. The one patient who was not fully anesthetized showed obvious learning and instantaneous recall of the test word, in spite of the distractions of the operating room. Despite the objections discussed above, our measures are probably the best available for clinically practical purposes.

The Psychobiology of Postanesthetic Amnesia.—The 2-stage theory of memory, first proposed by Hebb,[22] holds that memory traces are laid down in the form of short-term reverberatory electric circuits which may, during the process of consolidation, be fixed to produce long-term memory. The process by which permanent memory traces ("engrams") are formed has been said to involve DNA-dependent RNA or protein synthesis[19,24] changes in brain biogenic amines,[19] synaptic changes in memory circuits,[19] the formation of permanent reverberating electric circuits,[19,23] and structural or functional growth of neuronal and glial elements throughout the brain.[19] Anesthesia may act at one or many of these loci.

Anesthetic agents might interfere with the formation of the engram by blocking RNA synthesis. This has been shown in the rat to interfere with ongoing learning without disrupting previously learned behavior.[24] Ether has been shown to produce "localized seizures" which may interfere with short-term memory consolidation in animals.[18,25] A similar mechanism in man may interfere with the storage of information as cerebral electrical activity,[18,19] and many anesthetics have in fact been shown to depress EEG activity.[26] Anesthesia may also interfere with reverberating circuits by blocking polysynaptic transmission,[19] or it may disconnect the limbic-system and RAS input which add significance to information to be stored.[19] Indeed, "some of the experiments using anesthetics . . . confirm that interruption of brain activity (electrical or chemical) shortly after a learning experience impairs the memory of that experience."[23a] Atropine[18] and other anticholinergics,[19] and other premedicants, especially diazepam,[10] may further disrupt memory consolidation by altering electrocortical activity in as-yet-unknown ways.

Most studies of the effects of drugs on memory have been carried out in animals,[18] and the possibility that anesthetics interfere with retrieval of complex information in man is difficult to assess. It has been shown, however, that a variety of agents, including barbiturates, ether, transcortical electric shock, and flurothyl produce retrograde amnesia for conditioned responses in animals.[18] It is possible that learning in man may occur during anesthesia, but that the information learned is then unavailable or forgotten.

CONCLUSIONS

Whatever the possible mechanism of action, our findings suggest that recall following anesthesia does not occur. Many of our patients received light anesthesia of brief duration without evidence of recall. The fact that only a patient who was not fully anesthetized demonstrated unequivocal recall leads us to suspect that in previous studies which have demonstrated apparent recall following anesthesia, experimental material was presented when the patients were not truly anesthetized. It would be wise to bear in mind that many drugs used as adjuncts to general anesthesia, such as droperidol,[27] may disrupt the patient's initiative to complain, making him appear to be anesthetized even though he is awake. Patients experiencing such "cerebral curarization"[27] would of course remember and react to information presented during surgery.

The clinical implications of our findings are apparent. If care is taken that patients are fully anesthetized, discussion of clinical aspects of the patient's case in the operating room need not be curtailed, and attempts at promoting healing through verbal suggestion during surgery will probably not be successful. Evidence of apparent recall following anesthesia should alert the physician to the possibility that his patient has not been truly anesthetized, that a fluctuating depth of anesthesia is resulting in intermittent alertness, or that he is making remarks either before the patient is anesthetized or after he is awake.

ACKNOWLEDGMENT

The authors would like to thank Dr. Henry Casson for his help with the project and the preparation of the manuscript, and Dr. William Droegemueller for his very kind assistance with patient material.

Effect of Morphine-Diazepam on Signs of Anesthesia, Awareness, and Dreams of Patients Under N_2O for Cesarean Section

EZZAT ABOULEISH, MB, BCh, MD*
FLOYD H. TAYLOR, ScD†
Pittsburgh, Pennsylvania

Morphine (0.2 mg/kg) and diazepam (0.1 mg/kg) were injected IV after delivery of the fetus in 68 parturients undergoing cesarean section (CS). General anesthesia was with thiamylal-N_2O-O_2 (4:2) and muscle relaxant. Twenty-four to 36 hours postoperatively, 1 patient had recall, 1 had unpleasant dreams, and 2 had pleasant dreams. The incidence of recall and unpleasant dreams was 3.8 percent in elective CS and 0 percent in emergency cesareans. Morphine-diazepam combination caused anterograde and retrograde amnesia. During the cesarean, movement of patient, size of pupils, or changes in blood pressure were not indicative of awareness or dreams. During anesthesia, 33 percent O_2 produced adequate oxygenation of mother and fetus.

AWARENESS, pain, and/or unpleasant dreams constitute *undesirable side effects of light anesthesia* (USELA). The incidence of USELA during N_2O-O_2-muscle relaxant anesthesia for cesarean section (CS) is 36.1 percent in elective and 17.3 percent in emergency CS.[1] To reduce USELA, various measures have been attempted: injection of 0.6 mg of IV hyoscine before induction,[2] or adding halothane,[3] methoxyflurane,[4] or trichloroethylene[5] to N_2O-O_2. The combination of morphine and diazepam to supplement N_2O was also found to have amnesic effects in male surgical patients.[6,7] The purpose of our study was to evaluate such a combination in cesarean section.

METHODS

Since the incidence of USELA using N_2O alone is high and well documented, it was considered unfair to subject more patients to such a technic. Therefore, in this study, Wilson's series[1] was used as the control. This study group consisted of 68 patients undergoing cesarean deliveries, 53 of which were elective, under general anesthesia. Patients having had a narcotic within 6 hours, with respiratory or valvular cardiac disease, or a history of alcohol or drug addiction were excluded from the study. The possibility of awareness or dreams during the procedure was not discussed preoperatively with the patient, to eliminate suggestion and expectation, and no premedication was administered.

On arrival in the operating room (OR), an IV cannula was inserted in the patient's hand or forearm and an infusion was started. Blood pressure (BP) and pulse rate were measured, left uterine displacement device was placed, an ECG monitor was applied, and O_2 by facemask was administered. Two minutes before induction, 0.4 mg of atropine and 3 mg of curare were injected. Just before abdominal incision, anesthesia was induced by 4 mg/kg of thiamylal, cricoid pressure was applied, and 1.5 mg/kg of succinylcholine chloride (SCC) was injected,

followed by endotracheal intubation with a cuffed tube. Anesthesia was maintained until the end of operation with N_2O-O_2 (67:33) plus muscle relaxant. F_{IO_2} was continuously monitored using an IL 404 Oxygen Alarm System,* and ventilation was manually controlled. The muscle relaxants used were SCC in 43, curare in 22, and pancuronium in 3 cases.

Immediately after delivery, 0.2 mg/kg of morphine and 0.1 mg/kg of diazepam were separately administered to a maximum of 15 and 7.5 mg respectively by injection into the tubing of rapidly administered 5 percent dextrose solution containing 10 units of oxytocin per liter.

At the time of delivery, maternal arterial and fetal umbilical-vein blood gases were determined in 25 cases. Unless the BP and/or pulse changes required minute-to-minute surveillance, they were checked and recorded every 5 minutes. BP was measured by indirect auscultation and pulse rate was counted at the brachial artery. Any movement of the patient, the surgical step at which movement occurred and the part of the body moved, and the size and reaction of the pupils before and after administration of morphine-diazepam, were recorded.

At 24 to 36 hours postoperatively, patients were asked: (1) What was the last thing you remember before going to sleep? (2) What was the first thing you remembered on waking? (3) Do you remember anything between going to sleep and waking? (4) While you were sleeping, during the operation, did you dream? If yes, was the dream pleasant, unpleasant, or indifferent? (5) Do you usually remember your dreams vividly? (6) Have you ever had experience with alcohol? If yes, was the experience pleasant, unpleasant, or indifferent? (7) Have you ever had experience with drugs, such as LSD, "speed," Marijuana, etc? Was the experience pleasant, unpleasant, or indifferent? (8) If you must have another operation, would you like the same anesthetic or not, and why?

RESULTS

None of the 15 emergency patients had any recall or dreams during CS. In the 53 elective cases, 1 patient reported painless awareness of the abdominal incision, 1 had unpleasant, and 2 had pleasant dreams. Thus, the total number of patients having USELA was 2 (3.8%), a statistically significant ($p>0.01$) reduction over Wilson's series[1] (table 1).

Owing to difficulty in intubation, the induction-incision and induction-delivery times were much prolonged in patients with USELA compared with those who had no recall (table 2). However, the duration of operation in both groups was not markedly different.

During operation, 45 patients moved, of whom 42 had no recall, 2 had USELA, and 1 reported pleasant dreams. There was no correlation between the incidence of movement and the type of muscle relaxant. Under SCC drip, there was no specific surgical step at which patients moved. When a nondepolarizing muscle relaxant was used instead, 75 percent of the patients moved during closure of the subcutaneous tissue or skin.

During CS, there was no change in BP equal to or more than 50 percent of the original level. In 52 cases, BP changes were less than 25 percent. While 8 patients showed a 25 percent rise of BP, yet another 8 had more than 25 percent fall, mostly

after IV diazepam, morphine, and oxytocin drip.

During operation, the pupils of all patients were reactive to light: the more dilated the pupils, the more brisk the reaction. Before morphine-diazepam injection, 44 patients had dilated pupils. After morphine-diazepam administration, 9 patients, who had no recall or dreams, continued to have dilated pupils.

There was no apparent correlation between USELA and patient physical status, vivid remembrance of dreams, or experience with alcohol or drugs.

All patients recalled the events occurring in the OR before induction. Although 85 percent answered questions rationally before leaving the OR, only 9 percent remembered events before reaching the recovery room. The first event recalled by 65 percent of the mothers was related to their babies, e.g., sex and/or weight of the baby. Sixty-five patients considered recovery from anesthesia to be pleasant and smooth; 2 complained of abdominal pain and sore throat, and 63 (93%) would like to have the same anesthetic procedure if another operation is needed. There were no signs of maternal hypoxia, and the condition of the baby was dependent on its preoperative state rather than on the anesthetic technic.

DISCUSSION

An early report[8] described the use of diazepam for CS as disappointing. Preoperative oral and IM diazepam administration increased the incidence of USELA. A later study[9] reported that the preoperative administration of diazepam, narcotic, and/or scopolamine produced adequate amnesia, but the combination of the 3 drugs produced marked respiratory and circulatory depression. However, in our study, using only 2 drugs, diazepam and morphine, in the recommended dosage, no patient required postoperative ventilatory assistance. In fact, most were able to move themselves from the operating table to the recovery room bed.

The absence of significant cardiovascular depression due to morphine-diazepam was evidenced by the limited number of cases that showed hypotension despite the inclusion of emergency cases, and the limited decrease in BP despite the use of oxytocin. The safety of the use of morphine-diazepam in poor-risk surgical patients has also been reported.[6] Diazepam has been shown to result in anterograde amnesia by accelerating decay of the memory trace, thus impairing its consolidation.[10,11] From our study, diazepam together with morphine give both anterograde and retrograde amnesia.

One of the reported disadvantages of diazepam is venous thrombosis at the site of injection.[12] The absence of such a complication in our series may be due to the injection of 2.5-mg increments of diazepam into a rapidly infused solution. The vasodilative action of oxytocin[13] may have been a contributing factor against venous thrombosis. At term, the minimal alveolar concentration (MAC) of inhalation anesthetics is reduced by 25 to 40 percent.[14] Since both diazepam and morphine reduce the MAC of general anesthetics,[15-17] the use of morphine-diazepam during CS could have decreased USELA by further reducing the MAC of N_2O.

With increasing concentration of N_2O, spontaneous movements began at a concentration of 60 percent and increased with higher concentrations.[18] In our study, there

was no apparent correlation of movement with awareness, pain, or dreams, but rather with the degree of paralysis. Neither changes in BP nor pupil size were indicative of awareness or dreams. Our conclusion is that these changes are autonomic in origin, determined by the tone of the autonomic nervous system, modified by drug administration, and should not be relied on for evaluating the depth of anesthesia during N_2O administration.

The level of thiamylal in maternal blood falls steeply during the first 4 minutes following an IV bolus of 4 mg/kg.[19] During that period, there must be a buildup of a sufficient concentration of inhalation agent to take over from the waning effect of the agent. If intubation is difficult and induction time is prolonged, as occurred in 2 of our patients, awareness may occur. Therefore, with such difficulties, a second 1.3-mg/kg dose of thiamylal is advisable, and N_2O-O_2 should be administered for about 2 minutes before incision. The combination of these 2 doses of thiamylal has no depressant effect on the fetus.[19]

As reported above, the first event recalled by most mothers during recovery from anesthesia concerned their babies. The auditory and visual information of high emotional content results in memory consolidation to permit recall.[20] The only patient who had complete amnesia of her stay in the recovery room had her baby placed for adoption.

Relation of $Paco_2$ to Fresh Gas Flow in a Circle System

KANCHAN PATEL, MD*
EDWARD J. BENNETT, MD†
ERNEST M. GRUNDY, FFARCS‡
ARTEMIO IGNACIO, JR, MD§
Chicago, Illinois‖

Recent reports have described methods of controlling the level of CO_2 during anesthesia with a N_2O-relaxant sequence and controlled ventilation. This paper describes a method of predicting and controlling the $Paco_2$, using body weight for determination of the fresh gas flow from the anesthetic machine, removing the absorbent from the canister while leaving the canister in the circuit, and controlling ventilation at 12 ml/kg and at 12/min.

THERE is a tendency to use the terms hypocapnia and hyperventilation synonymously,[1] but the terms are not quite the same. It is possible to overventilate a person with a mixture containing CO_2, with resultant hypercapnia. Thus, hyperventilation can be defined more accurately as pulmonary ventilation in excess of that required to keep blood $Paco_2$ within desired limits.

The dangers of mechanical ventilation of the paralyzed patient are those of underventilation or overventilation and hypercapnia or hypocapnia. Because the problems of hypercapnia are well appreciated, there is a tendency to overventilate; the result usually is an undesirable and even detrimental degree of hypocapnia. The ideal appears to be to keep $Paco_2$ in the low normal range, 35 to 40 torr.

The purpose of this study was to determine whether $Paco_2$ could be controlled easily and simply by limiting the fresh gas flow (FGF) into a circle system without soda lime in the absorber, thus controlling $Paco_2$ independently of ventilation.

A recent report showed that $Paco_2$ could be accurately predicted and controlled by using the Nunn blood-gas predictor, setting the FGF at the same numerical value as the predicted alveolar ventilation ($\dot{V}_A$) to obtain the required $Paco_2$.[2] In the present study, FGF was related to body weight, with the amount of mechanical ventilation always kept in excess of FGF.[3] Under these circumstances, CO_2 elimination from the whole circuitry (patient + anesthetic system), was through the exhaust valve and at a rate proportional to the FGF from the machine.[2]

METHODS

Patients (table 1) were selected from the elective schedule for major abdominal operations. Most were in ASA categories I-III, and informed consent was obtained. Arterial cannulation was employed for monitoring during the study. Premedication consisted

Weight		
Mean	70 kg	
Range	40-96 kg	

of atropine with morphine, diazepam, or hydroxyzine IM 45 minutes before induction. Anesthesia was induced with a hypnotic dose of sodium thiopental followed by 120 mcg/kg of pancuronium and controlled ventilation was with N_2O 60 to 70 percent in O_2. Following topical anesthesia of the larynx and trachea, patients were intubated endotracheally with a snug-fitting cuffed plastic disposable tube. Ventilation was then instituted with a bellows-type mechanical ventilator (Air Shields Ventimeter®). The tidal volume (V_T) was set at 12 ml/kg at a respiratory rate of 12/min. V_T and minute volume ($\dot{V}_E$) were checked frequently on the expiratory side with a Wright respirometer, which was not left in the circuit. Anesthesia was supplemented with droperidol and fentanyl as indicated by the patient's vital signs.

The circle system was used without soda lime in the cannister but with the cannister left in the circuit. The FGF into the circuit and the spill valve for excess gases were separated from the patient by the inspiratory and expiratory valves.[4]

After 30 minutes with any FGF, blood gases were checked on an Instrumentation Laboratories IL 313 Blood Gas Analyzer, calibrated before every reading, and analyzed by the same technician using the same collection technic for each analysis. F_{IO_2} was monitored with a Teledyne® O_2 analyzer and kept constant throughout the procedure at 0.3 or 0.4, whichever was more appropriate. Keeping the ventilation constant, FGF was progressively lowered from 120 to 100, to 80, 60, and then 40 ml/kg/min. At each setting, 30 minutes was allowed for establishing a steady state; then measurements were taken as before. At the end of this part of the investigation, $\dot{V}$ varied from half to double that used earlier but was always greater than FGF, and blood gases were determined as before.

For full utilization of FGF, $\dot{V}$ must exceed FGF, to prevent possible reduction of V_T to where dead-space gas ventilation would result. In this study, to determine the role of $\dot{V}$, the rate and volume of ventilation were altered between 50 and 200 percent of those used earlier, with V_T always >5 ml/kg.

RESULTS

At the range of gas flow tested (120 to 40 ml/kg/min), $Paco_2$ ranged from 29.1 ± 3.4 to 46.2 ± 4.6 (table 2 and figure) and Pao_2 from 125 to 135 torr. The amount of ventilation did not change the readings obtained for $Paco_2$. Several different ventilators were used; results were similar so long as the ventilator was of the type colloquially termed an "automatic bag squeezer."

DISCUSSION

It has been predicted[5] that $Paco_2$ would be determined by the FGF into the particular anesthetic circuitry rather than by $\dot{V}_A$,

TABLE 2

Fresh Gas Flow Related to Blood-Gas Tension

Fresh gas flow, ml/kg/min	$Paco_2$ mean ± 1 SD torr	Pao_2, torr
120	29.1 ± 3.4	125
100	31.3 ± 3.1	114
80	34.4 ± 3.1	133
60	38.4 ± 3.3	134
40	46.2 ± 4.6	135
10 L/min	26.3 ± 3.0	134

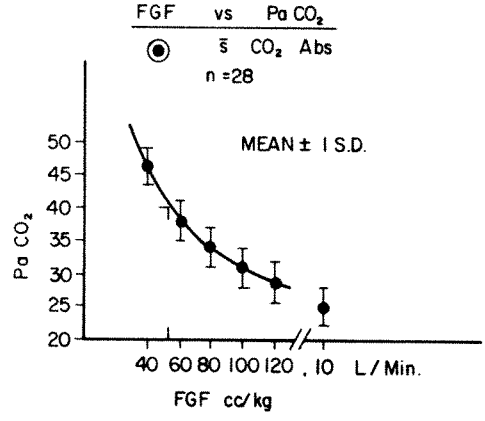

FIGURE. Relation of $Paco_2$ to fresh gas flow from machine.

even though the latter would be vital to proper ventilation. When closed-circle systems used cyclopropane or halothane, hyperventilation was avoided. But current technics employing N_2O supplemented by relaxants and narcotics require controlled ventilation.

In FGF into a semiopen system, using a Mapleson D modification, the flow needed for normocarbia was 100 ml/kg/min.[6] Using a Bain circuit, a flow of 70 ml/kg/min resulted in a $Paco_2$ of approximately 40 torr, provided the $\dot{V}_E$ was higher than the FGF.[7] At a V_T of 10 ml/kg, a slightly lower $Paco_2$ was achieved in another study with the Bain circuit (36.6 torr)[8] and the same flow rate. In yet another study,[2] using the Nunn blood-gas predictor, an instrument that provides data for CO_2 production and respiratory quotients under anesthesia,[3] FGF was set at the same numerical value as the predicted $\dot{V}_A$ to obtain normocarbia.

The concept that FGF from the machine determines $Paco_2$ has been developed further in that, under conditions of rebreathing, hyperventilation cannot alter the alveolar gas composition, which is determined by gas exchange, flow rate, and the composition of the fresh gas.[9]

Results from the present study will be valid if the FGF and the spill of excess gases are separated from the patient by the inspiratory and expiratory valves, and if V_T is not reduced below 5 ml/kg. The FGF shown does not appear to change with the respiratory status of the patient in the level of $Paco_2$ obtained, although O_2 will be affected. This type of control of $Paco_2$ will allow the Pao_2, $Paco_2$, and the pattern and type of ventilation to be varied independently of one another and tailored to suit the particular requirements of individual patients.

A problem of controlled ventilation during N_2O anesthesia has been that reducing the ventilation in order to lessen the degree of hypocapnia also tends to reduce Pao_2 levels. The other methods of increasing $Paco_2$ by adding dead space or by adding CO_2 to inspired gases do not appear to be widely used. Thus a method of predicting $Paco_2$ and then controlling it during anesthesia appears useful.

Removal of the CO_2 absorbent from the circuit (or elimination of the CO_2 absorber circuit in machines so equipped) will allow:

1. Better control of $Paco_2$ by varying FGF
2. No inhalation of dust (soda lime)[10]
3. No absorber exhaustion
4. No problem of soda lime/agent incompatibility
5. No bacterial colonization[11]
6. No added resistance in the cricuit

If, at any time, the limitation of gas flow is deemed unsuitable, the circle can be temporarily converted to a virtual nonrebreathing circuit by increasing the FGF.

A Comparative Interaction of Epinephrine with Enflurane, Isoflurane, and Halothane in Man

RICHARD R. JOHNSTON, MD*
EDMOND I. EGER, II, MD†
CHARLES WILSON, MD‡
San Francisco, California§

Forty-eight patients undergoing transphenoidal removal of pituitary tumors received submucosal injections of epinephrine in saline solution during halothane, enflurane, or isoflurane anesthesia. Twelve additional patients received epinephrine in 0.5 percent lidocaine while anesthetized with halothane. Positive evidence of ventricular irritability was given by the appearance of 3 or more premature ventricular contractions during or following injection. Positive or negative responses were plotted against the total dose of epinephrine in μg/kg body weight. From these data, the dose producing a positive response in 50 percent of patients (ED_{50}) was calculated. An ED_{50} of 2.1 μg/kg for halothane, 3.7 μg/kg for halothane-lidocaine, 10.9 μg/kg for enflurane, and 6.7 μg/kg for isoflurane indicates the relative safety of these agents when epinephrine is injected for hemostasis. The data also suggest that lidocaine given with the epinephrine protects against ventricular arrhythmias.

PREVIOUS studies in dogs suggested that isoflurane is compatible with epinephrine, while conflicting data suggest that enflurane, an isomer of isoflurane, may or may not sensitize the myocardium and increase the risk of ventricular fibrillation.[1-6] Knowledge of such interactions is important because of the widespread use of epinephrine to achieve hemostasis during surgical procedures. However, no reports have demonstrated the interaction of epinephrine with either anesthetic agent in man, nor has a comparison been made with a drug such as halothane, which is known to sensitize the heart.

Accordingly, we determined the dosage of epinephrine in saline solution required to produce premature ventricular extrasystoles (PVCs) in elective surgical patients anesthetized with halothane, enflurane, or isoflurane, and the epinephrine dosage that produced PVCs when administered in a lidocaine solution.

METHODS

Patients undergoing transphenoidal pituitary operations at our institution routinely receive nasal and oral submucosal injections of epinephrine to minimize surgical bleeding. Fifty such patients (ASA status I or II), divided into 4 groups (table) were studied. All were without evidence of significant cardiovascular disease. No premedication or IV inducing agent was given. Two groups were anesthetized with halothane, one with isoflurane, and one with enflurane. One halothane group and the enflurane and

TABLE

Patient Ages, Weights and Heights Are Listed Above the Estimates of the Dose (ED_{50}) of Epinephrine Which Produced 3 or More PVCs

	Halothane	Halothane-lidocaine	Enflurane	Isoflurane
Number of patients	10	9	15	16
Age, years	40.8 (±19.9)	39.9 (±14.7)	36.9 (±15.3)	41.9 (±12.7)
Weight, kg	80.9 (±24.4)	89.4 (±13.9)	69.2 (±16.3)	76.6 (±18.9)
Height, cm	163.0 (±15.0)	181.6 (±20.6)	162.6 (±7.0)	165.0 (±13.8)
Epinephrine ED_{50}, μg/kg	2.11 (±0.15)	3.69 (±0.42)	10.9 (±8.9)	6.72 (±0.66)

Each average number is followed by the standard deviation. The ED_{50} for halothane, halothane-lidocaine, and isoflurane differed significantly ($p<0.01$). No comparison could be made with enflurane because the slope of its dose-response curve (fig 1) did not parallel the slope for the other agents.

isoflurane groups received a freshly prepared solution of either 1:100,000; 1:150,000, or 1:200,000 epinephrine in saline solution (10, 6.7, or 5 μg/ml, respectively). The remaining halothane group received epinephrine, 1:200,000, freshly prepared in 0.5 percent lidocaine solution. After induction, the patient's trachea was intubated and ventilation was controlled to produce an arterialized venous blood-gas Pco_2 of 30 to 40 torr, measured with a standard Severinghaus electrode. Succinylcholine was used in 5 patients to assist endotracheal intubation.

During the 30 minutes usually required for positioning and preparation of the surgical site, anesthetic gas tensions, as measured by ultraviolet (halothane) or infrared (enflurane or isoflurane) analysis were adjusted to 1.25 times MAC,* and a control ECG lead with well-visualized P waves was recorded usually for 3 minutes immediately before injection. The surgeon then injected epinephrine into oral and nasal submucosal areas, as indicated by operative needs. A continuous ECG record was obtained during and for 3 to 10 minutes after termination of the injections, which required 3.5 to 11 minutes to complete. If PVCs occurred during injection, the injection was halted until the arrhythmias resolved. If frequent multifocal ventricular arrhythmias occurred, lidocaine (100 mg) was administered in a bolus and the injection was terminated.

We arbitrarily defined the appearance of 3 PVCs at any time during or immediately following epinephrine injection as indicating ventricular irritability, since an occasional single PVC may occur in the normal anesthetized patient. Patients were considered to have a positive or negative response based on this criterion; no positive responses were observed in any patient prior to injection. Positive and negative responses were plotted versus dose in μg/kg.

Data were analyzed with a UCSF† double-precision version of a quantal regression program, written by P. Clayton.‡ The significance of differences between the doses producing a positive response in 50 percent of patients (ED_{50}) was tested by Student's *t*-test, except that such testing was not done for the enflurane group because its response curve did not parallel those of the other agents.

RESULTS

Age, weight, and height (table) and $Paco_2$ did not differ significantly among the 4 groups. However, the epinephrine ED_{50} values for halothane, halothane-lidocaine, and isoflurane groups (table) differed significantly ($p<0.01$). The ED_{50} was least in patients given epinephrine in saline during halothane anesthesia (halothane group) (figs 1, 2). The ED_{50} in patients given epinephrine in 0.5 percent lidocaine (halothane-lidocaine group) was greater than that for the halothane group but less than that for the isoflurane group. The enflurane

*MAC is the alveolar concentration of anesthetic required to eliminate movement in response to an incision in 50% of patients.

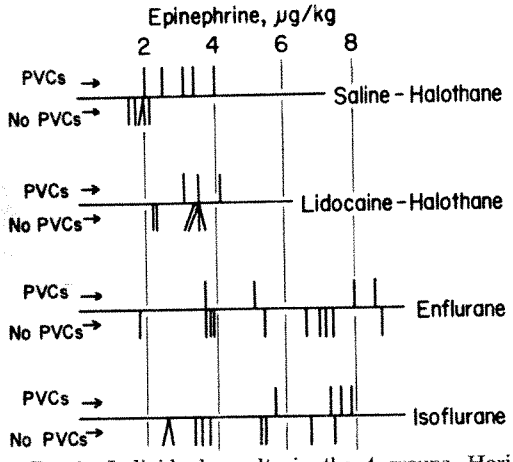

FIG 1. Individual results in the 4 groups. Horizontal lines indicate concentration of epinephrine injected submucosally. Each vertical line extending from horizontal lines represents 1 patient: an upward direction signifies that the patient experienced 3 or more PVCs; a downward deflection signifies that 2 or fewer PVCs appeared within 10 minutes after injection.

group had the highest ED_{50}, but the flatness and hence nonparallel nature of its dose-response curve made any statistical comparison invalid.

In the halothane group, 4/5 patients with arrhythmias had ventricular tachycardia. Two "negative-response" patients near the ED_{50} (1.9 and 1.8 μg/kg) had 1 PVC each. Although only PVCs were used to define ventricular irritability, other arrhythmias occurred. Heart rate increased in nearly all patients, most developing a sinus tachycardia (rate greater than 100 bpm). A nodal rhythm occurred in 8 patients: 2 in the halothane group, 1 in the halothane-lidocaine group, 3 in the enflurane group, and 2 in the isoflurane group. As might be expected, the number of PVCs correlated with the dose of epinephrine in the halothane groups. In the enflurane and isoflurane groups, although positive PVC responses were obtained, the total number of abnormal complexes were too few to permit a correlation.

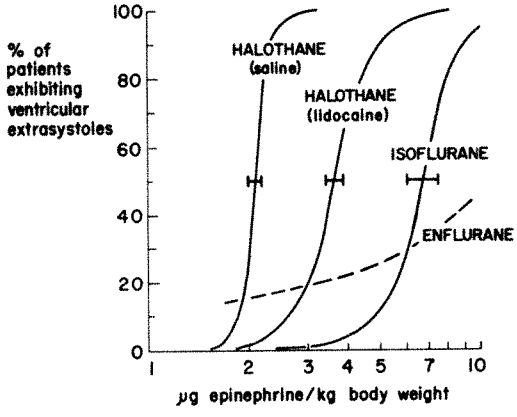

FIG 2. The results of the statistical analysis suggest that the two halothane and the isoflurane curves (but not the enflurane curve) are parallel and that the ED_{50}'s are significantly different from each other ($p<.01$). The bars indicate the standard deviation from the ED_{50}.

DISCUSSION

Approximately 3 times as much epinephrine was required to produce 3 or more PVCs during isoflurane as during halothane anesthesia, with enflurane probably comparable to isoflurane in this regard. If we assume (as suggested by the present study) that a dose equaling half the ED_{50} is unlikely to produce PVCs, then these potentially dangerous arrhythmias likely will not follow injections of up to 1 μg/kg during halothane and 3.4 μg/kg during isoflurane anesthesia. In a 70-kg patient, such doses would be produced, with halothane, by 14 ml and, with isoflurane, with 47 ml of a 1:200,000 solution of epinephrine in saline.

Furthermore, if 0.5 percent lidocaine were given concomitantly, these "maximum safe doses" probably could be increased by 50 percent. This protective effect of lidocaine was studied only with halothane. However, on the few occasions when PVCs appeared and were treated with lidocaine during isoflurane or enflurane anesthesia, the arrhythmias immediately disappeared. This would suggest that the protection offered by concomitant lidocaine also would apply to these anesthetics.

The maximum safe doses suggested above may be modified by several factors. In our study, injection was into vascular oral and nasal mucosa. Injection into less vascular subcutaneous tissues might decrease the rate of epinephrine uptake and thereby raise the maximum safe dose. Obviously, accidental intravenous injection would do the opposite. Although no ventricular arrhythmias may be induced by the maximum safe doses, transient tachycardia and hypertension may result. These cardiovascular effects may produce myocardial ischemia in patients with compromised coronary arteries.

We studied unmedicated patients whose ventilation and anesthetic dosage were comparable in all groups. We have not determined the effect of variations of these factors in man, nor are comparable data in

man available. However, studies in dogs by Joas and Stevens[4] indicated no effect or a protective effect from increases in anesthetic dose (halothane, fluroxene, isoflurane) or in $Paco_2$. Our results agree both qualitatively and quantitatively with the finding in dogs that the dose of epinephrine required to produce PVCs during isoflurane anesthesia is 4 times that required during halothane.[4,5]

In part our results agree with those of Katz and associates[7] who suggested a safe dose of epinephrine during halothane anesthesia of 1 μg/kg. We disagree with Katz's suggestion that the concomitant injection of lidocaine with epinephrine affords no increased protection from arrhythmias. However, the individual doses of epinephrine used in the Katz study were too low to evoke a significant increase in the incidence of arrhythmias; this would prevent discernment of the protective effect of lidocaine.

Halothane and enflurane or isoflurane appeared to differ in their propensity to sustain ventricular arrhythmias. When ventricular irritability appeared during halothane, it was often followed by frequent abnormal beats, leading to ventricular tachycardia. In contrast, when ventricular arrhythmias appeared with the other 2 anesthetics, the abnormal beats were occasional, intermittent, and not necessarily sustained. This impression is further supported in the case of isoflurane by 3 patients (data not included in present study) who each received 11 μg/kg of epinephrine and who failed to demonstrate any PVCs. One other patient anesthetized with enflurane was given 13 μg/kg and demonstrated a positive response (data also not included because epinephrine dosage exceeded 10 μg/kg).

While the dose-response relationships shown in figure 1 demonstrate a nonparallelism of enflurane with the other curves, precluding statistical evaluation, this should not suggest that these data are unimportant, since they can be compared clinically with other data. Our dose-response curve with enflurane may represent only the lower part of a larger dose-response curve which cannot be examined because such an examination would require unjustifiably high doses. Defining the larger part of the enflurane curve would be interesting, but would have to be done in animals, which would defeat the intent of our study.

CONCLUSIONS

Two clinical implications are suggested by our results. Catecholamine drug support often is required following cardiopulmonary bypass for cardiac surgery. If ventricular arrhythmias are of concern, enflurane or isoflurane might represent a better anesthetic choice for such patients. Finally, our results would suggest that ventricular arrhythmias would be less likely to occur in patients suffering from pheochromocytoma when these patients are anesthetized with isoflurane or enflurane rather than with halothane.

ACKNOWLEDGMENT

We appreciate the assistance provided by Dr. S. Wiley, who performed the quantal regression analyses.

A Preplanned Treatment for Malignant Hyperpyrexia

JOHN G. FRASER, MD*
ROBERT S. CRUMRINE, MD†
ROBERT J. IZANT, JR, MD‡
Cleveland, Ohio§

Although a rare complication of general anesthesia, unanticipated malignant hyperpyrexia requires a rapid, organized treatment plan. With the aid of a treatment protocol sheet and a compact drug and cooling package, treatment can be implemented quickly in each operating room.

THE clinical entity of malignant hyperpyrexia has been discussed in numerous articles in the anesthesiology literature over the past 10 years.[1-3] The syndrome has been defined as a pharmacogenic disorder of unknown cause, occurring during general anesthesia in humans and swine and resulting in life-threatening temperature elevations. The onset of hyperpyrexia may be evident upon induction of anesthesia, heralded by paradoxically induced rigidity in response to succinylcholine; or it may suddenly occur intraoperatively in association with potent inhalation agents or in the postoperative recovery room.[4,5] Even the previously implied safety of d-tubocurarine in susceptible patients has been questioned by Britt and her associates.[6] Cases of malignant hyperpyrexia have been reported during a 2nd or 3rd anesthetic procedure following previous uneventful exposures.[7]

In the orderly and predictably scientific investigations of the hyperpyrexia syndrome in susceptible swine, several treatments have proved successful. Epidural anesthesia and the drugs triiodothyronine, dantrolene sodium, and procainamide are among the treatments that have prevented or aborted the induced hyperpyrexia in swine.[8-11] The survival of a patient with malignant hyperpyrexia through cooling by a pump-oxygenator has been reported.[12]

In the years 1973-1976, a period during which approximately 17,000 pediatric anesthetics were administered, we encountered 6 cases of malignant hyperpyrexia, all in the pediatric age groups. All but one of these cases represented a paradoxical response to succinylcholine on induction or the development of a rapidly rising fever from a normal initial temperature, rising to above 40° C within 5 minutes under halothane anesthesia. All but one patient responded successfully to a termination of anesthetic and conservative cooling efforts. The 1 death was specifically attributed to uncontrolled malignant hyperpyrexia.

Until further evidence supports an increased clinical efficacy of a specific drug, we have chosen procainamide as the principal drug in our treatment regime. We recognize that parenterally injectable dantrolene sodium offers the advantages of quite specifically acting on skeletal muscle, without a negative inotropic cardiac effect.[10] However, its successful use in the hyperpyrexia syndrome in man has not yet been

*Assistant Professor of Anesthesiology.

Paper received: 10/1/75
Accepted for publication: 1/12/76

adequately tested. Also, the FDA has recently warned of hepatoxocity associated with dantrolene.

The difficulties in preparing for the use of a pump-oxygenator and the slow onset of an effective epidural anesthetic make these treatment modalities unattractive as a preplanned approach to the unexpected hyperpyrexia syndrome.

In forming our treatment regime, we seek the advantages of simplicity and immediate availability. Compactly stored and clearly labeled, each operating room (OR) contains the following items:

I. "Malignant Hyperpyrexia Protocol;" laminated in transparent plastic.

II. One translucent vinyl film plastic sheet: (0.006 gauge), 140 x 122 cm in size.

III. 10-ml vial of procainamide HCl (100 mg/ml).

IV. 10-ml syringe with an 18-gauge needle.

V. 500-ml bottle of 5% dextrose in water.

VI. 1000-ml bottle of normal saline solution, kept cold in OR refrigerator.

VII. A ready source of ice and a routinely stocked emergency cart.

The following protocol sheet, written in "cookbook" form, leads the physician quickly through a rare and stressful emergency.

MALIGNANT HYPERPYREXIA PROTOCOL

A. *Recognition of the Syndrome:*

1. Hypertonus of skeletal muscle may occur.
   a. IMMEDIATE: Immediately following the administration of succinylcholine. FAILURE OF SKELETAL MUSCLE TO RELAX AFTER SUCCINYLCHOLINE IS AN INDICATION TO POSTPONE SURGERY AND REEVALUATE.
   b. DELAYED: Later in the anesthetic when using potent agents, commonly halothane.
2. Unexplained tachypnea, tachycardia, sweating, cyanosis, or overheated soda lime are nonspecific early signs.
3. An unexplained rise in body temperature (1° C).

THE SYNDROME MUST BE RECOGNIZED BEFORE THE THERMAL REACTION IS SEVERE OR WELL ESTABLISHED. A RISE IN BODY TEMPERATURE MAY BE A LATE SIGN.

B. *Therapeutic Measures:*

1. DISCONTINUE ALL INHALATIONAL AGENTS AND RELAXANTS AND DISCONTINUE THE SURGERY AS SOON AS POSSIBLE.
2. HYPERVENTILATE WITH 100% OXYGEN.
3. DRUG THERAPY MUST BE STARTED IMMEDIATELY.
   a. If the patient develops muscle rigidity administer *diluted* procainamide intravenously. This solution containing 1 gm (10 cc) of procainamide in 500 cc can be infused rapidly until the rigidity subsides and then be reduced to a slower rate or discontinued. Observation of the EKG and the blood pressure are mandatory during this potent drug therapy. Vasopressors may be indicated.
   b. Sodium bicarbonate 2 mEq/kg IV stat and repeat in accordance with blood gas measurements.
   c. Mannitol—1 gram/kg IV.
4. COMMENCE ACTIVE COOLING, IF A RISING TEMPERATURE IS ENCOUNTERED. PLACE THE PATIENT IN THE PLASTIC SHEET, APPLY ICE BAGS AND ICE WATER. INTRAGASTRIC COOLING MAY ALSO BE CONSIDERED. IF THE PERITONEAL CAVITY IS OPENED, STERILE ICE SALINE MAY BE POURED INTO THE OPENING.
5. IF BODY TEMPERATURE FAILS TO QUICKLY RECEDE WITH EXTERNAL COOLING, VASODILATORS MAY BE INDICATED. INTRAVENOUS CHLORPROMAZINE (THORAZINE) CAN ACCOMPLISH THIS DESIRED VASODILATION, BUT ONLY AFTER ADEQUATE INTRAVASCULAR FLUID VOLUME HAS BEEN ATTAINED.

6. INSERT A SECOND INTRAVENOUS CANNULA AND GIVE REFRIGERATED NORMAL SALINE SOLUTION.

C. *Investigative Measures:*

1. Monitor by: esophageal stethoscope, blood pressure cuff, electrocardiogram, thermometer (rectal, esophageal and particularly intramuscle thermistor).
2. Insert an arterial cannula for sampling blood gases and pH.
3. Take blood specimens (10 ml) immediately and measure: electrolytes (Na, K, Cl, Ca, Po_4, and Mg), creatine phosphokinase (CPK), SGOT and LDH, and correct excesses and deficits in electrolytes. Repeat electrolyte determinations at frequent intervals.
4. Repeat the arterial blood measurements at 10-minute intervals and correct on the basis of the results.
5. Catheterize and take urine sample for hemoglobin and myoglobin estimation.
6. Measure urine output.
7. Anticipate massive disseminated intravascular coagulopathy. Draw blood for essential clotting factors; especially platelets, fibrinogen, prothrombin, factors V, VII, VIII, X, and calcium. If the diagnosis of DIC is made, administer heparin 250 mg/24 hours by continuous IV drip.

The admonitions in item C-7, on intravascular coagulopathy and its therapy are based on studies by Daniel's group[13] and Nemerson.[14]

The heavy gauge plastic sheet is rapidly unfolded under the patient and hung on IV poles to form an "instant bathtub" (figure). The sheet, even when filled with ice and water, allows clear access to the patient's head, airway, and extremities and allows adequate monitoring of vital signs and access to peripheral veins and arteries; the conventional bathtub permits none of these advantages. Additional IV routes for infusion of refrigerated normal saline solution are more easily established and arterial blood sampling is more easily obtained.

The 10-ml vial of procainamide (10%

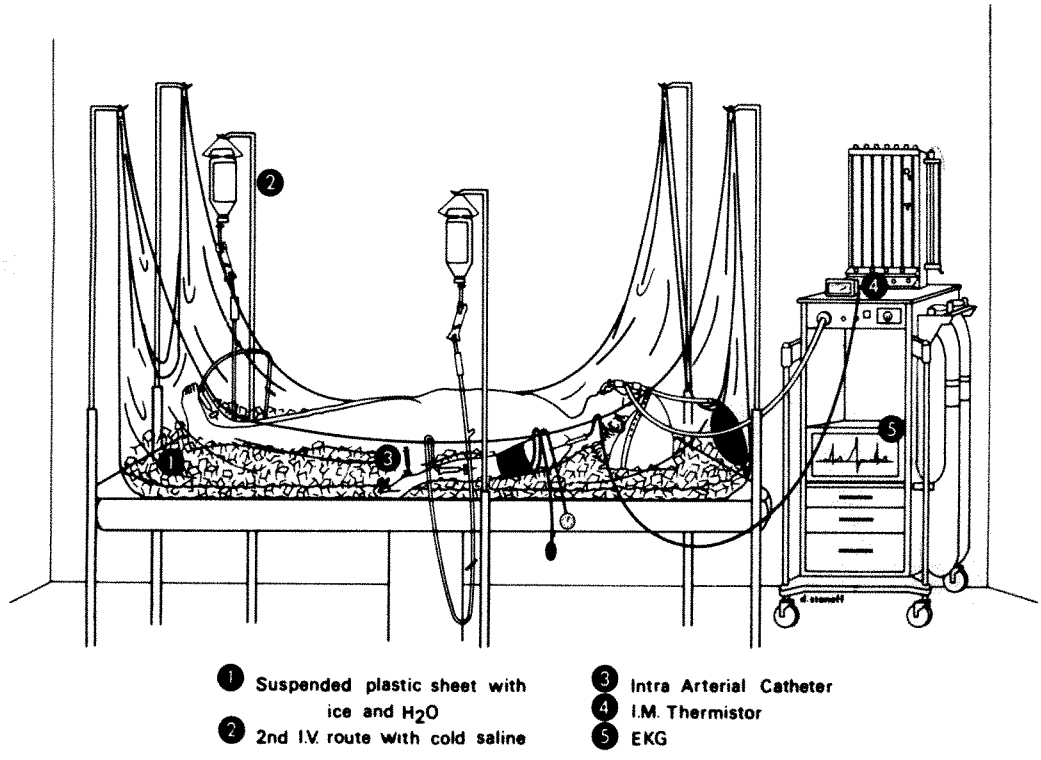

FIGURE. Active malignant hyperpyrexia treatment.

solution) when added to the 500 ml of diluent is a good concentration to be administered IV until the patient's rigor subsides.[11] Procainamide remains pharmacologically active at ordinary OR temperatures (under 29.4° C) for 2 years and then should be discarded.*

ACKNOWLEDGMENT

BLOOD CULTURES. Results of blood cultures drawn via intravascular venous or arterial catheters were compared with findings from simultaneously obtained samples via percutaneous venipuncture. Results were identical in 161 of 174 comparisons (92 percent). Staphylococcus epidermidis was more likely to be present in catheter obtained samples. It appears that blood cultures obtained from catheters are as reliable as venipuncture samples. The ease and lack of trauma in obtaining blood samples from indwelling catheters are additional advantages. *(Tonnesen A, Peuler M, Lockwood WR: Cultures of blood drawn by catheters vs venipuncture. JAMA 235:187, 1976)*

Editors share the belief that medical writing is capable of vast improvement. This article is one of a series of personal communications from Charles G. Roland, M.D., former Senior Editor of JAMA, to John T. Martin, M.D., Associate Editor of Anesthesia & Analgesia . . . Current Researches. Thoughts About Medical Writing

XXXVII. Verify Your References

Dear Tom:

Who was killed in 1938 and never had a mother? Don't you even want to guess? All right, it was O. Uplavici, the much-cited author of an important paper, published in 1887, on amebic dysentery. This paper first described the experimental transmission of amebic dysentery from man to the cat.

Why should any anesthesiologist be interested in this tale of infectious diarrhea? Because of the riddle I began with, and because I am writing today about verifying references. O. Uplavici was killed by the pen of Clifford Dobell, in 1938, and he had no mother—or father—because he never existed. The story is a classic of bibliographic error.

Jaroslav Hlava, of Prague, wrote an article on dysentery and published it in a Czech medical journal in 1887. Being a Czech, and writing in Czech, he understandably gave his title, "On Dysentery," in Czech also—"O. Uplavici." A German writer prepared a German-language abstract and, unaccountably, dropped Hlava's name and cited O. Uplavici as the author. The error was compounded in many interesting ways until finally exposed by Dobell.[1]

Similar, though less spectacular, errors occur often. Few studies seem to have been made of this phenomenon, but two recent ones perhaps deserve comment. In one, in which every reference in every paper accepted by a national journal for an entire year was checked, almost two-thirds of these 1,867 references were incorrect in some feature or were unverifiable.[2] And in another study, the error rates in references published in 10 major journals ranged from 13% to 50%.[3]

Does this really matter? Surely it ought to. References are supposed to be guides to the reader, indicating where the author derived data or ideas. And some readers do look up references, sometimes. If the citations are wrong, the reader may have difficulty finding what he or she wants, or may be unable to find it. Perhaps even more important is a philosophical-ethical issue: the published article is the culmination of an author's work. It should be error-free, for who can have confidence in a work in which he can find mistakes, whether in the data, the interpretations, or the references?

So verifying references is no mere exercise in pedantry. Yet obviously, it is something that few authors do—or do properly.

Most errors are simple enough to explain. Page 196 becomes 169. "Mar." becomes "May." "Ann Int Med" becomes "Arch Int Med." Little slips, typical of hurrying humanity. We all make this kind of error when we transcribe information. The sin occurs in passing understandable carelessness off as information.

The problem is universal. There is no cure except careful checking of the accuracy of every citation, late in the writing process

but well before the final typing stage. This checking must include every element of the citation. The author of the reference wants his name spelled correctly; moreover, ensuring that it is correct helps your reader and may prevent severe indigestion on the part of the computers that are now increasingly used to record, sort, and retrieve scientific information. Similarly, the title of the cited article must be given exactly as it appeared in the original publication; do not abbreviate in any way. The journal title must be precise, as well as the volume number, pagination, and date published.

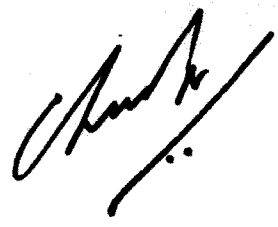
Most journals provide specific instructions about the way they want this data to be presented—their "style"—and you should try to follow their rules. If you have difficulty doing so, I advise that you send the complete reference—full journal title spelled out, for example—and let the journal convert it to their format. Unfortunately, minute differences in format exist between one journal and another, although most of the major clinical journals on this continent have agreed on a standard reference style. (For examples, see any article in this issue.)

A common reason for errors in reference citations probably is the frequency with which an untrained and uninstructed person is made responsible for checking the citations. All too often, a secretary or a clerk is sent off to the library with few or no directions except to "check the references." But a little training quickly cures this problem.

Indeed, of all the problems of medical writing, that of publishing incorrect references must be the easiest to solve. The solution requires only increased attention to a routine—and therefore often neglected—chore. Place[4] presented the matter succinctly just 60 years ago:

> Take no reference for granted. Verify the reference that your best friend gives you. Verify the reference that your revered chief gives you. Verify, most of all, the reference that you yourself found and jotted down. To err is human, to verify is necessary.

Best regards,



[Charles G. Roland, M.D.]

Maintenance of Body Temperature by Heated Humidification

HENRY C. TAUSK, MD*
RAYMOND MILLER, MD†
ROBERT B. ROBERTS, MD‡
New York, New York

Though difficult to prove conclusively, humidification of anesthetic gases during prolonged surgery appears beneficial. Even slight falls in body temperature are detrimental, causing significant increases in O_2 consumption in the immediate postoperative period. A new heated humidifier which supplies gases at 100% relative humidity at 35° C at the patient inlet has been used both to supply humidity and to prevent a fall in interoperative temperature. This was successfully employed in 19/25 prolonged procedures. The warmed humidified gases contributed significantly to the maintenance of homeostasis during anesthesia.

ADEQUATE humidification of the patient's tracheobronchial tree and the maintenance of normal body temperature are of paramount importance during prolonged surgical procedures.

The comfort of the surgical team necessitates cool air-conditioned operating rooms,[1] which may result in a decline in the patient's body temperature. Many methods have been used to maintain or raise body temperature, including thermal blankets[2] or garments,[3] warm IV fluids,[4] radiated heat, and heat exchangers.[5] These methods, while often effective, have the disadvantages of not being universally applicable. Thermal blankets and garments may still leave large areas of the body exposed, are difficult to use in such positions as knee-chest, and may cause skin burns.[6] Extracorporeal circulation incorporating a heat exchanger is expensive, complicated, and not always readily available.[5]

The importance of humidification during prolonged anesthesia has long been recognized; exposure to dry inhaled gases for over 1 hour produces damage to the epithelium of the respiratory tract.[7] Different means of humidification have been recommended but many fail to provide optimal humidity, since the relative humidity of gases delivered at room temperature falls when the gases attain body temperature. Satisfactory humidifiers are often adaptations of equipment used in respiratory therapy and, while eminently suitable during controlled ventilation, provide an unacceptable resistance to inhalation for the patient during spontaneous ventilation and therefore must be modified.[8]

Present Study.—A prototype of a new concept in humidifiers that provides heated humidified anesthetic gases to the patient without increased resistance during spontaneous ventilation, and in which gas temperature can be fairly rapidly adjusted, was used to investigate the efficacy of heated inspiratory gases in the maintenance of normothermia during prolonged anesthesia.

The humidifier* (fig 1, 2) consists of a simple reservoir containing a rotating brush whose fibers pass through heated water covering the lower half of the brush and then flick past a baffle above the water level, producing a fine spray of water droplets. The water is heated through a metal backplate that transmits heat directly from the

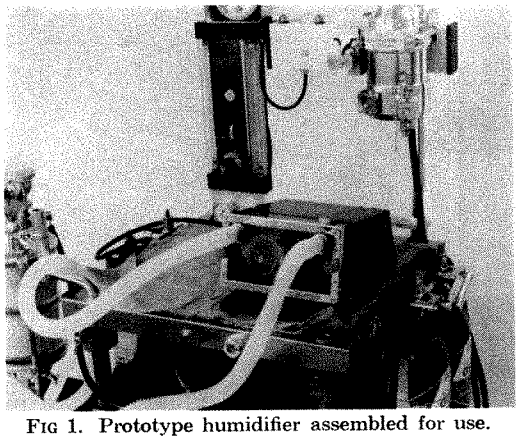

FIG 1. Prototype humidifier assembled for use.

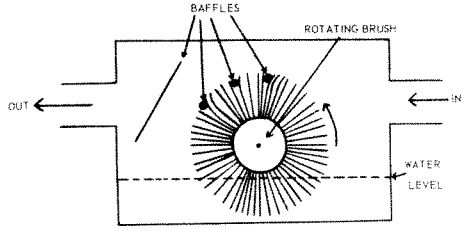

FIG 2. Diagramatic representation of humidifier. Heat both from the motor and an auxiliary rheostat-controlled heating bar is transmitted via the backplate to the water.

motor and also from an auxiliary rheostat-controlled heater which is turned on when more rapid heating of the water is required. While this is a prototype and is not approved for use with flammable anesthetic agents, it is anticipated that the production device will be so constructed as to meet Underwriter's Laboratories requirements for safe use in a hazardous atmosphere.

The high humidity over a wide range of temperatures safeguards against any static electricity problems. Gases from the anesthetic machine travel through the spray of water droplets and are thus exposed to a large water surface area, rapidly becoming heated and humidified. A further baffle close to the exit port causes most of the larger water particles to fall back into the reservoir.

When temperature was measured in the reservoir and at the Y-piece of a standard 101-cm polyethylene anesthetic circuit, a fall of approximately 10° C was found between the humidifier and the Y-piece. Relative humidity (RH) measured* at the Y-piece at 43, 36, and 22° C was 100 percent in all instances.

*Psychrometer, Taylor Instrument Company, Asheville, North Carolina.

The operating room temperature was kept between 20 and 21° C and the temperature at the inlet of the endotracheal tube was kept at approximately 35° C by manual control of the resistor controlling the humidifier heater.

Twenty-five patients, 24 of whom were undergoing neurosurgical procedures, were studied. Of these, 11 patients undergoing craniotomies had their heads draped but instrument stands over the operating table prevented their bodies from being directly covered; 4 patients underwent lumbar laminectomies and were almost completely covered by drapes; 9 patients were operated on in the sitting position and were wrapped in a Gardner antigravity ("G") suit. Though this latter might be considered to provide thermal insulation, our previous experience[3] indicated that its use might limit but not prevent the development of hypothermia. In 8 patients, induced hypotension achieved either by high concentrations of halothane or by trimethaphan infusion was an integral part of the procedure.

Patient ages ranged between 12 and 63 (mean 45) years; 12 were male and 13 female. Operating time ranged from 3½ to 15½ hours, with a mean of just under 9 hours. Inhalation anesthesia using controlled ventilation with halothane-N_2O-O_2 and muscle relaxants as necessary was used in all cases.

Patient temperature was monitored by tympanic (Arbrook Company), esophageal and rectal (Yellow Springs Instrument Company) routes and estimated to the nearest 0.2° C. Only tympanic temperature was monitored in 7 cases, while in the others tympanic plus either esophageal or rectal probes were used.

Four patients served as their own controls, body temperature being monitored throughout but the heated humidifier being introduced only after 2 to 3 hours of operation, after body temperature had already fallen.

RESULTS

All patients were normothermic at the start of anesthesia. After induction and preparation, the mean temperature was 35.7 ± 0.6° C. Fourteen patients (56%) showed an increase in temperature during the procedure, ranging from 0.5 to 2° C (mean 0.6 ± 0.3° C) (table). Five patients (20%) maintained a steady body temperature apart from minor oscillations of less than 0.4° C.

TABLE
Summary of Temperature Changes in 25 Patients Receiving Heated Humidified Anesthetic Gases

	Normotension	Induced hypotension	Total
Temperature ↑	11 (65%)	3 (38%)	14 (56%)
Temperature steady	4 (23%)	1 (12%)	5 (20%)
Temperature ↓	2 (12%)	4 (50%)	6 (24%)

Six patients (24%) showed a decline of between 0.5 and 1.1° C despite the warmed humidification, and additional means of warming was necessary to prevent a further fall in temperature. Warming was achieved by use of a thermal blanket.

Of the 6 cases showing a decline in body temperature, 4 were undergoing induced hypotension with high concentrations of halothane. Considering the 8 patients undergoing induced hypotension, 4 showed a decline in temperature and 3 an increase in temperature.

Of the 4 cases where temperature fell before warmed humidification was introduced, 2 showed a final increase in temperature and in the other 2, the temperature returned to the preoperative level.

All cases are summarized in figure 3.

CASE REPORTS

Case 1.—A 58-year-old woman underwent removal of a posterior fossa tumor in the sitting position. A left tympanic and an esophageal thermal probe were inserted and demonstrated a slight but constant discrepancy, the tympanic probe indicating a temperature of approximately 0.4° C lower than the esophageal probe. During the first 2 hours of anesthesia, a fall of 0.3° C/hr in body temperature occurred (fig 4). This downward trend was reversed when heated humidification was introduced into the anesthetic circuit and an increase in body temperature of almost 0.3° C/hr occurred over the next 4 hours. At the end of 6 hours of anesthesia (the end of operation) the body temperature was approximately 0.5° C higher than the initial temperature.

Case 2.—A 51-year-old woman underwent a craniotomy in the supine position for a pituitary tumor. Tympanic and esophageal probes showed almost identical readings. Heated humidification was used throughout the procedure. From 1120 to 1300 hr, her temperature rose approximately 0.5° C and

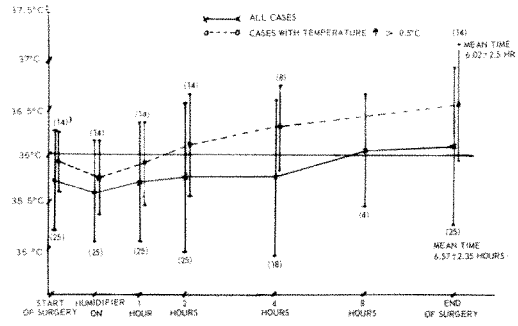

FIG. 3. Mean tympanic temperatures (±SD) related to humidifier time.

then remained constant for 1 hour (fig 5). At 1400 hr, hypotension was induced with halothane, maintaining a systolic pressure of 70 torr for 1 hour, during which time her temperature fell approximately 0.4° C. Normotension was restored at 1500 hr, following which her temperature again gradually rose.

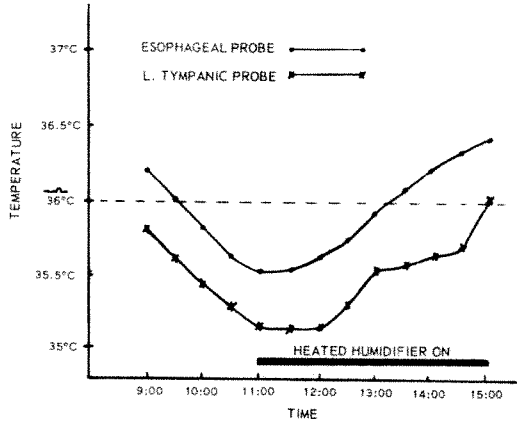

FIG 4. Temperature chart of a 58-year-old woman (case 1) undergoing removal of posterior fossa tumor.

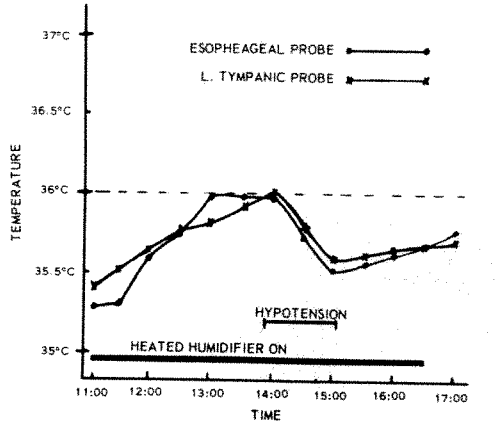

FIG. 5. Temperature chart of a 51-year-old woman (case 2) undergoing craniotomy for pituitary tumor.

No complications in any way referable to the heated humidification occurred in the postoperative period in any patient.

DISCUSSION

The value of humidification of anesthetic gases is still unclear despite the cytologic work of Chalon and colleagues,[7] who have conclusively demonstrated changes in tracheobronchial cells after 1 hour of dry gas anesthesia, although a recent statistically controlled series[9] failed to show any difference in the incidence of postoperative complications. However, a reduction in the incidence of cell decay after 3 hours of anesthesia from 45 percent with dry gases to 1 percent with adequate humidification,[10] the reduction in crusting, and the maintenance of ciliary movement are cogent arguments in favor of humidification.

Excessive addition of water to the tracheobronchial tree may produce harmful effects, including atelectasis and positive water balance, as reported with the use of ultrasonic humidifiers.[11,12] Dery,[13] while agreeing that dry anesthetic gases may be harmful, suggests that the use of a semiclosed circuit with a soda-lime absorber rather than a nonrebreathing circuit provides enough water for adequate humidification.

The prevention of hypothermia during operation is universally agreed to be desirable and the harmful consequences of even moderate falls in temperature are well documented.[14,15] Complications in the early postoperative phase, including cyanosis, respiratory distress, and hypotension, occur more frequently in patients whose body temperature has fallen. Roe and colleagues[14] showed that postoperative O_2 consumption more than doubled when the fall in temperature was between 0.3 and 1.2° C. The increase in O_2 consumption was less than 5 percent in patients whose temperatures did not fall. If the fall was over 1.3° C, the increase in O_2 consumption averaged approximately 40 percent.

Lunn[15] has pointed out the dangers of hypothermia in patients with arterial insufficiency where further vasoconstriction may occur, the almost complete absence of deep vein thrombosis as a complication of surgical procedures in warm operating rooms, and also the danger of vasodilation when the patient's temperature is restored in the recovery room, suddenly exposing an inadequate blood volume. Rashad and Benson[16] pointed out the dangers of prolongation of the effect of depolarizing muscle relaxants and too deep a level of anesthesia, due to low basal metabolism lowering anesthetic requirements.

Commonly, body temperature falls during anesthesia unless the operating room temperature is kept above 21° C. Morris[17] found that 30 percent of his patients' temperatures fell even if the room was kept between 21 and 24° C. Goldberg and Roe[18] reported that 78 percent of their patients showed a fall in temperature; the mean fall was 1.15° C during a 3-to-4-hour procedure. They calculated the average heat loss as 43.5 cal/sq m/hr.

Newman[4] used a warming blanket plus warm IV fluids for patients undergoing vascular surgery. Unwarmed patients aged 50 to 60 in his series, which had a mean operating time of 5½ hours, had a mean fall in temperature of 3.3° C. In those patients who were warmed, the mean temperature rose 0.3° C.

Most investigators report that temperature falls vary directly with the duration of the operative procedure, increased age, intrabody cavity procedures, and the use of air conditioning in the operating room. An association between the magnitude of temperature fall and anesthetic agents has not been conclusive; cutaneous vasodilation and the loss of muscular activity are the main mechanisms of intraoperative temperature fall.

Heated inhalation gases delivered at 30° C and RH 100 percent have been used for temperature control in pediatric surgery.[16] In cases of accidental hypothermia in adults,[19] a Waters canister with added CO_2 was used to produce heat and humidification. That heated humidification can increase body temperature was dramatically shown by the reported occurrence of hyperthermia while using the Emerson postoperative ventilator.[20]

As far back as 1945, experimental investigation showed that if heat is to be applied to the air passages, careful monitoring of airway temperature is mandatory.[21] An inspired gas temperature of up to 41° C is said by Miller[22] to be safely tolerated by the patient. Temperatures above this may cause tracheobronchial edema, as illustrated by a patient inadvertently given heated gases at 43.3° C.[23] Our own study has convinced us that use of a warming humidifier, such as described in the present report, offers distinct advantages, especially during prolonged surgical procedures.

CARDIAC ENZYMES. The enzyme tests most commonly used for the diagnosis of myocardial infarction (SGOT, LDH and CPK) are not specific for the myocardium. However, the MB isoenzyme of creatine kinase is specific for the myocardium. The authors measured total serum enzymes and the MB isoenzyme in patients with suspected acute myocardial infarction as well as in postoperative surgical patients. In patients with myocardial infarction the magnitude of the MB isoenzyme rise was 2 to 3 times greater than that of any other enzyme. The isoenzyme did not increase in postoperative patients which contrasts with the expected rise in SGOT, LDH and CPK after any major surgical procedure. *(Smith AF, Radford D, Wong CP et al: Creatine kinase MB isoenzyme studies in diagnosis of myocardial infarction. A Comparison of the Efficiency of Three Anesthesia Circle Systems

MARILYN HARPER, MD*
EDMOND I. EGER, II, MD†
San Francisco, California‡

Three commonly employed anesthesia circle systems were tested to determine what effect the placement of the inflow port, overflow valve, and inspiratory and expiratory valves, as well as inflow rate, had on the rate of rise of anesthetizing alveolar concentrations of halothane. System efficiency was evaluated on the basis of whether alveolar gases, containing low concentrations of halothane, or fresh and dead-space gases, containing higher concentrations of halothane, were eliminated through the overflow valve. Small potentially significant differences in efficiency were found: greatest efficiency (greatest ejection of alveolar gas) occurred when inspiratory and expiratory valves were close to the endotracheal tube and the overflow valve was immediately distal to the expiratory valve. Increasing inflow rate from 1 to 3 L/min had a large impact on the rate of rise of alveolar halothane concentration. A further increase to 5 L/min had a relatively small effect.

DESPITE its widespread use, the effect of the anesthesia circuit on the development of inspired and alveolar anesthetic concentrations has not been well studied. We previously[1] measured the rate of rise of N_2O during marked hyperventilation considered sufficient to cause equality of inspired and alveolar concentrations. The rate at which the N_2O concentration rose was a function of inflow rate, system volume, and the concentration delivered (concentration effect).[2] We are not aware of any report of a similar study at normal ventilation with N_2O or, more importantly, with a moderately or highly soluble agent.

Theoretic considerations would suggest that the insertion of an anesthetic circuit between inflow and patient may hinder the development of an anesthetizing alveolar anesthetic partial pressure.[3] The circuit contains a volume which must be washed out in order to develop an inspired partial pressure, and hence that volume and the inflow rate both are determinants of the alveolar rate of rise. Furthermore, the inflow rate is important, since it also controls the amount of rebreathing. Rebreathing is of particular importance with more soluble agents, since the alveolar concentrations of such agents will be well below those delivered in the inflow.

Finally, we have suggested from both theoretic calculations[4] and mechanical models[5] that particular arrangements of anesthetic circuits are more efficient, in that some arrangements preferentially eliminate alveolar gas. Less efficient circuits do not distinguish between alveolar and fresh inflowing or dead-space gases, all three being subject to concomitant elimination.

Our recent examination of the above issues in surgical patients ventilated to normal CO_2 levels has given results in agreement with earlier predictions concerning the

Paper received: 11/3/75
Accepted for publication: 1/20/76

importance of inflow rate. We find that system arrangement has little impact on the development of the inspired and alveolar anesthetic concentration, but choice of one arrangement as opposed to another may result in significant conservation of fresh gas and hence a reduction in cost.

METHODS

Thirty-seven healthy (ASA I or II) adult patients who were to undergo elective surgery were selected for study if (1) they agreed to participate; (2) they weighed between 55 and 85 kg, and (3) there was no contraindication to the use of halothane. Premedication consisted of atropine plus barbiturate or diazepam in doses selected by the attending anesthesiologist. Induction was achieved with thiopental and endotracheal intubation facilitated with pancuronium. Ventilation was controlled at a rate of about 10/min and a volume of 10 ml/kg body weight. This ventilatory pattern produced average arterialized venous P_{CO_2} values between 32.7 and 44.4 torr (average for each group), as described below. Nasopharyngeal temperature was measured with either a mercury thermometer or Yellow Springs temperature probe. Average temperatures ranged betwen 35.4 and 36.3° C.

The arrangement of the 3 anesthetic systems selected for study is shown in figure 1. System A (Foregger) has the inspiratory and expiratory valves near the CO_2 absorber, with the inflow between the inspiratory valve and the patient. The overflow (pop-off) is between expiratory valve and absorber. System C (Ohio Medical Products) differs from system A only in that the inflow is between the absorber and the inspiratory valve. System H (Anesthesia Associates) has the inspiratory and expiratory valves placed close to the patient, with the inflow between the absorber and the inspiratory valve. The overflow is between the expiratory valve and absorber and is immediately adjacent to the expiratory valve.

Either a 1, 3, or 5 L/min O_2 inflow rate was chosen and maintained throughout the 60 minutes of study in each patient. Systems A and C were tested at all inflow rates, whereas system H only was tested at the 3 L/min inflow rate. Oxygen was delivered from a flowmeter, previously calibrated against a Collins spirometer. Halothane was added from a temperature-compensated vaporizer (Fluomatic®) at a constant predetermined concentration which, on the average, produced an alveolar concentration close to MAC.[6]

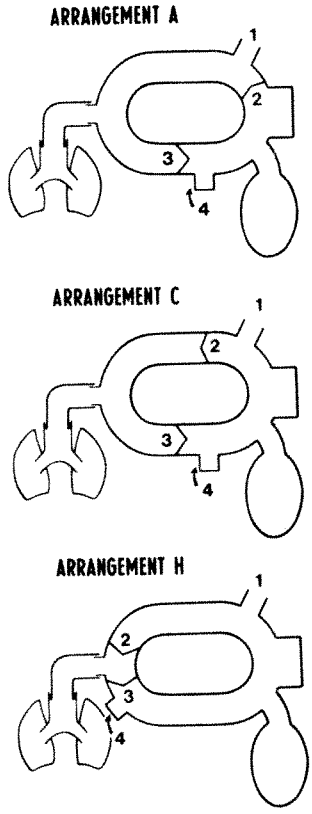

FIG 1. The 3 anesthetic arrangements (systems) described in the text. Numbers indicate system parts: 1 = inflow; 2 = inspiratory valve; 3 = expiratory valve; 4 = overflow (pop-off) valve.

End-tidal, inspired, overflow, and inflow halothane concentrations were measured at 1, 2, 4, 6, 8, and 10 minutes after the start of halothane delivery and every 10 minutes thereafter for a total of 60 minutes. Halothane concentrations were determined with an ultraviolet analyzer, calibrated every 5 to 10 minutes against an internal optical standard. End-tidal samples were taken from a nylon catheter which extended to the tracheal end of the endotracheal tube.

From the halothane concentrations obtained as indicated above, 3 ratios were determined. The first relates the inflowing concentration (F_{INF}) to the inspired concentration (F_I) and defines how rapidly the inspired concentration approaches that delivered. The second relates the alveolar (end-tidal) concentration (F_A) to F_{INF} and defines how rapidly the alveolar concentration approaches that delivered.

The 3rd ratio is the difference between

TABLE 1
Mean Age, Weight, Body Temperature, End-Tidal P_{CO_2}, and Arterialized P_{CO_2} by Groups

System	Flow, L/min	Number of subjects	Age	Weight, kg	Temperature, °C	$P_{E_{CO_2}}$	P_{CO_2}
A	1	5	35 ± 6.5	60.4 ± 3.5	36.3 ± 0.2	32.7 ± 0.9	37.8 ± 1.3
	3	5	41 ± 7.1	67.8 ± 5.4	36.3 ± 0.3	31.4 ± 1.8	35.6 ± 0.1
	5	5	45 ± 9.3	76.0 ± 4.5	35.4 ± 0.2	28.2 ± 0.5	32.7 ± 0.6
C	1	4	43 ± 9.2	64.0 ± 3.3	36.0 ± 0.2	39.9 ± 2.2	44.4 ± 2.7
	3	6	36 ± 5.3	66.8 ± 4.4	36.1 ± 0.2	34.7 ± 1.2	34.2 ± 1.2
	5	5	47 ± 2.9	66.4 ± 1.8	36.1 ± 0.1	31.0 ± 2.1	37.4 ± 1.2
H	3	7	49 ± 5.9	77.4 ± 3.0	35.9 ± 0.1	32.0 ± 2.2	40.9 ± 2.7

the pop-off (F_{PO}) and alveolar concentrations divided by the difference between alveolar and inspired concentrations; this defines the proportion of the gases popped-off which contain alveolar as opposed to inspired gas: a smaller ratio indicates a relatively greater contribution of alveolar gas. A value of zero would indicate that the popped-off gases consisted entirely of alveolar gas; a value of 1 would indicate that the popped-off gas concentration equalled the inspired concentration.

An arterialized venous blood sample was drawn at about 30 minutes and analyzed for CO_2, pH, and O_2 with electrodes and corrected for body temperature. Samples were not accepted if the P_{VO_2} did not indicate a saturation exceeding 90 percent. At the same time, we obtained an end-tidal sample for CO_2 analysis (infrared).

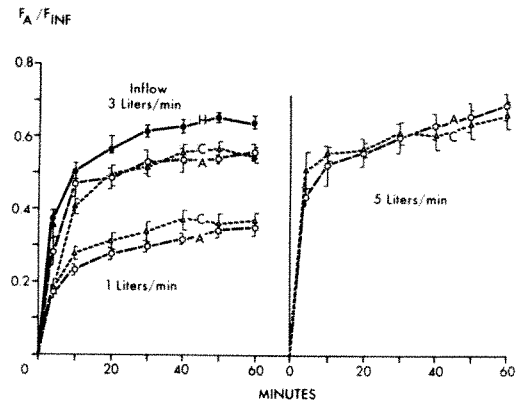

FIG 2. The rate of rise of alveolar concentration toward inflow concentration (F_A/F_{INF}) increases with higher flow rates. Low flow rates (1 L/min) prevent development of high alveolar concentrations for 1 hour, while there are only small differences between 3 L/min and 5 L/min after 20 minutes. There are no differences between systems A and C; system H achieves a slightly higher alveolar concentration.

RESULTS

The ages, weights, body temperatures, and end-tidal and arterialized P_{CO_2} values were similar among groups (table 1). As anticipated, an increase in inflow rate accelerated the inspired and alveolar anesthetic rate of rise for all systems (table 2, fig 2 and 3). The ratio $(F_{PO}-F_A)/(F_I-F_A)$ varied between systems, being highest in A and lowest in H (table 2, fig 4). No consistent relationship of this ratio to flow rate was found.

DISCUSSION

As anticipated, inspired and alveolar concentrations rose more rapidly at higher inflow rates. This is illustrated most dramatically during the first 10 minutes (fig 5). After 10 minutes, the curves for all systems tend to flatten, but differences between levels at different inflow rates are sustained (fig 2 and 3). The greatest effect of inflow is seen between the 1 and 3 L/min graphs: the difference between 3 and 5 L/min is relatively small. The reason for this is apparent from the figures giving the rate of rise of the inspired concentration. At 3 L/min, these already have reached 74 to 82 percent of that in the inflowing gas by 20 minutes. Thus, any further increase in inspired concentration that might be achieved by increasing the inflow rate would be limited.

The above describes the effect for halothane, a moderately soluble gas. A more

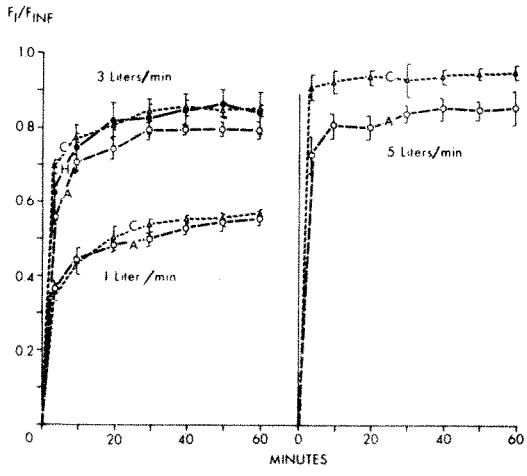

FIG 3. The inspired-to-inflow concentration ratio (F_I/F_{INF}) increases more rapidly with increasing flow rates. Both 5 L/min and 3 L/min flow rates achieve high inspired concentrations within 10 minutes. The inspired concentration at a 1 L/min inflow rate rises slowly and remains low for 1 hour. There are only slight differences between systems.

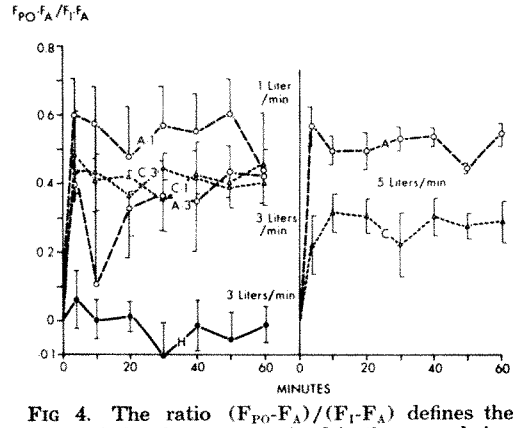

FIG 4. The ratio $(F_{PO}-F_A)/(F_I-F_A)$ defines the amount of alveolar gas contained in the gases being popped-off. A ratio of 0 would indicate only alveolar gases being evacuated and conservation of gases containing higher concentrations of anesthetic. System C is slightly more efficient that A at 1 L/min and 5 L/min, while system H is most efficient.

soluble gas such as methoxyflurane or diethyl ether might be more affected by the increase from 3 to 5 L/min, since uptake and hence rebreathing would have a greater effect on the inspired concentration.[3]

At any given flow rate, the rise of alveolar or inspired concentration to the inflow concentration tended to be slowest with system A and fastest with system H. The overflow valve position in system H permitted loss of primarily alveolar gas, thereby retaining fresh inflowing gas for rebreathing.[5] Evidence for this is seen in the low $(F_{PO}-F_A)/(F_I-F_A)$ values for system H (table 2). Although the differences between systems A and C in the above ratio are not as consistent, in general the ratio at any given inflow rate is lower with C. This accords with the prediction made in an earlier report[1] that suggested that system C conserved fresh inflow gas while system A permitted its loss through the pop-off valve.

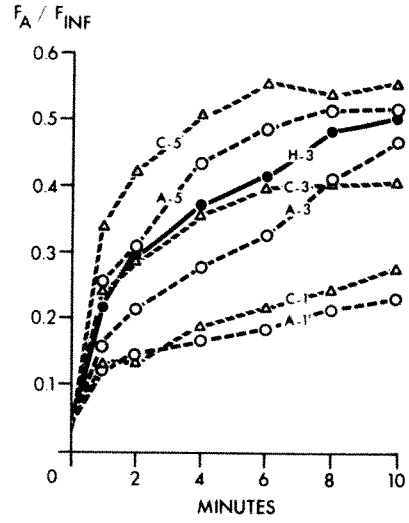

FIG 5. The rate of rise of alveolar anesthetic concentration is most rapid during the first 10 minutes of administration, and is influenced primarily by inflow rate. There is little difference between systems at any given inflow rate. Symbols along the curves refer to system and inflow rate.

Although the differences between the systems are consistent with our previous predictions,[3] they are somewhat smaller than we suggested there and are only of modest clinical significance. For halothane anesthesia, little economic gain may be realized by the choice of one system as opposed to another. A small but significant economic gain might accrue to the use of system H if the anesthetic were enflurane.* The difference between enflurane and halothane lies in the higher cost and lower potency of enflurane. Unfortunately, our data cannot be applied directly to enflurane because of the differences between enflurane and halothane solubility and uptake.

Of greater clinical and economic importance is the inflow rate. It would appear that inflow rates need not exceed 3 L/min after the first 10 minutes of anesthesia in order to sustain an inspired halothane concentration close to that delivered in the inflow.

*See Appendix.

APPENDIX

The data in table 2 for $(F_{EO}-F_A)/(F_I-F_A)$ indicate that, for system A or C, about half of the gases popped-off at a 3 L/min inflow are unabsorbed inspired gases which must be replaced. With the H system, only alveolar gas is eliminated and all inspired gas is conserved. On the average, the inspired concentration is about 50 percent higher than the alveolar concentration. If these data were applied to an alveolar enflurane concentration of 1.5 percent (a concentration giving a moderate level of anesthesia with 50 to 60 percent N_2O) they would predict a required average inspired concentration of 2.25 percent. With system A or C, half of this would be wasted but with H it would be conserved.

At a 3 L/min inflow, the wastage with A and C would equal $0.5 \times (0.0225 - 0.015) \times 3000 \times 60$, or 675 ml/hr of enflurane vapor. Since 1 ml of liquid enflurane produces 200 ml of vapor, this represents a loss of 3.38 ml liquid; each liquid ml costs approximately \$0.25, giving an hourly cost of \$0.84. Presuming 5 hours of anesthetic administration per day and 230 working days, the annual loss would be \$970, which would be regained by substituting system H for A or C. However, as noted in the discussion, our data with halothane cannot be applied directly to enflurane because of the difference in solubility.

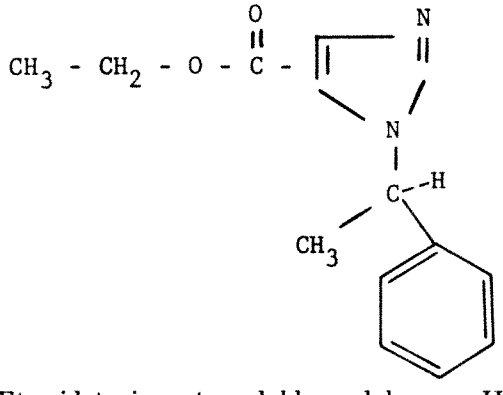
ENTERAL OXYGEN. The authors evaluated the effect of intestinal oxygen, nitrogen or carbon dioxide on the electrical activity of the stomach and intestine. The gases were injected into the intestinal lumen at a rate of 5 to 7 ml/min. Electrical activity increased with enteral oxygen but not nitrogen or carbon dioxide. Pharmacologic blockade of alpha and beta effector sites did not alter the response to enteral oxygen. The mechanism for this response is not known but unlikely explanations include increased intestinal pressure, decreased pH or reflex response. Earlier work has shown that enteral oxygen modifies the reduction in splanchnic blood flow associated with anesthesia and operation. *(Gelman S, Paz M, Levy E: Influence of enteral oxygen administration on the slow electrical activity of the intestine and stomach. Arch Surg 111: 566-574, 1976)*

Clinical Use of Etomidate for Anesthesia Induction: A Preliminary Report

ROBERT J. FRAGEN, MD*
NANCY CALDWELL, CRNA†
EDWARD A. BRUNNER, MD, PhD‡
Chicago, Illinois§

Etomidate (0.3 mg/kg) and thiopental (4 mg/kg) were administered IV for induction of general anesthesia, comparing heart rate, blood pressure, respiration, and side effects. No significant difference between the drugs was found in the circulatory parameters, but respiration was more depressed by thiopental. A high incidence of the side effects of myoclonia and pain on injection was seen with etomidate. The incidence of side effects was not affected by speed of injection or type of premedication. Mechanisms to reduce the incidence of side effects are needed for etomidate to become a useful induction agent.

ETOMIDATE, first synthesized in 1972, is (R-(+)-ethyl-1-(1-phenylethyl)-1H-imidazole-5-carboxylate sulfate. It is a new, potent, short-acting, and safe IV hypnotic with the following structural formula:



Etomidate is water-soluble and has a pH of 3.4. It is metabolized in the liver by hydrolysis of the ester group. Seventy-five percent of a single dose is excreted by the kidney in 24 hours and 13 percent is found in the feces. It is a pure hypnotic and is without analgesic activity.[1] Animal experiments and human studies have shown that etomidate causes no organ toxicity nor teratogenicity and that it has fewer side effects on the cardiovascular and respiratory systems than other short-acting IV induction agents.[1-4]

On the basis of these reports, etomidate should be expected to be a good IV induction agent for general anesthesia. It acts rapidly (one circulation time), and the duration of action of a single dose is between 4 and 10 minutes. This duration can be prolonged by increasing the dose or administering the drug as a constant infusion.[1] Etomidate would seem particularly beneficial for outpatients and patients with heart disease. However, 2 side effects have been prominent with etomidate: pain on injection

and myoclonia.* Other stimulatory effects, such as nystagmus, hypertonus, coughing, and hiccup,* have been seen with etomidate. These side effects can also be seen with barbiturates such as thiopental and methohexital.

A randomized, controlled study was undertaken to compare etomidate with thiopental with regard to blood pressure, heart rate, respiration, and side effects.

METHODS

Sixty ASA physical status I, II, and III adult surgical patients were admitted to the study (after giving informed consent). They were divided into 4 groups of 15 patients each, homogeneous for age, weight, height, and ASA status (table 1). Groups I and II received etomidate (0.3 mg/kg body weight) from a freshly prepared solution of 1.5 mg/ml lyophilized etomidate in sterile water. Group I received the injection over 30 seconds and group II over 60 seconds. Groups III and IV received 4 mg/kg of 2.5 percent sodium thiopental. Group III received the injection over 30 seconds and group IV over 60 seconds. All injections were given into the injection port of a rapidly running IV infusion of 5 percent dextrose in lactated Ringer's solution.

One-third of the patients received atropine (0.5 mg IM) 15 to 45 minutes before induction; one-third received diazepam (10 mg) and atropine (0.5 mg IM) 30 to 45 minutes before induction, and one-third received fentanyl (2 ml) and atropine (0.5 mg IM) 15 to 30 minutes before induction. Blood pressure was taken by the Riva-Rocci method, and heart rate was counted by the radial, brachial, or carotid pulse. All patients were monitored with a Tektronix® 410 cardioscope in the operating room. Blood pressure and heart rate were recorded before and 3 minutes after premdication, 3 minutes before and 1 to 2 minutes after the hypnotic, and then every 5 minutes during the course of anesthesia.

Respiratory rate was counted and the depth of respiration was observed 3 minutes before and between 1 to 2 minutes after etomidate or thiopental. The patient was observed for side effects from the onset of injection until 2 minutes after hypnotic injection. No other medications were allowed during this time except for O_2 by face mask, if necessary. Any observed changes, therefore, could be ascribed to the hypnotic. After 2 minutes, there was no restriction on the choice of anesthetic agents or technics of general anesthesia.

All patients stayed in the recovery room for the usual length of time and no restrictions were placed upon medications used there. All patients were seen 24 hours later, and, when possible, again 48 hours later, and were inspected for phlebitis at the injection site. They were also asked to rate the experience of induction of general anesthesia as good, satisfactory, or bad. An investigator (R.F.) also rated the injection. When blood pressure changes of 25 percent above or below control occurred, hypertension or hypotension were recorded as present. A similar percentage of change in heart

TABLE 1

Demographic Data

Group	I Etomidate, 0.3 mg/kg 30 sec	II Etomidate, 0.3 mg/kg 60 sec	III Thiopental, 4 mg/kg 30 sec	IV Thiopental, 4 mg/kg 60 sec
Age (average), yr	41.67	41.87	39.80	43.53
Weight (average), kg	68.93	62.13	67.93	68.47
Height (average), cm	167.27	163.80	171	169.73
Sex: Female (n)	11	12	9	8
Male (n)	4	3	6	7
ASA physical status (n)				
I	7	9	8	6
II	7	6	6	8
III	1	0	1	1

rate (25%) was considered as indicating tachycardia or bradycardia. Data were submitted to chi-square analysis.

RESULTS

There were no significant changes in blood pressure or heart rate in any group. No arrhythmias were observed during the 2-minute observation period.

Respiration rate and depth were stimulated in 6 etomidate patients, 5 in group I and 1 in group II, but were not stimulated in any thiopental patients. Either hypoventilation or apnea occurred in 15/30 patients in groups III and IV and in only 3 patients in group I. All patients in group II maintained respiration near normal.

Myoclonia, classified as mild or severe, was seen in both etomidate groups. In group I, 8 patients showed mild and 3 patients severe myoclonia. In group II, 10/15 patients had mild and none had severe myoclonia. No myoclonia was seen in groups III or IV.

Pain at the injection site occurred in 9 patients in group I, 6 patients in group II, and 1 patient in group III. In group I, pain occurred in 7/11 patients who had the IV catheter inserted in a hand or forearm vein and in 2/4 patients who had the IV in an antecubital vein. In group II, pain was experienced in 4/7 patients who had a hand or forearm IV infusion and in 2/8 with an antecubital IV infusion.

For etomidate patients, pain at the injection site occurred in 5/10 patients who received atropine only for premedication, in 6/10 who received diazepam and atropine, and in 4/10 who received fentanyl and atropine.

Hyperventilation was seen in 3/10 etomidate patients receiving atropine only and in 3/10 etomidate patients given diazepam and atropine. No patients receiving fentanyl premedication hyperventilated, and 2/3 patients who hypoventilated or were apneic after etomidate were in the fentanyl premedication group.

Nystagmus was seen in 6/30 etomidate patients ($p<0.01$), 3 each in groups I and II. Four of these patients received only atropine for premedication and 2 received diazepam and atropine. Other side effects observed are noted in table 2.

No adverse experiences occurred during maintenance of anesthesia or in the recovery room in any patient, nor was any instance of phlebitis observed.

TABLE 2

Miscellaneous Side Effects

Group / Side effect	Etomidate I 30 sec	Etomidate II 60 sec	Thiopental III 30 sec	Thiopental IV 60 sec
Coughing	1	0	0	1
Salivation	1	0	0	0
Retching	1	0	0	1
Hiccup	2	0	0	1

TABLE 3

Rating of Hypnotic by Patient and Investigation

Reaction	Good	Satisfactory	Bad
Group I Etomidate 0.3 mg/kg (30 sec)			
Patient	12	3	0
Investigator	7	2	5
Group II Etomidate 0.3 mg/kg (60 sec)			
Patient	10	4	1
Investigator	7	6	2
Group III Thiopental 4 mg/kg (30 sec)			
Patient	11	4	0
Investigator	15	0	0
Group IV Thiopental 4 mg/kg (60 sec)			
Patient	11	4	0
Investigator	14	1	0

Hypnotics were rated somewhat differently by the patients and the investigator (table 3).

DISCUSSION

All patients in the study were asleep within 1 minute of the injection of either hypnotic, and none showed any untoward effects on blood pressure or heart rate. However, we might not expect adverse cardiovascular effects in patients in ASA status I and II, nor in the 3 ASA status III patients who were under 50 years of age and were normovolemic. Since previously reported experiments[2-4] were performed on healthy

patients or dogs, etomidate should be tested in patients with known coronary artery and/or myocardial disease, to determine whether cardiac function can be maintained without increasing myocardial O_2 requirements.

Since anesthesiologists are skilled at ventilating patients and maintaining patent airways, one could question whether respiratory depression of short duration is undesirable. There was a significantly higher incidence of respiratory depression with thiopental than with etomidate ($p<0.001$). When respiration changed after etomidate, twice as many patients hyperventilated as hypoventilated; furthermore, hypoventilation occurred in 2 patients and apnea in 1. Thus, etomidate should not be used for patients in whom it may be important to maintain adequate spontaneous ventilation.

For a hypnotic drug to be useful while lacking adverse cardiovascular and respiratory side effects, it must also not have other untoward side effects. Pain on injection and myoclonia are known side effects of etomidate. In Admiraal's series of 1000 patients, myoclonia (slight, 6.7%, and severe, 4.2%) and pain on injection (11.2%) occurred. In the present study, the incidence of these side effects was higher—myoclonia, 70 percent (slight, 60%; severe, 10%) and pain on injection, 50 percent. It was thought that narcotic premedication would reduce the incidence of pain on injection and that diazepam would reduce the incidence of myoclonia, but neither happened.

The speed of injection was also thought to affect the incidence of side effects. It was noted that no severe myoclonia occurred with the 60-second injection time, but the overall incidence of myoclonia was unrelated to speed of injection. Pain on injection was less frequent with slower injection, but more patients in this group had the IV infusion placed in an antecubital vein. The diameter of the vein used for injection appears to be a more important factor than speed of injection, but the combination of slow injection and the use of a large vein appeared best. The incidence of pain on injection might also be reduced with an etomidate solution buffered to a more normal pH.

Since low-dose premedication was used in this study, it would be interesting to see what more premedication would do to the incidence of myoclonia and pain on injection. The cause of the myoclonia has not been identified, so a rational approach to reducing its incidence is not available. These side effects, although frequent, were of short duration and did not significantly affect the rating the patients gave etomidate. However, the investigator rated the induction as bad when severe myoclonia or severe pain on injection occurred.

The present study showed generally similar but slightly different results from those recently reported by Gooding and Corssen.[5]

The Anesthetic Effect of Oxygen

RAYMOND A. SMITH, DPhil*
WILLIAM D. M. PATON, DM, FRS, FRCP†

Low pressures of O_2 (3 to 5 atm) cause convulsions in mice but higher pressures produce a state very similar to anesthesia. The authors estimated the anesthetic potency of O_2 in mice which were exposed to either N_2O alone, N_2O + NaBr, or O_2 + NaBr. From the dose-response curves, ED_{50}s were derived for the gases. The ED_{50} for N_2O alone was 1.50 ± 0.036 atm (n = 12) and 1.11 ± 0.041 atm (n = 12) in the presence of NaBr, a reduction of 25 percent. The O_2 ED_{50} with NaBr was 3.91 ± 0.077 atm (n = 12). After correction for the NaBr, the ED_{50} of O_2 is estimated at 5.3 atm. This is lower than predicted from the lipid solubility of O_2.

IT IS well known that high pressures of O_2 between 3 and 5 atmospheres (atm) cause convulsions in both mice and men.[1,2] At pressures above 10 atm, the convulsant effect of O_2 in mice and rats appears to be less dominant; the convulsions are fewer and less vigorous, and the mice appear to enter a depressed state resembling that of anesthetized animals. If mice are pretreated with sodium bromide (NaBr) (800 mg/kg) the convulsant period can be eliminated, and the animals pass directly into a state of peaceful anesthesia.[3]

An interesting theoretic point arises out of this observation. Since the lipid solubility of O_2 is about 1/10 that of N_2O (Ostwald solubility coefficient in olive oil at 37° C of O_2 is 0.132, and of N_2O is 1.4) the anesthetic partial pressure of O_2, barring other effects, would be expected to be about 10 times that of N_2O (ED_{50}=1.5 atm), or 15 atm in mice. We therefore decided to estimate the potency of O_2 as an anesthetic agent and to see how well this potency correlated with its lipid solubility.

In order to test mice under high pressures of O_2, the O_2-induced convulsions must be abolished or at least heavily suppressed. Many drugs have been tested for such suppressant action. Amongst those found to have some utility are diethazine, mephenesin, trimethadione, paramethadione, chlorpromazine, and NaBr.[3] Some investigators have used sulphydryl-group-containing compounds such as glutathione, cysteine, and thiourea to provide a reducing environment which may protect vulnerable sulphydryl groups in, for example, metabolic enzymes; others have used metabolic agents, in the belief that normal cellular respiration and oxidative phosphorylation are impaired and that agents such as succinate, glutamate, glucose, or gamma-aminobutyric acid (GABA) might stimulate adenosine triphosphate production to keep up with cellular demands.[4,5]

Using these approaches, Currie's group[4] showed glutathione or cysteine combined with sodium succinate to be the most effective in postponing convulsions in dogs, although these are less effective and more variable in small rodents. Of the other drugs tested, bromide was protective at high pressures of O_2, with the least evidence of depression and, since its rate of excretion is

very slow, a constant drug level may be expected over a long period. We decided to determine first the degree of depression caused by a bromide alone and then to use a bromide to protect mice against convulsions during the determination of the O_2 anesthetic effect.

METHODS

First we determined the partial pressure of N_2O alone required to abolish the righting reflex in half the animals tested by a rolling stimulus (the median effective dose, or ED_{50}). We used male albino mice from CD Tuck #1 stock, previously used in this laboratory for the determination of anesthetic potencies. Mice were placed individually in 300-ml stainless-steel pressure chambers equipped with close-fitting soda-lime-filled CO_2 scrubbers, which were slid up and down the chamber at regular intervals during the course of an experiment. The chambers were flushed with O_2 for 2 minutes, sealed, and then N_2O was admitted to the desired partial pressure.

The chambers were placed in a water bath maintained at 30° C, from which they were removed after an equilibration period of 15 minutes to make the test. Rotation of the chambers at 4 rpm for a total of 5 revolutions provided the stimulus. Response was scored as follows: animals which fell onto their sides and were themselves rolled through 360° twice or more during the 5-revolution sequence were assigned scores of 0. Those remaining upright or falling only once were assigned scores of 1. The resulting quantal data enabled construction of a dose-response curve from which the ED_{50} was determined, using a logit transformation by the method of Waud.[6]

Second, we determined the partial pressure of N_2O required to eliminate the righting reflex in other mice treated with the bromide. NaBr in an 8 percent aqueous solution was injected IP at a dose of 0.8 mg/gm 45 minutes before testing. Twenty-five minutes after injection, these mice were placed in the chambers, flushed with O_2 and N_2O introduced to the desired partial pressure 30 minutes after the injection. The mice were tested and results analyzed as before.

Last, the partial pressure of O_2 required to eliminate the righting reflex was determined in a 3rd group of mice. These mice were treated with the same dose of NaBr as above and after 25 minutes were placed in the chambers and flushed with O_2. O_2 was admitted to the desired pressure 30 minutes after injection and the animals were tested 15 minutes later. Responses, dose-response curves, and ED_{50} were determined.

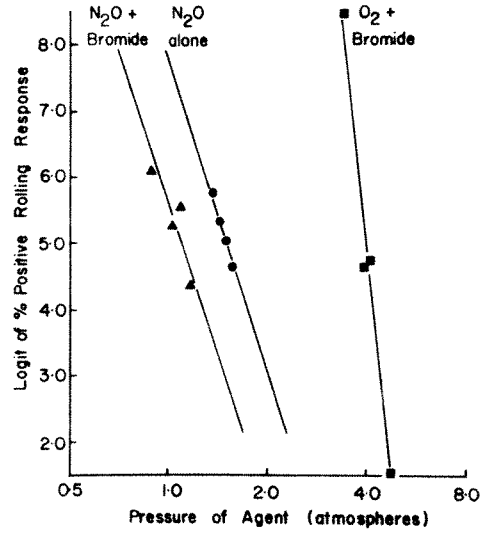

FIGURE. Dose response curves • N_2O alone. ▲ N_2O + 0.8 mg/gm NaBr. ■ O_2 + 0.8 mg/gm NaBr.

RESULTS

The 3 dose-response curves are shown in the figure, in which the logit of the percent positive response is plotted against the dose on a logarithmic scale. The reduction in the required N_2O partial pressure caused by the bromide pretreatment can be clearly seen. The ED_{50} values in gauge pressures above 1 atm of O_2 were: N_2O alone, 1.50 ± 0.036 atm (n = 12); N_2O + NaBr, 1.11 ± 0.041 atm (n = 12; and O_2 + NaBr, 3.91 ± 0.077 atm (n = 12). The dose of NaBr used reduced the N_2O ED_{50} by 26 percent of its normal value. It is also evident that the slope of the O_2 dose-response curve is somewhat steeper than that for N_2O, either with or without NaBr.

If both NaBr and N_2O and NaBr and O_2 act independently and additively, then allowing for the effect of the bromide, the O_2 ED_{50} would be 5.3 atm gauge pressure. This figure may be compared with ED_{50} values for other agents in the presence of 1 atm of O_2. Although the absolute dose of O_2 is 6.3 atm, it must be remembered that 1 atm of O_2 is almost always present in the determinations of anesthetic potency of other agents in mice.

DISCUSSION

The finding of a 25 percent contribution from NaBr to the anesthesia produced by N_2O is not surprising in view of the long history of the use of bromides as a depressant to control epileptiform convulsions. Although bromism is now rare and anesthesia during bromide intoxication unlikely, it is worth noting that the bromide can itself make a significant contribution to the total anesthetic effect.

The estimated requirement for O_2 anesthesia is less than half that expected on the basis of its lipid solubility. Two effects could contribute to alter the true requirement of O_2 for anesthesia. First the metabolic removal of O_2 from solution rather than from oxyhemoglobin would tend to lower the actual tension of dissolved O_2 in the brain leading to an overestimation of the required O_2 tension for anesthesia. Second, cerebral CO_2 tension and tissue acidity will tend to increase due to the absence of reduced hemoglobin and thus impair removal of CO_2. The degree of this latter effect is probably negligible, but would tend to underestimate the true O_2 tension for anesthesia.

A possible explanation of the greater-than-predicted potency of O_2 is that NaBr is incapable of removing completely the deleterious effects of high-pressure O_2. Since the convulsant properties of O_2 are probably mediated through the inhibition of synthesis or reduction of the levels of metabolites such as GABA,[7] it is unlikely that NaBr acts reciprocally to restore or maintain these levels. In other words, the convulsant properties of O_2 and the protective properties of NaBr are probably mediated via different mechanisms.

The NaBr may confer a certain amount of protection, by virtue of its depressant effects, against increased neuronal activity, but beyond that amount, convulsions will prevail, although in an attenuated form. In this case, the rolling response test may be unable to differentiate between the prostration following an attenuated convulsion and that associated with anesthesia. That we are indeed observing either a different mechanism of depression or even a different phenomenon with O_2 is suggested by the steeper dose-response curve compared with N_2O. The interaction of the stimulatory effects of O_2 may indicate that our assumptions concerning additivity and independence of action of NaBr and O_2 or N_2O are questionable.

Case History Number 92: Prolonged Apnea After Succinylcholine in a Dental Outpatient

RICHARD G. McLAREN, MB*
EMERSON A. MOFFITT, MD†
Halifax, Canada‡

A 28-YEAR-OLD man, 185 cm tall and weighing 77.3 kg, was admitted as an outpatient for dental extractions under general anesthesia. There were no positive findings in his history; he had had an uneventful tonsillectomy as a child, details on the anesthetic are not known but it seems highly unlikely that he received succinylcholine (SCh). On admission, all physical and laboratory findings, including hemoglobin and urinalysis, were within normal limits.

He came to the operating room unpremedicated, and after atropine (0.6 mg) IV, anesthesia was induced with sodium thiopental (350 mg). Succinylcholine (80 mg) was given to facilitate nasotracheal intubation. Anesthesia was maintained with halothane-N_2O-O_2. Initially, he was ventilated manually, but apnea persisted following the SCh despite CO_2 challenge, obtained by hypoventilation and increasing the inspired concentration. Accordingly, mechanical ventilation was instituted. At no time were there untoward changes in his pulse and blood pressure; the operation proceeded uneventfully.

At the end of operation, he was transferred to the recovery room with the endotracheal tube in place, under controlled manual ventilation. Spontaneous respiratory activity returned after arrival in the recovery room, approximately 60 minutes after the SCh injection. The patient's minute volume increased to 5 L/min and he began coughing on the endotracheal tube. Peripheral muscle tone was still clinically reduced, but he was conscious and alert and was therefore extubated. A blood sample was taken for pseudocholinesterase activity and phenotyping. He was discharged home 2 hours postoperatively with no residual effects.

The cholinesterase estimation, by the King modification of the Kalow-Lindsay method,* showed pseudocholinesterase, 588 mμ/ml (normal 620 to 1370 mμ/ml), dibucaine 18, fluoride 21, chloride 55. These results indicate that the patient is an atypical homozygote for cholinesterase, an E_1^a E_1^a phenotype. He is thus invariably at risk regarding SCh apnea and has been so advised. Unfortunately, surviving members of the patient's family are not available for phenotyping.

Comment

EMERSON A. MOFFITT, MD

Soon after SCh began to be used clinically, it was found that prolonged apnea, after a small dose, occurred in a small proportion of patients. The causal relation to low serum levels of cholinesterase was brought out between 1955 and 1960 by Dr. Walter Kalow of the University of Toronto. Since then, more work on this subject has been done by many investigators, among them Dr. King at the Royal Infirmary, Glasgow.

Succinylcholine apnea can be easily managed by artificial ventilation. But it still occurs unexpectedly, as seen here in a dental outpatient. When it does, phenotyping of the patient and family should be done, that they may alert the anesthesiologist prior to future anesthetic procedures.

The pharmacologic properties of succinylcholine were first described in 1906,[1] but its value as a short-acting muscle relaxant was not realized until 1949.[2] Since then, many cases similar to this have been described. It provides a timely reminder that since it is well understood in modern anesthetic practice, this phenomenon does not represent a major hazard to the patient. It is, however, a legitimate cause for concern, and may demand prolonged intensive attention.

This patient did not exhibit spontaneous respiratory activity until approximately 60 minutes after the SCh injection. The apneic response is due to an alteration in the enzyme molecule which results in the drug not being hydrolyzed as rapidly as normally and thereby prolonging the effect. This molecular change carries only a pharmacologic, not a physiologic, penalty.

Before discussing the relationship between enzyme levels and the length of the apneic episode, we would like to stress the need for adherence to international agreements relating to enzyme nomenclature. In human tissues there are 2 enzymes which hydrolyze choline esters.[3] Several terms have been used for the enzyme which predominates in nerve tissue and is also present in erythrocytes, including "specific," "true," "aceto," or "e-type" cholinesterase. The liver-synthesized enzyme found in blood serum has been called "nonspecific," "pseudo," "butyro," or "s-type" cholinesterase.

Such a proliferation of names has served to confuse. The modern nomenclature, while recognizing that these hydrolases have overlapping substrate specificities, acknowledges that the nerve and erythrocyte enzyme directs its specificity toward acetyl esters and is called acetylcholinesterase (E.C.3.1.1.7, acetyl choline acetyl-hydrolase). The serum enzyme of interest in this case report directs its specificity toward choline esters and is correctly called cholinesterase (E.C.3.1.1.8, acylcholine acyl-hydrolase).

Apart from the confusing biochemical terminology, the multiplicity of methods and reference values with which anesthesiologists have been bombarded, a major problem has been in attempting to correlate the sensitivity of the patient with the reported cholinesterase activity and inhibitor numbers. The present "state of the art" indicates that 50 percent of cases of SCh apnea cannot be predicted[4,5] and occur in individuals who are homozygotes or heterozygotes for the usual enzyme ($E_1^uE_1^u$; $E_1^uE_1^s$; $E_1^uE_1^a$; $E_1^uE_1^f$). A screening procedure to cover all patients being served by the surgical services in a 3,000,000 population area would reveal 1 patient every 10 days with a predictably sensitive phenotype. Unfortunately, during the same period 1 unpredictable SCh apnea would have occurred.[6] This is not the basis for a satisfactory screening program, particularly when modern anesthetic practice can handle the apneic problem so well. There is no significant morbidity or mortality directly attributable to SCh apnea which

requires to be balanced against a limited success rate for screening.

A linear relationship does not exist between reported cholinesterase activity and sensitivity in individuals of predictable sensitivity. As a generalization, it is true that the lower the cholinesterase activity and dibucaine and fluoride numbers, the more prolonged the apneic response to succinylcholine. It is necessary to consider the biochemical procedures in use in order to understand why this relationship is not invariably present.

The assay procedure for cholinesterase activity reported in this case was that of Kalow and Lindsay[7] modified by King[8] and measured at 25° C. There is a wide overlap of activities from all phenotypes, and a number of SCh-sensitive people have normal cholinesterase activities. When the same procedure is carried out at 37° C, the distribution of activities for the usual homozygotes shows no significant changes. However, the activities of the SCh-sensitive phenotypes is substantially reduced and none remain in the normal range. This indicates that a valid assay of cholinesterase activity can be carried out only at 37° C. Such an assay shows a good correlation between cholinesterase activity and patient sensitivity.

However, it has been shown[9] that accurate phenotyping requires at least two inhibitor numbers, of which one must be fluoride. The phenotype discrimination of dibucaine can be retained at 37° C, but no manipulation of substrate and inhibitor concentrations preserves the discriminatory ability of fluoride at 37° C. On balance, we believe that it is better to be able to phenotype precisely and, hopefully, avoid future problems for the patient and his family, rather than to have the enzyme activity correlate with the patient sensitivity after the event has occurred.

Little attention appears to have been paid to the effects of substrate and temperature on the predictive value of the test. It has already been pointed out[10] that in an official selected method of the American Association of Clinical Chemists,[11] the combination of the substrate propionylthiocholine and a reaction temperature of 37° C results in poor phenotype discrimination. A recent report[12] has supported aspects of this earlier observation.

It is also indicated in the present case report that phenotyping of the patient's family is desirable. While we do not consider population screening to be a worthwhile exercise, we do agree strongly that phenotyping should be offered to close blood relatives of any patient who has had an SCh apnea. Sensitivity cards can then be issued to all individuals of the 4 phenotypes invariably at risk: $E_1^aE_1^a$, $E_1^aE_1^f$, $E_1^fE_1^f$, and $E_1^sE_1^s$.

Not enough attention generally seems to be paid to the necessity of assuring the patient and his family that current knowledge knows of no other genetic problems or drug sensitivities associated with these phenotypes. Patients are also reassured by the knowledge that the existence of other muscle relaxants means that any future operations they may require will not be a major departure from normal anesthetic procedure.

A Precordial ECG Lead for Chest Operations

BRIAN DALTON, MD*

THE limitations of the standard ECG limb leads in detecting myocardial ischemia have led to the adoption of various left precordial leads (V_4, V_5, CS_5, or CM_2) in stress testing of coronary heart disease patients.[1] During anesthesia in such patients, tachycardia, hypertension, excessive myocardial contractility, hypotension, and hypoxia may invoke myocardial distress. Use of a precordial lead to detect myocardial ischemia does not appear to be widely practiced. Objections include prior skin trauma and, in thoracic operations, concern about proximity to the sterile area.

A sterile technic has been used in over 1500 cardiac operations performed through a median sternotomy. After completion of the preoperative bacteriocidal preparation of the skin, a sterile all-metal spinal needle is inserted in the V_4 or V_5 area. One end of a sterile 15-meter-long insulated wire with alligator clips at either end is attached to the needle hub (fig 1). The needle and adjacent wire are secured to the chest with sterile adhesive sheet plastic and sterile draping is completed. The free end of the insulated wire is connected to the precordial exploring lead of a conventionally applied ECG cable.

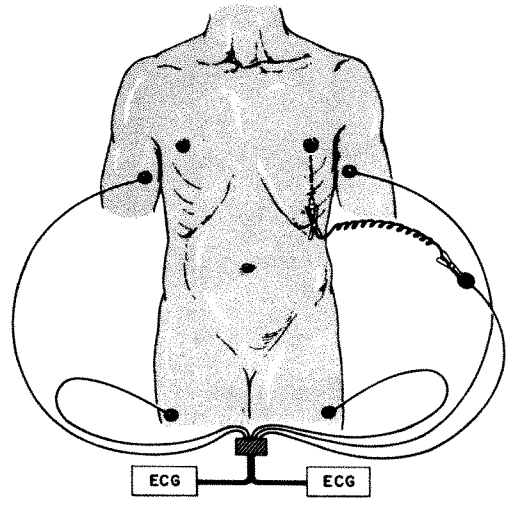

FIG 1. Schema of sterile needle and wire connected to the precordial (exporing) electrode and 2 electrocardiographs.

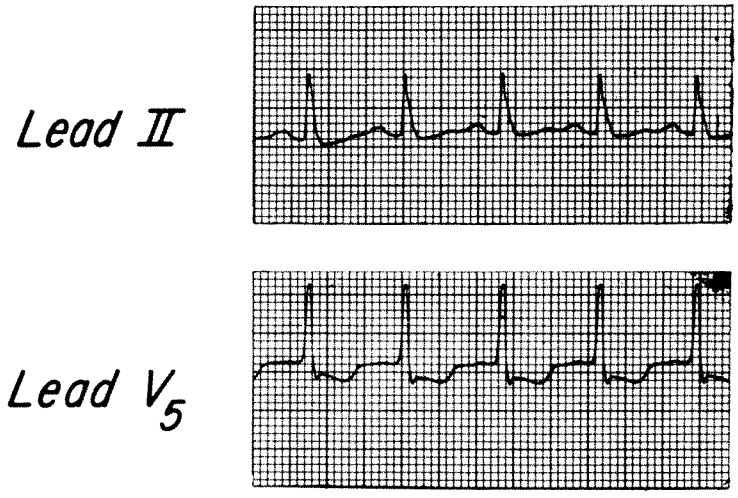

FIG 2. Simultaneous ECG tracings displaying ST segment depression in V_5 only.

A second ECG allows simultaneous recording of a precordial and standard lead. ST segment depression characteristic of subendocardial ischemia is frequently observed in only the precordial lead (fig 2).

No complications involving pneumothorax, hemorrhage, or electric burns have been encountered. To prevent burns at the site of ECG electrode placement during use of an electrosurgical unit, inductors have been recommended[2,3] to provide essential energy return.

A Safety Valve for the Pediatric Rees System

SIVAM RAMANATHAN, MD*
JACK CHALON, MD†
HERMAN TURNDORF, MD‡
New York, New York§

TAYLOR and Stoelting[1] have pointed out the dangers associated with the use of the Rees pediatric system: (1) pneumothorax, which may follow a sudden rise in system pressure caused by inadvertent kinking of the free-flow connector, malfunction of the bag-tail pop-off valve, or accidental use of the O_2 flush mechanism with the bag-tail pop-off closed, and (2) complications (or death) arising from spillage of liquid anesthetics from the vaporizer into the T-piece, caused by the sudden release of a kink in

the delivery tube in a system constructed without a liquid trap. Rees[2] also has mentioned the high system pressure that may result from the manual compression of small bags in which the force per unit area ratio is high. Although pressure-release systems have been advocated at the patient end of the system,[1] we have investigated the use of a safety valve placed at the common gas outlet of the anesthesia machine.

METHODS

The pressure-release mechanism of a Hope pediatric resuscitator,* the most commonly used pediatric resuscitator bag,[3] was employed to devise a safety valve for the Rees system. The patient end of the Hope resuscitator was removed from its inflator bag. This plastic assembly consists of a nonrebreathing valve, a pressure-relief valve set to pop off at 31 torr, and a tube-mask mount. The nonrebreathing valve was removed by unscrewing it from its plastic seat. The orifice through which the valve had been removed was then sealed. The modified plastic assembly, now only incorporating the pressure-relief mechanism, was then attached to the common gas outlet of an anesthesia machine by its bag attachment port, and placed in such a fashion that the tube-mask mount faced upward (fig 1).

The machine end of the gas delivery tube of a Rees pediatric system was joined to the tube-mask mount of the resuscitator by a 6-mm endotracheal-tube connector. The Rees system was composed of a 0.5 L anesthesia bag with a tail pop-off valve, a 30-cm corrugated free-flow connector, a T-piece, and an elbow connector with a side arm. Finally, a 1 L anesthesia bag was attached to the patient end of the elbow connector, and the side arm of the elbow connector was joined to a pressure transducer by a short piece of tubing. The transducer was electrically connected to a multichannel recorder. The anesthesia system was used with a 5 L/min fresh gas flow and the bag tail was closed.

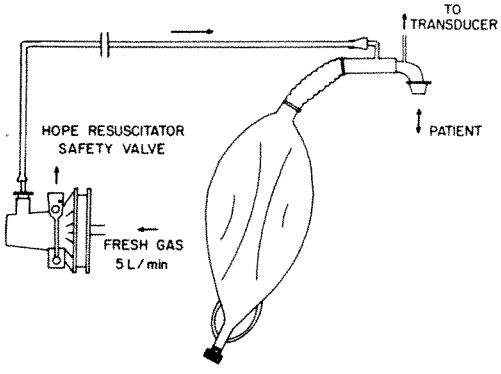

FIG 1. Jackson-Rees system attached to pressure-release system of an Ohio Pediatric Hope Resuscitator. The patient end is connected to a 1-L anesthesia bag for the experiments shown in figure 2.

*Ohio Medical Products, Madison, Wisconsin.

Three sets of pressure recordings were made: (1) without applying pressure on the bag of the Rees system, (2) by strongly compressing the bag, and (3) with the O_2 flush valve of the anesthesia machine at first partly and then fully opened.

RESULTS

In the pressure tracings shown in figure 2, panel A depicts the pressure recording when a 5 L/min fresh gas inflow only is introduced into the system. Over a 4-second period, the pressure gradually rises from 15 to 30 torr and then drops back abruptly to 15 torr within 1 second, after which the

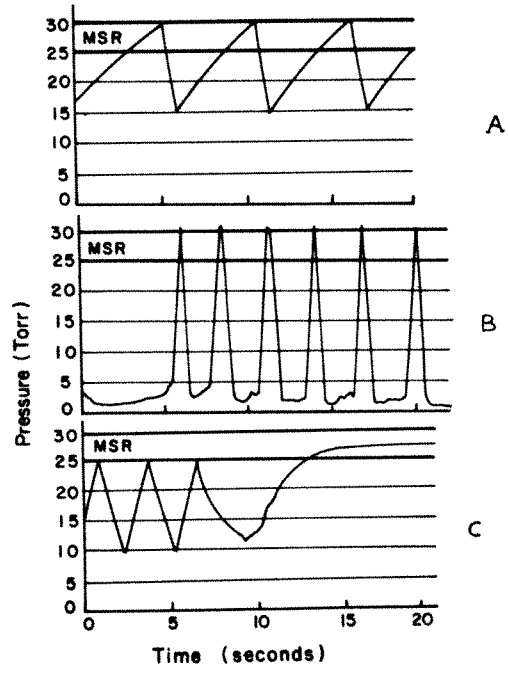

FIG 2. Pressure variations within the Rees system with a fresh gas flow of 5 L/min and without gas escape from the bag tail: Panel A: With constant flow and without external compression of the bag. Panel B: With forcible manual compression of the bag. Panel C: Without external compression of the bag but with the O_2 flush system at first partially and later fully operating. MSR = maximum safe pressure range.

cycle is repeated. Panel B demonstrates the pressure variations within the system when the bag is forcibly compressed manually. Maximum pressures recorded do not exceed 31 torr. Panel C is a tracing of system pressures when the O_2 flush of the anesthesia machine is at first partly and later fully opened; the curve obtained is at first similar to that depicted in panel A but the pressures reached are lower (10 to 25 torr). Later, when the O_2 flush valve is fully opened, system pressure rises to and remains at 27 torr.

DISCUSSION

All experiments showed that, under the conditions studied, the pressure within the Rees system never rose above 40 cm H_2O (31 torr), which is below the safe maximum limit of 50 cm H_2O advised by Avery.[4] In addition, the pressure-release valve assembly can also act as a receptacle for accidentally spilled liquid anesthetics so long as the tube-mask adapter is placed face upward. Fitting this device at the machine end of the system eliminates the addition of bulky components within the anesthesia circuit, as recommended by Taylor and Stoelting.[1]

We strongly recommend the use of this instrument whenever a Rees system is used, as it will prevent the development of pneumothorax caused by a sudden rise in system pressure or the inhalation of liquid anesthetics. The eventual manufacture of this apparatus will avoid the dismantling of existing equipment.

Hazards of Disposable Rebreathing Circuits

JAMES E. COTTRELL, MD*
WILLIAM BERNHARD, MD†
HERMAN TURNDORF, MD‡
New York, New York§

THE use of disposable rebreathing circuits has increased greatly in the past decade, largely because of the decreased likelihood of pulmonary cross-contamination.[1,2] We have noticed that circuits frequently are defective as delivered by the manufacturer. The most frequently seen faults include:

1. Kinking, which occurs easily in some circuits (fig 1-a). Partial kinking will markedly increase the resistance to breathing. Complete kinking, if not detected, may be life threatening.

2. Indentation into the breathing circuit lumen (fig 1-b), which may disturb laminar air flow enough to increase system flow resistance.[3]

3. Fractures in the polyethylene connectors (fig 2-a) that create leaks large enough to decrease gas delivery to the patient. This is particularly hazardous during mechanical

ventilation or closed-circuit anesthetic administration, and theoretically may create hazards to operating-room personnel because of environmental pollution.[4,5]

4. Separation of the swivel connector of some circuits (fig 2-b), which occurs commonly and may be difficult or even impossible to restore during an anesthetic procedure.

5. Leaks, which have been noted at connector sites, as well as at various sites along the corrugated tubing itself. Because such leaks are not ordinarily anticipated, they may not be looked for when they occur. Scavenger devices, of course, are ineffective at these sites.[6]

One of the disadvantages of disposable circuitry has been increased cost. If circuits must be discarded because of defects, real costs become higher.

Disposable anesthesia circuitry may be a potential source of unexplained airway obstruction or leak; close inspection of anesthesia circuitry before use is therefore mandatory. Sufficiently rigid quality control must be initiated to avoid unnecessary hazards to patients as well as to attending personnel.

A PEEP Device for a Manual Bag Ventilator

AZRIEL PEREL, MD*
DAN EIMERL, MD†
MORRIS GROSSBERG, IRIT‡
Jerusalem, Israel§

PEEP (positive end-expiratory pressure) is one of the major therapeutic technics in the treatment of various forms of adult respiratory-distress syndrome. Commonly used volume respirators have built-in PEEP valves. There are, however, situations in which the patient cannot be ventilated by a mechanical respirator, such as during transportation within or to another hospital. Ventilation is then usually accomplished using a manual bag ventilator. The discontinuation of PEEP can be hazardous in patients with severely compromised oxygenating capacity, since Pao_2 may decrease immediately when ventilation in these patients is changed from continuous to intermittent positive-pressure.[1]

The usual means of maintaining PEEP while the patient is disconnected from the respirator is by submerging an extension from the expiratory valve below water or by using a weight-operated valve. These methods require that the PEEP device be maintained in the upright position. We propose, instead, the use of the Exhalation Pressure Valve* originally designed to produce continuous positive airway pressure during spontaneous ventilation.

The exhalation pressure valve consists of a body with a spring-loaded exhalation valve. A knob adjusts the exhalation pressure between 0 and 6 cm H_2O. Calibration marks indicate the pressure setting.

The valve is attached to the expiratory port of a manual respirator with a short length of corrugated rubber tubing (figure). The end-expiratory pressure can be controlled by adjusting the pressure knob. This simple device enables the maintenance of PEEP within the limits of the apparatus (up to 6 cm H_2O) without the difficulties involved in maintaining the PEEP device upright during transport. It also provides better oxygenation while inflating the lungs during physiotherapy and suction procedures in patients with respiratory failure. It may further prove useful in the early institution of PEEP in battle casualties with pulmonary edema, after initial resuscitation.

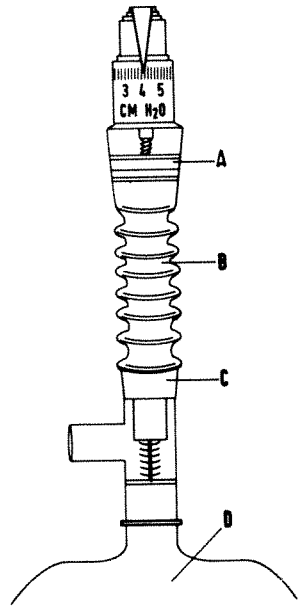

FIGURE. Exhalation pressure valve (A) connected with a short corrugated tube (B) to the expiratory port (C) of a manual respirator (D). The tube is attached to the side adapter between C and D.

The Tracheal Bronchus: An Unusual Airway Problem

TAMERISA VENKATESWARLU, MD*
CECIL J. TURNER, MD†
JAMES D. CARTER, MD‡
DEAN H. MORROW, MD§
Houston, Texas‖

ANATOMIC abnormalities of the airway are of particular concern to the anesthesiologist. This report, which describes a patient with a congenital tracheal bronchus, is presented to alert the anesthesiologist to an unusual developmental defect of potential importance in airway management.

REPORT OF A CASE

A 2-year-old girl was admitted to the hospital with a history of recurrent croup. The child had experienced recurrent pulmonary infections, bronchiolitis, and asthma since 2 months of age. At the time of admission, the mother described fairly characteristic croup symptoms which seemed to coincide with periods of moderate exercise. The past medical history was negative except for several hospitalizations related to the present illness. Approximately 1 year before the present admittance, cardiac catheterization had ruled out a left pulmonary arterial vascular ring.

Physical examination on admission showed inspiratory and expiratory stridor. Hemoglobin, hematocrit, and WBC were within normal limits. Immunoglobulins were normal and a sweat test was negative. Throat culture grew a mixed bacterial flora. The admission chest x-ray was considered consistent with nonspecific peribronchial disease. Two series of esophagograms, a week apart, were inconclusive for the presence of a vascular ring.

The child was placed in a croup tent and treated with IPPB using racemic epinephrine, and with parenteral ampicillin. On the 10th hospital day, bronchoscopy was performed under halothane anesthesia. The postbronchoscopy diagnosis was deformity of the carina, of unknown etiology. Two days later, bronchograms were obtained under general endotracheal anesthesia using the same agents. This study revealed a right tracheal bronchus arising approximately 2.5 cm proximal to the carina (figure). Two days later the child was discharged with arrangements for home respiratory therapy.

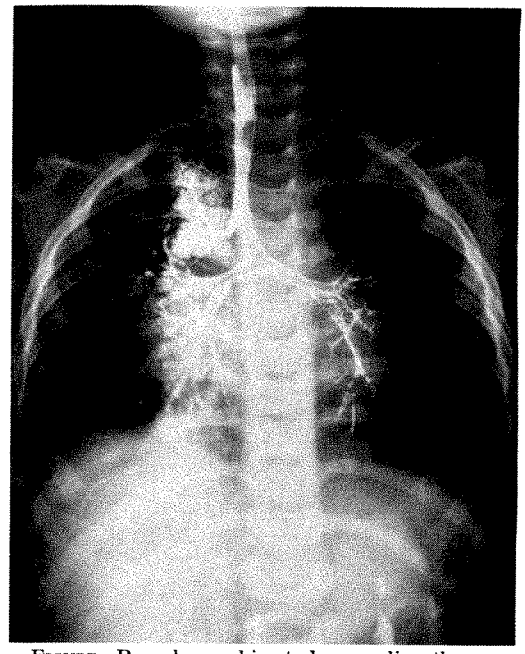

FIGURE. Bronchographic study revealing the presence of an apical displaced, right tracheal bronchus. The left tracheal shadow at the level of the 1st rib is suggestive of a vascular ring, although this was not verified by cardiac catheterization or esophagograms. The potential for inadvertent intubation or occlusion of this lower airway anomaly is apparent.

COMMENT

The respiratory tract originates from the anterior division of the embryonic foregut at about 4 weeks of gestation.[1] The tracheobronchial diverticulum originates in the pharynx and divides into the 2 major bronchial branches which subsequently give rise to the segmental bronchi, bronchioli, terminal bronchi, and alveoli.[2] During the 1st weeks of life, a tracheal bronchus is present but usually resorbs in the human, although it persists as a normal anatomic feature in swine, cattle, sheep, and other ruminants.[3]

Two variants of the persistent tracheal bronchus have been reported: (1) the supernumerary, which is an additional airway supplying the right upper lobe, and (2) the more-common apical displaced variant, in which the bronchus to the right apical lung segment arises directly from the trachea.[1] As can be seen in the figure, the apical displaced variant was present in the child described.

To our knowledge, this is the 2nd report of a tracheal bronchus in infancy and childhood. The first, reported by Iancu and colleagues,[1] was in a 7-month-old boy. However, comments by bronchoscopists suggest that this form of airway anomaly may be more frequent than the literature indicates.

From a practical clinical point of view, inadvertent intubation or occlusion of the tracheal bronchus with secondary unanticipated ventilatory difficulties are significant potential hazards in patients with this congenital anomaly. Bronchial intubation during the 2nd anesthetic procedure in our patient could have resulted had the endotracheal tube been advanced an additional 3 to 4 cm, resulting in overdistention of the right upper lobe, with compression of adjacent lung tissue or pneumothorax. Additionally, this airway segment could easily be occluded by the cuff of an endotracheal tube, causing collapse of the lobe.

Thus, although statistically uncommon, the presence of a persistent tracheal bronchus warrants consideration in the differential diagnosis of unanticipated airway problems, particularly those which occur following intubation.

SUBCUTANEOUS HEPARIN. The effect of low dose heparin prophylaxis on the incidence of vein thrombosis, surgical bleeding and wound hematoma, was determined after abdominothoracic surgery. Subcutaneous heparin, 5000 units, was administered two hours preoperatively and then every eight hours postoperatively for seven days. The incidence of vein thrombosis was reduced from 16 percent in control patients to 3.6 percent with heparin prophylaxis. More significantly, the incidence of popliteal or femoral vein thrombosis was reduced from 2.9 percent to 0.8 percent. Heparin prophylaxis resulted in clinically insignificant increases in blood loss, wound hematoma and fall in hematocrit. *(Gallus AS, Hirsh J, O'Brien SE et al: Prevention of venous thrombosis with small subcutaneous doses of heparin. Innominate Artery Compression Simulating Cardiac Arrest During Mediastinoscopy: A Case Report

JAE-HWAN LEE, MD*
ANTHONY SALVATORE, MD†
White Plains, New York‡

MEDIASTINOSCOPY has become a recognized means of diagnosis and of determination of resectability, bronchogenic carcinoma, sarcoidosis, and other mediastinal masses. A case is presented of innominate (brachiocephalic) artery compression simulating cardiac arrest, with severe bradycardia, during mediastinoscopy. Unusual problems and anatomic relationships are described, and the importance of continuous monitoring during mediastinoscopy is stressed.

Carlens[1] first described mediastinoscopy, the technic of examining the paratracheal, subcarinal, and suprahilar areas of the mediastinum, in 1959. Since that time, the procedure has become generally familiar for diagnosis and preoperative evaluation.[2-5]

The rationale for mediastinoscopy depends on the fact that intrathoracic lymphatic drainage is from the periphery of the lung toward the centrally placed paratracheal lymph nodes. Previous mediastinoscopy is an absolute contraindication, because scarring eliminates the plane of dissection. Severe tracheal deviation, vascular problems such as thoracic aneurysms, and increased pressure in the superior vena cava are relative contraindications.[2]

An alarming and potentially dangerous intraprocedural event may be the appearance of innominate artery compression, as described following.

REPORT OF A CASE

A 27-year-old black girl was hospitalized with a persistent cough associated with dyspnea of 1-month duration. Her medical history was otherwise unremarkable. Chest x-rays showed marked hilar adenopathy with an interstitial fibrotic pattern throughout the lung fields. Other laboratory findings were normal. She underwent mediastinoscopy on the 5th day of hospitalization. Preanesthetic medication consisted of 10 mg of morphine sulfate and 0.4 mg of scopolamine. Anesthesia was induced with 250 mg of thiopental, intubation of the trachea was facilitated with 40 mg of succinylcholine, and anesthesia was maintained with enflurane-N_2O-O_2. Ventilation was assisted manually.

The patient was placed supine with a pillow under the shoulders to extend the head slightly, with the head up about 15° to relieve venous congestion. We monitored the arterial pressure of the right arm by cuff, digital pulse with a Datascope® finger plethysmograph, and heart action by ECG lead II. Fifteen minutes after the mediastinoscopy was started, the finger plethysmographic tracing suddenly disappeared. There was no recordable blood pressure and no right radial pulse in the presence of a normal ECG tracing. Cardiac arrest was suspected and the mediastinoscope was quickly removed.

Immediately after withdrawal of the mediastinoscope, a normal plethysmographic tracing was restored, with adequate blood pressure and radial pulsation. No further treatment was required. Mediastinoscopy was resumed, monitoring heart sounds through esophageal stethoscope, and compression of the innominate artery recurring on several occasions for 20 to 30-second intervals. A few minutes after the 1st incident, the pulse rate decreased from 80 to 85 to 45 to 50/minute. The blood pressure

Paper received: 12/15/75
Accepted for publication: 2/13/76

was stable and no cardiac arrhythmias were observed. This severe bradycardia lasted for about 1.5 minutes and returned to a normal rate spontaneously. The postanesthetic course was uneventful. Mediastinal lymph nodes were seen to contain marked granulomatous change compatible with sarcoidosis.

DISCUSSION

The innominate artery may be compressed by the mediastinoscope, diminishing blood flow not only to the arm but, more importantly, to the brain through the right common carotid and vertebral arteries. We believe that judicious monitoring of carotid arterial blood flow is important with patients known to have significant arteriosclerotic disease of the carotid artery.

Transient left hemiparesis following mediastinoscopy have been reported.[3] Mediastinoscopy under local anesthesia[4] might be advantageous for patients with obstructive disease of the carotid artery, so that the patient's level of consciousness can be continuously evaluated. Use of the Doppler apparatus to monitor carotid blood flow might offer further advantage.

In our case, production of simulated cardiac arrest was likely due to compression of the innominate artery (figure). The vagi and their branches may be mechanically stimulated, injured directly by sectioning or contusion, or injured indirectly by compression from hematoma or edema in surrounding tissues. The severe bradycardia was probably related to the transient mechanical stimulation of the vagus by the mediastinoscope. Since the vagus and cardiac nerves may be manipulated, the ECG should be continuously monitored during this procedure.

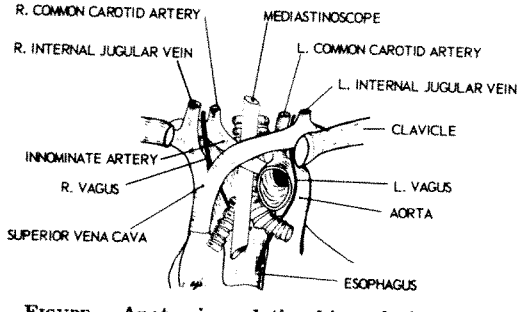

FIGURE. Anatomic relationships during mediastinoscopy.

The esophagus lies posterior to the trachea and usually is not in the mediastinoscopic area of dissection except in the subcarinal region, where it may be vulnerable. Laceration of major vessels in the superior mediastinum is also possible. The mediastinal pleura, particularly on the right side, lies close to the trachea and the pleural space can be entered inadvertently. Other complications include death after biopsy of pulmonary and innominate arteries, superior vena cava and azygos vein, in addition to injury of the vagus and recurrent laryngeal nerve, air embolism, tumor invasion of the suprasternal wound, subcutaneous emphysema, and cardiac arrhythmias due to inadvertent cardiac biopsy.[5]

One should constantly monitor the right radial pulse, since vigorous anterior retraction on the mediastinoscope will occasionally compress the innominate artery. Monitoring of arterial pressure of the right arm and heart sounds through an esophageal or precordial stethoscope is also desirable, as is auscultation of the chest for breath sounds, and airway problems related to recurrent laryngeal nerve injuries should be observed postoperatively.

ACKNOWLEDGMENT

The authors are grateful to Dr. S. H. Ngai, Department of Anesthesiology, The Presbyterian Hospital, New York, for his helpful advice in the preparation of this manuscript.

Anesthesia for Vanishing Lung Syndrome:
Report of a Case

NELSON ISENHOWER, MD*
ROY F. CUCCHIARA, MD†

A patient with severe bullous emphysema in whom one bulla occupied an entire hemithorax and shifted the mediastinum to the opposite side was anesthetized for bullectomy in a lateral thoracotomy position using an awake intubation with a Bryce-Smith double-lumen endotracheal tube under spontaneous ventilation on room air. The maintenance anesthetic was halothane and oxygen, with pancuronium bromide for relaxation and ventilation of the good lung only. This technique avoids many of the potential problems presented by this type of patient.

INTRODUCTION

CHRONIC obstructive pulmonary disease (COPD), the most common chronic lung disease, presents many problems to the anesthesiologist.[1,2] A Hospital Records survey revealed that 22% (175,000) of the emphysematous patients discharged in 1974 had undergone surgery.[3]

We wish to describe an emphysematous patient who developed a bullous lesion so large that it completely filled the right hemithorax without causing a pneumothorax (vanishing lung syndrome). The patient's respiratory function was so impaired that operative resection of the lesion was required.

CASE REPORT

A 52-year-old known emphysematous male was referred for evaluation of dyspnea on minimal exertion and a "right pneumothorax" on chest roentgenogram. His chest films at admission, however, showed a large bulla covering almost the entire right thorax, with the right lung compressed and a left shift of the mediastinum. Physical examination at admission revealed a slender Negro male in moderate respiratory distress at rest, with a tracheal tug and intercostal retractions, increased anteroposterior diameter of the chest wall, and jugular venous distention to 45°. Breath sounds were absent on the right side and decreased on the left. He was treated with low-flow oxygen and antibiotics while being evaluated.

Pulmonary function tests (Table 1) were interpreted as showing a severe obstructive defect with hyperinflation. Arterial blood gases revealed hypoxemia with carbon dioxide retention (room air: pH 7.41, Po_2 52 mm Hg, Pco_2 55 mm Hg). When low-flow oxygen was administered (2 liters/min), he showed an even greater retention of carbon dioxide (pH 7.34, Po_2 71 mm Hg, Pco_2 64 mm Hg). Pulmonary arteriogram revealed pronounced bullous changes in the right upper lung field extending across the midline and severe compression of the right pulmonary artery vessels to the lower portion of the right hemithorax. Pulmonary hypertension was also noted. A xenon ventilation-perfusion scan showed a large ventilation defect of the right lung.

On the 10th hospital day, the patient underwent right bullectomy through a right lateral thoracotomy. The patient received

no preoperative medication. A central venous pressure catheter, arterial catheter, electrocardiogram, and Foley catheter were used for monitoring. After diazepam 5 mg was intravenously administered, bilateral superior laryngeal nerve blocks were performed with 1% lidocaine, and topical anesthesia of mouth and pharynx was accomplished with 2 cc of 4% cocaine. A 6.5-mm, Bryce-Smith double-lumen endotracheal tube was inserted while the patient was awake and spontaneously ventilating with room air. The cuff to the left lung was inflated, and positive-pressure ventilation was begun to the left lung only. The lumen to the right lung was left open to room air. Induction was accomplished with thiopental, and relaxation was accomplished with pancuronium bromide. Anesthesia was maintained with halothane, oxygen, and controlled ventilation. Arterial blood gas values were satisfactory in the supine and left lateral positions.

The thorax was opened. The right lung was noted to be compressed, and one large bulla occupied approximately 95% of the hemithorax. The surgeon was unable to express air from the bulla. Ventilation of both lungs with equal pressure was then attempted, and nearly the entire tidal volume appeared to enter the bulla in the right upper lobe. Bullectomy was performed. Several smaller (3-cm) bullae were noted and also removed. The right lung was expanded. Intercostal nerve blocks were performed with 0.25% bupivacaine. Anterior and posterior chest tubes were inserted. The double-lumen endotracheal tube was replaced by an oral, 8.0-mm, Portex endotracheal tube with a low-pressure cuff. The patient was taken to the recovery room and placed on a volume ventilator (Bennett MA-1). A 600 to 800 ml leak per breath via the chest tubes was noted.

On the first postoperative day, paravertebral blocks were performed. The right lung gradually filled the entire right side of the chest. On the second post-operative day, the patient was weaned by intermittent mandatory ventilation and the endotracheal tube was removed. The patient continued to do well, and on the fourth postoperative day, the posterior chest tube was removed. The air leak gradually decreased, and the second chest tube was removed on the eighth postoperative day.

Postoperative pulmonary function tests showed improvement (Table 1). Arterial blood gases on room air revealed a pH 7.39, Po_2 64 mm Hg, Pco_2 40 mm Hg. The patient noted much improvement in his activity tolerance and was dismissed on the 12th postoperative day. He was both objectively and subjectively greatly improved and returned to work. Pulmonary function tests six weeks after the operation showed little further improvement (Table 1).

DISCUSSION

The patient with COPD presents several different problems to the anesthesiologist.[4] The problems that this patient exemplifies were related to three major areas: positive-pressure ventilation, oxygenation, and anesthetic management.

In bullous emphysema, when one bulla is very large while other bullae are small, Laplace's law relating to the expanding force in a hollow structure to the cross-sectional area applies. Laplace's law (when the thickness of the wall of the sphere is assumed to be negligible in comparison with the radius of curvature) could be stated as: the pressure within a bulla equals two times the wall tension of the bulla divided by the radius of the bulla.

If positive pressure is applied to the airway (that is, by way of an anesthesia bag), the large bleb tends to increase in size even more.[5-7] This increase could rupture the wall and cause a pneumothorax, and in this case, probably a tension pneumothorax. In a patient with marginal pulmonary and cardiovascular status, the results could be devastating.[8] A second consideration is that, even if a tension pneumothorax did not occur, the large bulla could allow most, if not all, of the tidal volume to enter its cavity. The increase in size of the bulla could shift the mediastinum, compress the good lung, and allow more of each succeeding tidal volume to enter the bulla. However, if a pneumothorax would occur and the patient could be treated with a chest tube of large bore, a large bronchial-cutaneous fistula could be created, and this could divert the entire tidal volume into the chest tube.

Like many patients with COPD this patient demonstrated that his drive to breathe was based on hypoxia and not on hypercapnia. A high inspired F_{IO_2} in our patient might have removed his only drive to spontaneous ventilation. This patient's oxygenation problems were compounded because, not only did he have decreased function of lung tissue but he also was effectively ventilating only one functioning lung.

Because of this patient's decreased pulmonary reserve, premedication was omitted before his arrival to the operating room. In order to ensure that no positive pressure would be applied to the airway, an awake intubation was chosen under spontaneous ventilation. A double-lumen endotracheal tube (left Bryce-Smith) was chosen firstly, to ensure that no positive pressure would be applied to the bulla and, thus, prevent ventilating only the bulla or causing a pneumothorax, and secondly, that ventilation could be guaranteed to the good lung, even in the presence of a possible bronchial-cutaneous fistula. The lumen to the right lung was left open to prevent any increase in pressure which might be caused by expansion of the partially compressed left lung.

Oxygen was added only after an airway was assured and positive pressure could be applied to the lungs independently. Halothane was chosen so that a high F_{IO_2} could be delivered, as this may be needed for any patient in the lateral thoracotomy position and especially in one who has decreased pulmonary function. As in any patient with a ventilatory defect, the uptake of an inhalation agent may be decreased somewhat owing to the $\dot{V}/\dot{Q}$ abnormalities present. The use of nitrous oxide in the presence of an air-filled body cavity must be very judicious.[9] Nitrous oxide was avoided because of its probable diffusion into the bulla, thus increasing its size, and because the nitrous oxide would decrease the inspired oxygen concentration.

During the surgery, it became obvious that several of the theoretic complications were no longer theoretic. By avoiding positive pressure, hyperinflation of the bulla on induction was avoided. After the chest was opened, both lungs were ventilated with equal pressure. Almost the entire tidal volume was displaced into the bulla, and adequate ventilation could not be maintained. By utilization of the double-lumen tube the ventilation could be directed away from the bulla and into the better lung. The ability to inflate or rest the poor lung was helpful to the surgeons in locating and isolating other resectable bullous areas.

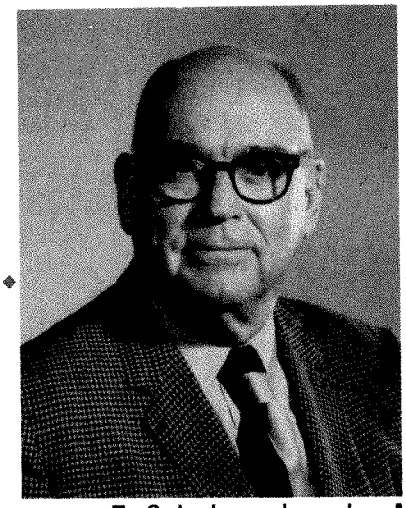
We Salute . . . .



Lawrence F. Schuhmacher, Jr., M.D.

FREQUENTLY, superlatives are used to salute colleagues and to describe their accomplishments. In contrast, there are a unique few for whom superlatives somehow seem out of place, and who are more comfortably identified by their sincerity and qualities as real human beings. Dr. Lawrence F. Schuhmacher, Jr., Professor and Chairman of Anesthesiology at the Baylor College of Medicine, is truly one of these unique few.

Larry was born in Meade, Kansas, the oldest of three boys. During his youth and early adulthood, he and his brothers alternated between the summertime physical labors of a large wheat farm and the wintertime mental labors of school. In 1933, the trio graduated together from the University of Kansas, two physicians and an engineer.

Following graduation, Dr. Schuhmacher migrated from Kansas to New York City for an internship at the Fifth Avenue Hospital. During the year he met and married Florence M. Stout, an obstetrics supervisor. During the subsequent 5 years, Larry carried on a busy general practice in the Dust Bowl depression of Western Kansas. In 1940, the Schuhmachers again returned to the East Coast, where Larry served 2 years as an anesthesia resident at the Lahey Clinic in Boston. Immediately after training, Larry entered the Army. After a year in Iceland, his unit was transferred to England. Shortly after D-day, he was assigned to a Thoracic Surgical Center in the European Theater of Operations, where he remained until the end of World War II. He was a major at the time of his discharge and the recipient of the Bronze Star.

In 1945, Dr. Schuhmacher accepted the joint responsibilities of Professor and Chairman of the Department of Anesthesiology at the Baylor University College of Medicine and Director of Anesthesiology at the Hermann Hospital in Houston, Texas. There is little question that the Gulf Coast sunshine after the miserable damp-cold of the European winters may have influenced this move as much as the challenge of the rapidly developing Texas Medical Center.

Once relocated permanently in the South, Larry organized a formal residency program and actively promoted the growth of anesthesiology to parallel the growth of surgery

in Houston. Dr. Schuhmacher stepped down as Chairman of the Baylor program in 1953 but retained a Clinical Professorship in the Department until 1960. In 1969, he also resigned his responsibilities at the Hermann Hospital. This training program continues, however, and is now incorporated into the University of Texas Health Science Center at Houston.

After a brief but "active effort" at retirement, Dr. Schuhmacher came back to teaching and the operating room. He returned first to Hermann Hospital and then, on a part-time basis, to the Houston Veteran's Administration Hospital. In 1974, he accepted the appointment as Professor and Chairman of Anesthesiology at Baylor for the second time. On an almost daily basis, Larry can be found in the Fondren-Brown Cardiovascular Unit of The Methodist Hospital, caring for patients and imparting to trainees what he has learned on the basis of two careers in anesthesiology.

Despite his propensity for patient care, Larry finds time to enjoy the great outdoors. Frequently he is accompanied by Mrs. Schuhmacher when he is hunting or fishing, although with the recent sale of his boat, Florence lost her position as First Mate on excursions onto the Gulf of Mexico. The Schuhmachers' only child, Lawrence F. III ("Mike"), is an anesthesiologist practicing in San Antonio, and Larry's brother, Nelson R., is an anesthesiologist who has recently retired from practice in California.

Dr. Schuhmacher is a Diplomate of the American Board of Anesthesiology, a Fellow of the American College of Anesthesiologists, and a long-time supporter of the International Anesthesia Research Society. He has served as President of both the Houston Surgical Society and the Doctors' Club of Houston and was an ASA Director for 9 years.

It is with pleasure that we salute Lawrence F. Schuhmacher, Jr., M.D., a colleague and friend who has devoted his professional lifetime to our specialty.

SHOCK LUNG. Shock lung syndrome follows profound hypotensive episodes secondary to hemorrhage or sepsis and is associated with a 60 to 90 percent mortality. The present study sought to determine the efficacy of pharmacologic doses of steroids in the treatment of this syndrome. Ten patients with the diagnosis of shock lung syndrome were treated with methylprednisolone 30 mg/kg intravenously every 6 hours. All patients were mechanically ventilated and positive end expiratory pressure (PEEP) was necessary in 5 patients. There was a progressive increase in arterial oxygenation and resolution of pulmonary edema that was not influenced by PEEP. Nine patients survived and one died from disseminated intravascular coagulation. The author concludes that methylprednisolone improved survival in patients developing shock lung syndrome. *(Sladen A: Methylprednisolone. Pharmacologic doses in shock lung syndrome. J Thorac Cardiovas Surg 71:800-806, 1976)*

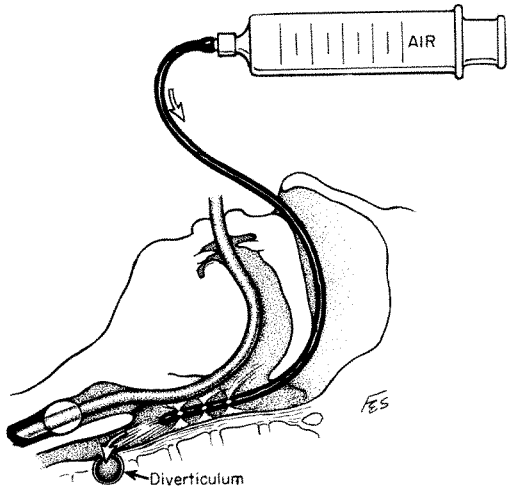
PLASTIC-COVERED WIRE STYLET

To the Editor:

I read with interest Dr. Morris J. Nicholson's article on a plastic-covered solid copper wire stylet, which appeared in *Anesthesia and Analgesia* (55:150, 1976). This brought back memories.

On several occasions, pieces of plastic on our stylets would be sheared off and left in the patient's tracheobronchial tree. I wondered if the plastic covering on the new TW (thermoplastic, weatherproof) copper wire described by Dr. Nicholson would also shear. I inserted the TW coated wire through 2 randomly selected metal endotracheal tube connectors, made a kink in the wire, and then pulled the stylet out of the endotracheal connector. The results—a partially sheared-off piece of plastic (figure).

No doubt Dr. Nicholson's material is superior to that which I used many years ago; however, I wonder if a warning should be included that the possibility of shearing some of the coating still exists. I am sure that the chances of this plastic covering being sheared while using plastic endotracheal tube connectors would be almost nil.



The stylet described by Dr. Nicholson is an improvement over other forms of coated-wire stylets and I plan to replace the spiral-wire stylets because of the distinct advantages of these plastic-covered stylets.

Charles J. Restall, MD
Department of Anesthesiology
Mayo Clinic
Rochester, Minnesota

* * *

To the Editor:

Dr. Restall raises a very important question concerning the safety of the plastic-covered solid copper wire (#12) stylet which I described. To date we have not been aware of this complication occurring in our practice. Recently, I have tried to reproduce the shearing effect described by Dr. Restall when he pulled a kinked stylet through a metal endotracheal tube connector; however, I had the metal connector inserted in an endotracheal tube as it would be used in clinical practice. Even when the tube and stylet were bent at a 90° angle or greater, I was not able to produce any shearing of the plastic coating. Nevertheless, this is an important consideration which must be constantly kept in mind and for which these stylets should be examined after each use.

If any of our readers have experienced this complication (a piece of the sheared plastic coating remaining in the tracheobronchial tree), I would greatly appreciate hearing from them.

Lahey Clinic
Boston, Massachusetts

In each issue of the Journal an article of particular interest and value to anesthesiologists, which has been published elsewhere, will be presented. Primarily the material will contain fundamental basic information which has been presented by anesthesiologists, physiologists, pharmacologists, and others and, on occasion, by commercial firms. In the last instance, these reprintings are not to be construed as an endorsement of the particular commercial firm or its product by Anesthesia and Analgesia—Current Researches.

Attorney Urges Study of Doctors' Professional Relationships

E. BLAKE MOORE
Spears, Moore, Rebman & Williams
Law Offices
Chattanooga, Tennessee

E. Blake Moore delivered the following address at a meeting of the Tennessee Valley Medical Association in 1975. Among the audience were a number of doctors whom Moore has defended in medical malpractice suits. Moore speaks candidly and gets directly at the heart of a fundamental issue in the malpractice situation. That is, doctors' relationships—with their patients, with other doctors, and with lawyers.

A GOOD bit of my professional life has been dedicated to the defense of medical malpractice claims. It is something I like to do. Defending you is a challenging and personally satisfying part of my work. In short, I like you people and would like to be put in the category of friend, not foe.

I say this introduction because I want to talk to you in a way that might be acceptable to you only if you keep it firmly in your mind that I really am on your side.

My topic is an effort to demonstrate some of the common sense, simple things that go so far to make you good doctors and good people—and, therefore, believe it or not, "immune" from claims of malpractice. So, what are some of these simple things?

Let's start with the most obvious—your relationship (or lack of one) with your patients. Isn't it strange that the person who first comes to you in complete confidence, fully prepared to refer to you fondly as "my doctor," is the very same person who sues the heck out of you?

Quite obviously, somewhere along the line, something went wrong to cause such a wonderful start in a mutually beneficial relationship to end up fraught with suspicion, frustration and anger.

It's right here—in the midst of your relationship with your patient that most of the malpractice cases get started.

You can blame anyone or anything you want—the law, lawyers, courts, juries, insurance companies, or the changing times. But if you don't examine yourself, your patient and how the two of you are doing in your human relationship, you will be putting the

Reprinted with permission from MALPRACTICE DIGEST and the author.

blame in the wrong place. Moreover, you will be ignoring a major cause of malpractice litigation and you will be contributing to making the situation worse.

As you look at yourself and your patients, do you see how you are isolating yourself from your patient? Do you have one of those offices where the patients are herded into a corral, often called a "waiting room," or out into the hall?

Is your office built so that a great wall separates all "your people" from "them?" (Oh, yes, I know you cut a hole through which one can talk and hand money). Those walls are terrible mistakes.

Have you got a "front line" of women whose only goal in life is to protect you from your patients? Do you take time to find out if those front line ladies are as nice to your patients as they are to you? Do you realize how much harm is done by the women who "man" the wall? Do your patients wait for hours, even 30 minutes, to have a few precious moments of your time? Are you oblivious to the value of your patients' time?

Do you enjoy your work and your patients or, is your practice more like a production line with quotas to make?

What caused you to become a doctor in the first place? What impels you in your practice? Is it a genuine interest in serving mankind or is it the profit potential? Do you place financial considerations above the physical or emotional needs of your patients?

Have you "had to" develop a good many hard-headed business practices as part of your handling of your patients? Has your idealism been replaced by "practical business considerations?"

Are you job-oriented? That is, do you attempt to serve your patients by a cold purely scientific approach wherein the patient is merely another case, a detached problem, to be solved and disposed of? Do you have the attitude that you should refuse to be led around by the nose by your patients? And, the companion attitude—that you must train your patients to adhere to your schedules and patterns of life—indeed even to timing their illnesses?

Do you or "your people" at the wall indulge in untruthful representations that you are "in surgery" or "had an emergency" when the truth is you are lingering over a cup of coffee—or some other personal matter? Are you willing to listen to your patients about non-medical factors which may bear upon the patient's illness?

Do you get out in the world—the non-doctor world—or do you go to doctor meetings, doctor luncheons, doctor social events, doctors' homes, and, when you play golf, it's in the "doctor dog fight?". Do people get to know you in places and circumstances far removed from your doctor's office?—like school work, church work, Boy Scouts, Clubs, social gatherings where there may not be any other doctors, etc.?

O.K., enough is enough! But I hope the point is made—that you may be making a lot of mistakes in your relationships with your patients, and other members of the outside world. It is a situation that needs attention. For instance, it doesn't take much imagination to visualize what is happening when these relational mistakes are being made thousands of times a day in almost every doctor's office.

We are seeing the practice of medicine, more and more, as an impersonal, scientific, sterile, unpleasant business. More and more a doctor's office is like a computer into which we are fed—rather than a place of warmth and tender loving care.

Solve some of these relational problems, and you will see a real minimizing of malpractice claims.

While we're talking straight I'd like to say something about "The Conspiracy"—the conspiracy of silence that alleges that no doctor will testify against another doctor simply because he's a doctor.

First, I don't believe there is such a thing. In my experience, I've seen many doctors ready to testify against their colleagues.

Second, of course, it is wrong to "conspire" against anyone in the way "The Conspiracy" makes it sound.

Third, there may be a lot of good considerations that went into a doctor's decision not to testify. It often meant a recognition that very few medical problems are either black or white. It recognizes that a lot of what you do is a matter of judgment and that someone else's way of practicing medicine may be as good as yours. It recognizes your own capacity to be wrong and an interdependence among all doctors—the

general practitioner and the specialist as partners in a mutual endeavor. So, only to the extent that "The Conspirary" made you think and act along these lines, I wish it would make a comeback.

Along this line, we ought to mention how your relationships with each other have deteriorated—resulting in too much criticism and "loose talk." How often are the seeds of suspicion sown by the raised eyebrow, evasive answer, or sarcastic or critical remarks of the doctor who next sees the patient? How many times have petty personality conflicts given rise to unwarranted criticism? How often does a jurisdictional dispute between two warring specialty groups give the patient cause to wonder if he was mistreated? What you do to each other is awful! One is reminded of 2 or 3 old expressions:

1. "Loose lips sink ships"—and doctors.

2. "Who needs enemies with friends like these?"

3. "Button your lip."

One other point I would like to discuss is the antagonism that too often exists between your profession and mine.

You very often see attorneys as the real enemy—not the patient. You resent the ways of attorneys and fear whatever it is that goes on in the court room.

Your tendency toward isolation may be one reason for this resentment but there may be another—it may stem from the different (really opposite) ways that we in the two professions go about solving problems. Our training and practice have a basic difference.

We lawyers are trained in a curriculum that is essentially a continuing Socratic dialogue, whereas you doctors are instructed in a method that is largely doctrinal and authoritative. The lawyer's meat is controversy and he functions in the adversary system wherein each side takes its best shot before an impartial tribunal that decides what is "right." The doctor, on the other hand, is conditioned to objective scientific inquiry. To a doctor, notorious contest is disruptive and has no place in the search for solutions.

The lawyer, typically, sees a challenge in open dispute, whereas the doctor may see it only as an unnecessary insult.

We attorneys live in controversy and are constantly aware of the other person's point of view and possible criticism. We spend a lot of time as the "Devil's Advocate"—not a reference to your disgruntled patient and his attorney.

As a doctor, you are not prepared for criticism of how you practice medicine. Your status has been only a "Little Less Than God." You give orders all day long and seldom take any. You are the protector of our health and well-being. Most of the public still treats you with a certain reverence.

So, it's not at all surprising that you would have a problem with criticism, depreciation or attack. Very little, if anything, has prepared you for it.

We, in two professions, then, have two essentially different professional lifestyles—two approaches to problem solving. Neither is wrong. Both are time-tested. Both are working rather well.

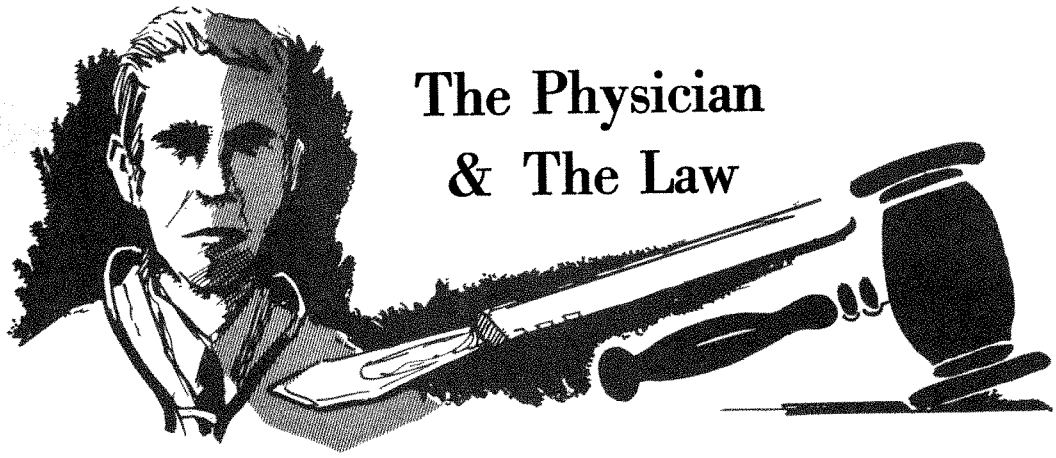
What neither profession has had, in surplus, is a good understanding of each other.

So, my summation and plea is:

(1) Take a hard look at yourself as a doctor and your relationship with each patient.

(2) Take a hard look at yourselves, not as individual superstars, but as a *group* of professional people with no real reason to exist, except to work together—to bring as much good health and happiness to your patients as possible.

(3) Take a good open-minded look at the legal profession, and the system within which it works, and your relation to it.



No Liability for Death of Patient During Anesthesia

A TRIAL court properly rendered a verdict in favor of several physicians, an anesthetist, and a hospital in a negligence suit, a Texas appellate court ruled.

A patient died of a cardiac arrest while undergoing anesthesia before surgery to repair a diaphragmatic hernia. Her husband brought the negligence suit against the physicians, the anesthetist, and the hospital. A trial court ruled that they were not liable. Appeals were eventually taken to the state supreme court, which remanded the case for a new trial. After a retrial, the jury again refused to find negligence.

On appeal, this trial court's decision was affirmed. The appellate court overruled several points of error in reaching its decision. A written consent to surgery signed by the patient was properly admitted into evidence, the court said. Medical textbooks not recognized by the testifying experts were properly excluded by the court as hearsay.

The appellate court also said that the manufacturer's recommendation of flow rate for anesthesia equipment could not be used to establish a medical standard to determine whether the anesthetist was negligent in using a different flow rate.

The decision in favor of the physicians, anesthetist, and hospital was affirmed.—*Webb v. Jorns*, 530 S.W.2d 847 (Tex. Ct. of Civil App., Oct. 10, 1975; rehearings denied, Nov. 21, 1975 and Dec. 19, 1975).

Editor's Note: Prior decisions in this case were reported in THE CITATION, Vol. 24, No. 10, p. 146 and Vol. 27, No. 2, p. 26.

QUESTION: *A healthy 22-year-old married but (planned) childless operating-room nurse, who has worked full time in the operating room for the past 6 months and is aware of the harmful effects of waste anesthetic gases on parturients, desires to start a family. She asks: "Should I quit working in the operating room and wait a specific length of time before getting pregnant? If so, how long? Should I wait until I am pregnant and then quit? If so, how long after I become pregnant could I safely work in the operating room?"*

MD, Tennessee

ANSWER: This young operating-room (OR) nurse asks very pertinent questions with respect to her planned pregnancy and continued work in the OR. Unfortunately, there are little firm data with which to answer her. Hopefully, additional information will be available following completion of the second phase of the National Study on the Effects of Trace Anesthetic Agents on the Health of Operating Room Personnel. At that time, a comparison of health experience before and after the installation of scavenging equipment will be possible. This should allow an estimate of the time factors involved in the pregnancy-exposure hazard.

Although a relationship between these health hazards and OR exposure has been established by the National Study, a cause-effect response to the anesthetic gases remains to be confirmed in man. There are, however, consistent animal data to establish this possibility.

From a practical point of view, and on the assumption that anesthetic gases are causal, the important consideration is whether this individual has been working in a scavenged OR. Efficient scavenging systems remove 90 to 95% of the anesthetic gases formerly present. Since in the experimental animal the concentrations producing fetal resorptions are at least a factor of 10 away from those trace anesthetic-gas concentrations present in a scavenged OR, one may presume that scavenging offers a reasonable degree of safety.

In view of the increased incidence of congenital abnormality in the children of exposed OR personnel, one might be especially cautious with the woman who is in an increased risk category. Thus, a family history of congenital abnormality might suggest the importance of the added precaution of her removal from the OR several months prior to and during the first trimester of pregnancy. The advisability of such a move for the normal individual working in a scavenged OR is debatable. Thus, if our nurse has no positive family history, our recommendation would be for her to continue her work, but make certain that anesthetic gas scavenging is efficiently practiced.

QUESTION: *I am not a purist, but as a physician brought up (in Canada) to respect the nuances of the King's (or Queen's) English, I am puzzled by the frequent encounters in "the literature" with* metabolism *used as a synonym for* destruction *or* biodegradability. *I was taught that metabolism is a function of a living organism. I*

can find no authority (Oxford English Dictionary, Oxford International Dictionary, Merriam-Webster International, Stedman's Medical Dictionary, Dorland's Medical Dictionary) that recognizes substitution of metabolism *for* catabolism *when meaning the degradation of an inorganic drug or other product. I would appreciate the opinion of your editorial associates.*

MD, Toronto

ANSWER #1: According to Stedman's Medical Dictionary (22nd edition, 1972), "Metabolism . . . consists of anabolism, or those energy consuming processes that convert small molecules into large (eg, amino acids to proteins), and catabolism, or those energy producing processes that convert large molecules into small (eg, glycogen to pyruvic acid)." Consequently, the questioner is right, as far as being a purist, in that metabolism refers to both the processes involved in the synthesis of tissue and in the processes involved in the breakdown or degradation of tissue. However, when one is talking about biodegradation of a drug, obviously, the use of metabolism refers to the subdivision of catabolism rather than the subdivision of anabolism. I would think that the substitution of this word for the other word is not something that should seriously interfere with the reader's understanding of the published articles on the subject.

Robert G. Merin, MD
Department of Anesthesia
University of Rochester Medical School
Rochester, New York

* * *

ANSWER #2: The term metabolism has come to mean the sum total of all the enzymatic reactions that occur in an organism. This definition, while very general, would include the obtaining of chemical energy for the needs of the cell, as occurs when the endogenous or nutrient chemicals are broken down, the conversion of nutrient chemicals from one form to another, and the synthesis of larger molecules such as proteins, etc, from the smaller endogenous or nutrient chemicals. Thus, metabolism includes both *anabolism*, which means the synthesis of a larger molecule from smaller components, and *catabolism*, meaning the breakdown of a larger molecule into smaller parts. This is easily understandable in terms of endogenous and nutrient chemicals, but in recent years the term metabolism has been expanded to include the metabolism of foreign chemicals, including drugs.

It is true that in many instances the term metabolism has been used to mean the breakdown or catabolism of a compound, and this is still within the definition of metabolism, since catabolism is a part of metabolism. In addition, many drugs or foreign chemicals that enter the biologic system also undergo an increase in size of molecule by conjugation of one type or another; thus, drug metabolism involves anabolism as well. It is not important what size the final product of drug metabolism is, the important consideration is that it loses its biologic activity and this can be accomplished in some cases by catabolism and in some by anabolism. Thus, the term "degradation" may refer as much to loss of biologic activity as to size of molecule.

Therefore, the term metabolism is appropriate when referring to the enzymatic transformations undergone by foreign chemicals or drugs as well as nutrient chemicals, because it covers, generally, all such transformations of these chemicals, whether by degradation or enlargement of the molecule.

Oxygen Measurements in Biology and Medicine—Edited by J. P. Payne, MB, ChB, DA, FFARCS, and D. W. Hill, MSc, PhD, FInstP, FIEE, London, Butterworths, 1975, 415 pp.

This book consists of a series of presentations by a select group of workers and investigators. Although it hardly represents an up-to-the-minute definition of the "state of the art," it does provide the clinician with an overview of the major problems associated with oxygen measurement and the directions various researchers are taking toward solutions.

The first session of the symposium deals with some of the intricacies of oxygen transport and presumes a fairly detailed knowledge of the subject on the part of the reader. The subsequent seven sessions deal with various items of hardware used in oxygen measurements, along with a clear statement, in most instances, of the advantages and shortcomings of each. Each session is followed by a transcript of the discussion of the previous papers by the symposium participants. These exchanges are interesting and entertaining, since the editor has preserved the feelings of enthusiasm, doubt, sarcasm, and respect characteristic of such free-flowing, spontaneous discussion among experts.

Even though the volume does not qualify entirely as a reference work, it is sufficiently complete to provide the reader with a good idea of where we are in oxygen measurement and where we are likely to go.

Childbirth, A Joy—Not Suffering—Abouleish, Ezzat, M.D., Philadelphia, Dorrance & Company, 1975, 110 pages, price $2.95.

This little book was written by Dr. Abouleish to describe to the expectant mother the various methods of obstetric anesthesia. The terminology is simple and allows a layperson to understand the book easily and to read it in a short period of time. Most of the chapters are presented in question-and-answer format. Many of the questions most frequently asked by women are answered. Fears and misconceptions about anesthesia are handled well by the author.

The book briefly discusses physiologic changes during pregnancy, stages of labor, and the anatomy involved in parturition. The psychology and physiology of pain during childbirth are discussed, as is the supportive role of the father. Types of anesthesia described include paracervical, pudendal, spinal, epidural, and caudal block, as well as general anesthesia and analgesia. The advantages and disadvantages of each type of anesthetic procedure are compared. Also included are short chapters on natural childbirth and on hypnosis and acupuncture for the control of pain. Anesthesia and indications for cesarean section are discussed.

While epidural block is discussed well and is obviously the preference of Dr. Abouleish for childbirth, he also clearly points out that no one method of analgesia is good for all parturients under all circumstances.

A Guide for Authors

Anesthesia and Analgesia . . . Current Researches invites manuscripts on subjects pertinent to the specialty of Anesthesia.

Send manuscripts and illustrations in *triplicate* to:

T. H. Seldon, MD, Editor
Kahler East, Suite C
Rochester, Minnesota 55901

Four categories of reports will be considered for publication.

1. Original articles describing clinical or laboratory research.

2. Brief Reports describing new anesthetic technics, equipment, clinical, or laboratory studies.

3. Case Reports.

4. Letters-to-the-Editor.

EDITORIAL POLICIES

Peer review.—All papers submitted are reviewed by selected referees with respect to validity, pertinence, completeness, and originality. If accepted for publication, editorial revisions may be made to aid clarity and understanding. Edited copy will be submitted to authors for approval before the paper goes to the printer. Pageproofs also will be submitted to the authors for final approval. Reprint order forms will accompany pageproofs.

Cover letter.—A letter must accompany each manuscript, stating that the work has not been simultaneously submitted to another journal or previously published in part or whole. The name and address of the author to whom correspondence may be directed should be given.

Legal and ethical considerations.—Information or illustrations which might permit identification of patients must not be used.

Reports describing data from experiments performed on humans must contain a statement in the Methods section, when appropriate, that written informed consent and/or institutional approval of the investigation has been obtained, and that procedures involving the use of animals was conducted so as to minimize discomfort.

Excerpts from material published elsewhere must be accompanied by written permission from the author and publisher to reproduce the material.

JOURNAL STYLE

Format.—All portions of the manuscript should be typewritten and double-spaced, including lists of reference citations. Each component of the paper (title page, with authors' academic rank and addresses, Introduction, Methods, Results, Discussion, References, Legends) should begin on a separate page. Original articles must be preceded by an Abstract concisely describing the purpose, methods, results, and conclusions. Abstracts should not exceed 1 typewritten page in length. Brief Reports and Case Reports do not require an Abstract, but a Summary at the end may be appropriate.

Original articles should be concise (not over 3000 words) and present new information pertinent to anesthesia. Preliminary reports or fragments of material that may better be included in a single, more detailed, report should not be submitted. Brief Reports describing new equipment or technics should present new advances, with advantages over the alternatives. Descriptions of new equipment must be sufficient to permit the reader to either construct or purchase the equipment. Case Reports should emphasize important clinical conditions or variations in typical patient responses. Letters-to-the-Editor must be brief (250-500 words) and should offer constructive comments on

recently published articles or discuss areas of general interest to anesthesiologists.

Measurement units.—The metric system should be used for all such data as length, mass, volume, and temperatures. Torr should be used in place of mm Hg for partial pressures. Authors are encouraged to adopt the International System of units (moles per liter rather than mg percent) for concentrations or amounts of substances. (See Padmore GRA, Nunn JF: SI Units in relation to anaesthesia. A review of the present position. Br J Anaesth 46:236-243, 1974).

Drug names.—Generic or chemical drug names are required. Brand names may be inserted in parentheses after the generic name, if pertinent.

Abbreviations.—The first time an abbreviation appears it should be preceded by the full word it represents.

Respiratory symbols.—Symbols for respiratory physiology should be defined the first time used and should follow Pappenheimer J et al: Standardization of definitions and symbols in respiratory physiology. Fed Proc 9:602-605, 1950.

References.—References should correspond to Index Medicus style and should be listed in the same numerical order as they appear in the text. Reports that are not accessible to all readers or that have not undergone editorial review (abstracts, correspondence, or personal communications) should not be included in numerical listings but may be footnoted. They should include pertinent addresses as well as source and authors' names.

Illustrations.—Drawings and photographs (unmounted glossy prints) should be numbered in order of appearance in the manuscript and labeled on the back with the first author's name and indicate the top edge of the picture.

Tables.—These should carry a title or caption and should supplement, not duplicate, the text.

Ref: Corneal Injuries During General Anesthesia. Anesthesia and Analgesia, Vol. 54, No. 4, July-August, 1975

Protect patients' eyes with

OPTI-GARD™

Why tape eyelids shut and risk skin abrasion, loss of eyelashes, and contact dermatitis? Dupaco Opti-Gard,™ for use during general anesthesia and post-op recovery, effectively and comfortably helps prevent corneal abrasion, lacerations, and scleral hemorrhage. Opti-Gard™ also protects against blood, fluid, or other foreign materials entering the eyes . . . a vital consideration in ENT, head, or neck surgery. Sterile packaged and boxed in convenient dispenser, Opti-Gard™ clear plastic protective covers come with self adhesive foam cushion. **Send for free sample.**

RALS POWER UNIT

. . . INSTANT ATOMIZATION FOR FAST TOPICAL ANESTHESIA

Fast, measured topical anesthesia is ready at your finger tips in a Rals Power Unit. Forget about pumping bulbs, uneven atomization, and limited spraying duration. The Rals Power Unit uses a non-toxic propellant, dichlorodifluoromethane (freon) to activate standard DeVilbiss Atomizers No's. 151, 152 and 163. Instantly, a fine mistlike spray is produced. A graduated solution vial is available for measuring the amount of solution administered.

The Rals Power Unit has been proven effective in cocainization prior to endotracheal intubation, endoscopic instrumentation, laryngotracheal insufflation, and in a variety of nose and throat procedures.

Rals Power Unit #168 are supplied six to a box with adaptor top and metal base. Illustration shows #152 atomizer. All styles in stock.

In 16 years of use in the United States, FLUOTHANE (halothane) has been administered over 100 million times in a wide variety of surgical procedures. 100 million . . . extensive usage and evaluation that attests to FLUOTHANE as the most widely used inhalant anesthetic.

Since it was first introduced, over 4,000 papers worldwide have been published, ranging from review articles to in-depth studies. 4,000 papers . . . a bibliographic record of note on the most widely used inhalant anesthetic.

In a continuing program of informational services on anesthesiology, Ayerst provides printed and audiovisual aids reflecting the opinions and experiences of recognized authorities in the field. These include the highly regarded series on *Anesthesia Rounds* and *Clinical Aspects of Anesthesiology*, as well as several films of educational value—all available through your Ayerst Representative.

FLUOTHANE® (HALOTHANE) ...OVER 100 MILLION ADMINISTRATIONS

- nonflammable, nonexplosive
- permits use of high concentrations of oxygen
- allows free use of cautery for more adequate control of bleeding
- minimal odor facilitates smooth, rapid induction, reduces patient distress
- early obtundation of pharyngeal and laryngeal reflexes facilitates intubation
- lessens airway problems
- permits rapid adjustment of depth of anesthesia
- emergence is rapid and tranquil with quick recovery of protective reflexes
- minimal nausea and vomiting, shorter recovery room stay

Ayerst®

See last page of advertisement for prescribing information.

FLUOTHANE®

brand of halothane

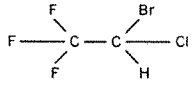
the most widely used inhalant anesthetic

from **Ayerst**

for precision, experience, quality, and service

(Complete text of package circular.)

Description. FLUOTHANE, brand of halothane, is an inhalation anesthetic. It is 2-bromo-2-chloro-1, 1, 1-trifluoroethane and has the following structural formula:



The specific gravity is 1.872-1.877 at 20° C., and the boiling point (range) is 49° C.-51° C. at 760 mm. Hg. The vapor pressure is 243 mm. Hg at 20° C. The blood/gas coefficient is 2.5 at 37° C., and the olive oil/water coefficient is 220 at 37° C. Vapor concentrations within anesthetic range are nonirritating and have a pleasant odor. FLUOTHANE is nonflammable, and its vapors mixed with oxygen in proportions from 0.5 to 50 per cent (v/v) are not explosive.

FLUOTHANE does not decompose in contact with warm soda lime. When moisture is present, the vapor attacks aluminum, brass, and lead, but not copper. Rubber, some plastics, and similar materials are soluble in FLUOTHANE; such materials will deteriorate rapidly in contact with FLUOTHANE vapor or liquid. Stability of FLUOTHANE is maintained by the addition of 0.01 per cent thymol (w/w), and storage is in amber colored bottles.

FLUOTHANE should not be kept indefinitely in vaporizer bottles not specifically designed for its use. Thymol does not volatilize along with FLUOTHANE, and therefore accumulates in the vaporizer, and may, in time, impart a yellow color to the remaining liquid or to wicks in vaporizers. The development of such discoloration may be used as an indicator that the vaporizer should be drained and cleaned, and the discolored FLUOTHANE (halothane) discarded. Accumulation of thymol may be removed by washing with diethyl ether. After cleaning a wick or vaporizer, make certain all the diethyl ether has been removed before reusing the equipment to avoid introducing ether into the system.

Actions. FLUOTHANE is an inhalation anesthetic. Induction and recovery are rapid and depth of anesthesia can be rapidly altered. FLUOTHANE progressively depresses respiration. There may be tachypnea with reduced tidal volume and alveolar ventilation. FLUOTHANE is not an irritant to the respiratory tract, and no increase in salivary or bronchial secretions ordinarily occurs. Pharyngeal and laryngeal reflexes are rapidly obtunded. It causes bronchodilation. Hypoxia, acidosis, or apnea may develop during deep anesthesia.

FLUOTHANE reduces the blood pressure, and frequently decreases the pulse rate. The greater the concentration of the drug, the more evident these changes become. Atropine may reverse the bradycardia. FLUOTHANE does not cause the release of catecholamines from adrenergic stores. FLUOTHANE also causes dilation of the vessels of the skin and skeletal muscles.

Cardiac arrhythmias may occur during FLUOTHANE anesthesia. These include nodal rhythm, AV dissociation, ventricular extrasystoles and asystole. FLUOTHANE sensitizes the myocardial conduction system to the action of epinephrine and norepinephrine, and the combination may cause serious cardiac arrhythmias. FLUOTHANE increases cerebral spinal fluid pressure. FLUOTHANE produces moderate muscular relaxation. Muscle relaxants are used as adjuncts in order to maintain lighter levels of anesthesia. FLUOTHANE augments the action of nondepolarizing relaxants and ganglionic blocking agents. FLUOTHANE is a potent uterine relaxant.

Indications. FLUOTHANE (halothane) is indicated for the induction and maintenance of general anesthesia.

Contraindications. FLUOTHANE is not recommended for obstetrical anesthesia except when uterine relaxation is required.

Warnings. When previous exposure to FLUOTHANE was followed by unexplained jaundice, consideration should be given to the use of other agents.

FLUOTHANE should be used in vaporizers that permit a reasonable approximation of output, and preferably of the calibrated type. The vaporizer should be placed out of circuit in closed circuit rebreathing systems; otherwise overdosage is difficult to avoid. The patient should be closely observed for signs of overdosage, *i.e.*, depression of blood pressure, pulse rate, and ventilation, particularly during assisted or controlled ventilation.

Usage in Pregnancy: Safe use of FLUOTHANE has not been established with respect to possible adverse effects upon fetal development. Therefore, FLUOTHANE should not be used in women where pregnancy is possible and particularly during early pregnancy, unless, in the judgment of the physician, the potential benefits outweigh the unknown hazards to the fetus.

Precautions. The uterine relaxation obtained with FLUOTHANE, unless carefully controlled, may fail to respond to ergot derivatives and oxytocic posterior pituitary extract.

FLUOTHANE increases cerebrospinal fluid pressure. Therefore, in patients with markedly raised intracranial pressure, if FLUOTHANE is indicated, administration should be preceded by measures ordinarily used to reduce cerebrospinal fluid pressure. Ventilation should be carefully assessed, and it may be necessary to assist or control ventilation to insure adequate oxygenation and carbon dioxide removal.

Epinephrine or norepinephrine should be employed cautiously, if at all, during FLUOTHANE (halothane) anesthesia since their simultaneous use may induce ventricular tachycardia or fibrillation.

Nondepolarizing relaxants and ganglionic blocking agents should be administered cautiously, since their actions are augmented by FLUOTHANE.

Adverse Reactions. The following adverse reactions have been reported: hepatic necrosis, cardiac arrest, hypotension, respiratory arrest, cardiac arrhythmias, hyperpyrexia, shivering, nausea, and emesis.

Dosage and Administration. FLUOTHANE may be administered by the nonrebreathing technic, partial rebreathing, or closed technic. The induction dose varies from patient to patient. The maintenance dose varies from 0.5 per cent to 1.5 per cent.

FLUOTHANE may be administered with either oxygen or a mixture of oxygen and nitrous oxide.

How Supplied. No. 3125—Unit packages of 125 cc. and 250 cc. of halothane stabilized with 0.01% thymol (w/w).

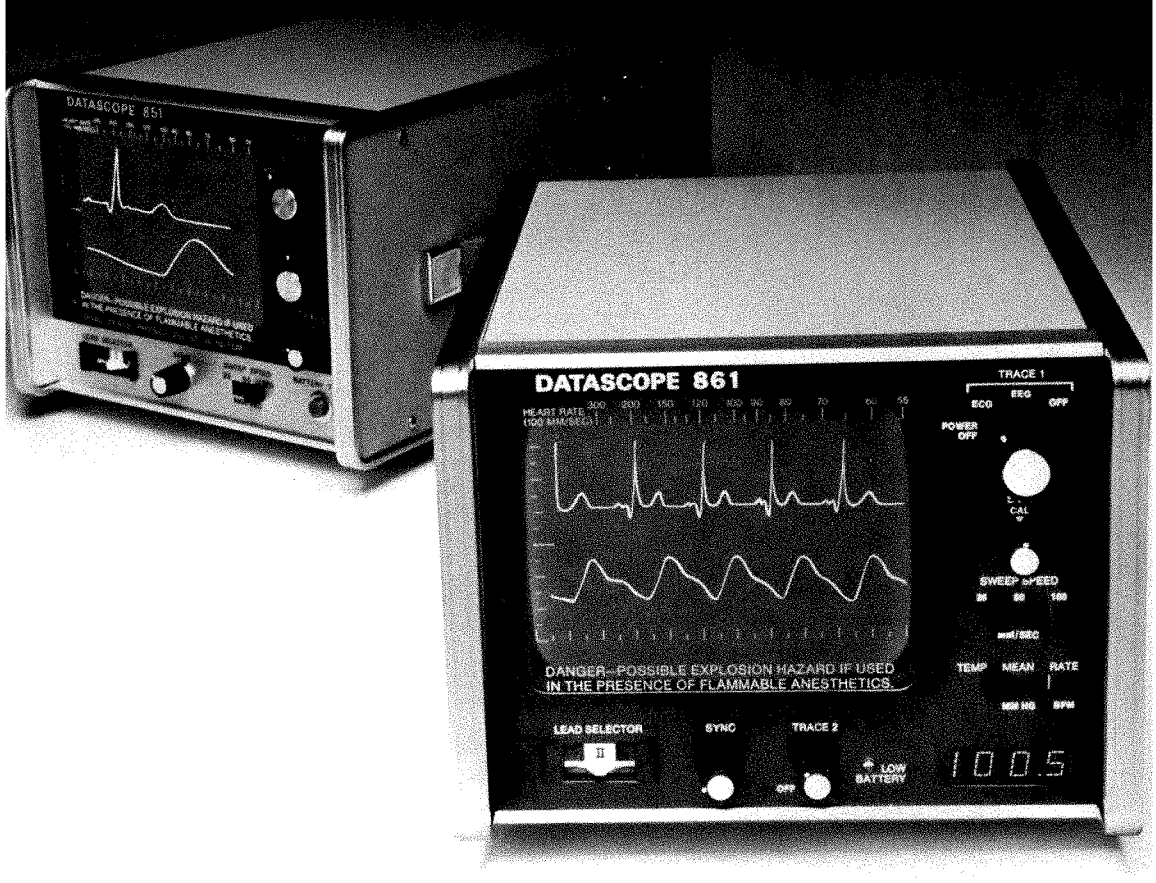
New York, N.Y. 10017

THE MOST POPULAR MONITORS MADE. MADE EVEN BETTER.



For some time now, our monitors have been selected for use in surgery by more medical people than any other battery-powered monitors in the world. Because we give you more of what you want in a monitor than any other monitors in the world.

However, this didn't stop us from improving them.

Our new Datascope 851 and 861 will now give you heart rate not only from ECG, but also from pulse or blood pressure.

And both monitors will give you 2 traces. So you can monitor ECG (or EEG) and pulse simultaneously.

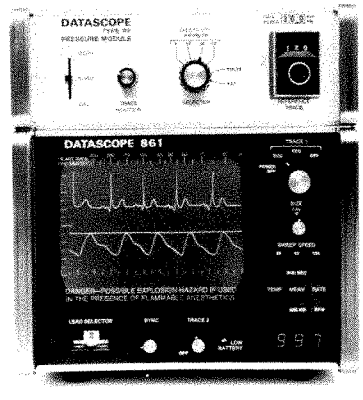
And both give you beat by beat synchronization†. So a single ECG complex shows up with each full sweep.

The 861 does even more. It monitors body temperature. On a digital read-out. And this same digital display will give you heart rate when you want it; or mean blood pressure when you are using the 861 with our Pressure Module.

For all the things our 851 and 861 do, they're surprisingly portable. And they offer longer battery-operating time than any other monitors. In some cases, actually twice as long.

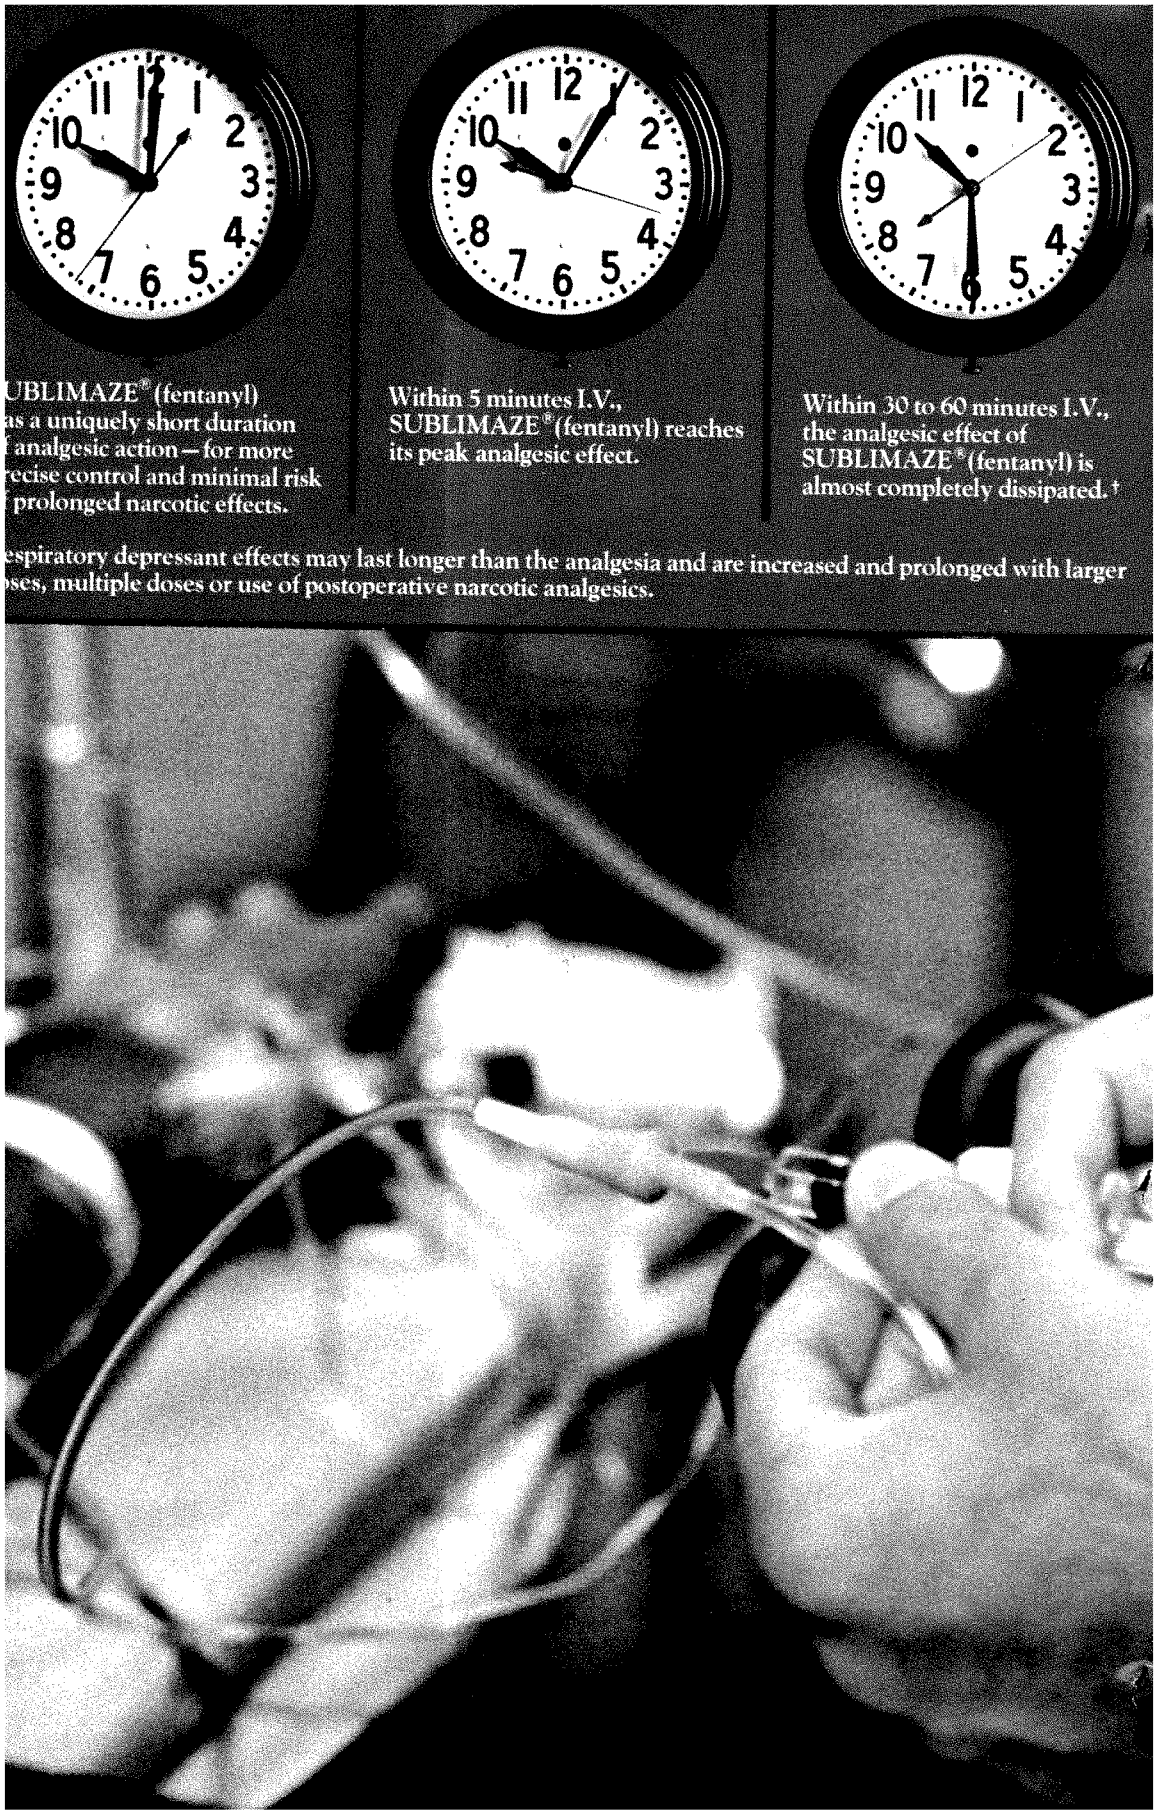
Will they continue to be the most popular monitors made? More so.

For further information about our new 851, 861, or our Pressure Module, write Datascope Corp., 580 Winters Ave., Paramus, NJ 07652.



The 861 with Pressure Module.

THE DATASCOPE 851/861



UBLIMAZE® (fentanyl)
as a uniquely short duration
f analgesic action—for more
recise control and minimal risk
prolonged narcotic effects.
Within 5 minutes I.V.,
SUBLIMAZE® (fentanyl) reaches
its peak analgesic effect.
Within 30 to 60 minutes I.V.,
the analgesic effect of
SUBLIMAZE® (fentanyl) is
almost completely dissipated.†
espiratory depressant effects may last longer than the analgesia and are increased and prolonged with larger
oses, multiple doses or use of postoperative narcotic analgesics.

For potent narcotic analgesic action with rapid onset and short duration:

SUBLIMAZE fentanyl provides profound analgesia without hypnosis and with little or no sedation. With this analgesia as a foundation, it is possible to use light general anesthesia in most cases.

SUBLIMAZE fentanyl is particularly suited for maintenance of analgesia after INNOVAR® injection* has been used for induction. It may also be used preoperatively, during surgery with any common general or regional anesthetic agent, and in the immediate postoperative period whenever the need for potent analgesic action arises.

SUBLIMAZE fentanyl is available both alone and as a component of INNOVAR injection.*

*INNOVAR injection is composed of a 50:1 mixture of droperidol 2.5 mg./cc. and fentanyl 0.05 mg./cc., with lactic acid for adjustment of pH to 3.5 ± 0.3.

SUBLIMAZE® (fentanyl) offers:

☐ Almost immediate analgesia—peak effect within 5 minutes I.V., 8 minutes I.M.

☐ Short duration of analgesic action—30 to 60 minutes with a single I.V. dose of up to 0.1 mg. (Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with larger doses, multiple doses or use of postoperative narcotic analgesics.)

☐ No evidence of liver, heart, or kidney toxicity—expecially valuable in poor-risk patients. However, the drug should be administered cautiously in the presence of liver or kidney dysfunction or cardiac arrhythmias, and the dose should be appropriately reduced in poor-risk patients.

☐ Immediate reversibility by narcotic antagonists.

☐ Little or no histamine release—decreasing the risk of cardiovascular instability.

☐ Minimal emetic effect—has been used successfully to prepare nonfasting patients for awake intubation.

☐ Prevention or reversal of emergence delirium and tachypnea.

SUBLIMAZE® (fentanyl) injection

0.05 mg./cc. as the citrate.
Warning: May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0—7.5

INNOVAR® injection and SUBLIMAZE® (fentanyl) injection are available for use only upon direction of a physician. For information relating to Contraindications, Warnings, Precautions and Adverse Reactions for SUBLIMAZE fentanyl, please turn page.

© McNeil Laboratories, Inc., 1974

SUBLIMAZE® (fentanyl) injection

Description
Each cc. contains:
Fentanyl as the citrate ..... 0.05 mg.
Warning—May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0–7.5

FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY.

Actions SUBLIMAZE fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. SUBLIMAZE fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. SUBLIMAZE fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays and skin wheal testing in man, as well as *in vivo* testing in dogs, indicate that histamine release rarely occurs with SUBLIMAZE fentanyl.

SUBLIMAZE fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of SUBLIMAZE fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours.

Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics it may be considerably longer than the analgesic effect.

Indications SUBLIMAZE fentanyl is indicated:
—for analgesic action of short duration during the anesthetic periods, premedication, induction, and maintenance, and in the immediate postoperative period (recovery room) as the need arises.
—for use as a narcotic analgesic supplement in general or regional anesthesia.
—for administration with a neuroleptic such as INAPSINE® (droperidol) injection as an anesthetic premedication, for the induction of anesthesia and as an adjunct in the maintenance of general and regional anesthesia.

Contraindications SUBLIMAZE fentanyl is contraindicated in patients who are hypersensitive to the drug.

Warnings PATIENTS WHO HAVE RECEIVED *SUBLIMAZE* FENTANYL SHOULD HAVE APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

If SUBLIMAZE fentanyl is administered with a tranquilizer such as INAPSINE droperidol, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action. In addition, when such a combination is used *fluids and other countermeasures to manage hypotension should be available.*

As with other potent narcotics, the respiratory depressant effect of SUBLIMAZE fentanyl persists longer than the measured analgesic effect. The total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, should be used in reduced doses initially, as low as 1/4 to 1/3 those usually recommended. A neuromuscular blocking agent compatible with the patient's condition may be required to control muscle rigidity which may develop with the use of SUBLIMAZE fentanyl.

Drug Dependence: SUBLIMAZE fentanyl can produce drug dependence of the morphine type and therefore has the potential for being abused.

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl in this regard has not been established, the use of SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: SUBLIMAZE fentanyl should be used with caution in patients who may be particularly susceptible to respiratory depression, such as comatose patients who may have a head injury or brain tumor. In addition, SUBLIMAZE fentanyl may obscure the clinical course of patients with head injury.

Usage in Children: The safety of SUBLIMAZE fentanyl in children younger than two years of age has not been established.

Usage in Pregnancy: The safe use of SUBLIMAZE fentanyl has not been established with respect to possible adverse effects upon fetal development. Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects; therefore, safety for the infant in obstetrics has not been established.

Precautions *The initial dose of SUBLIMAZE fentanyl should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and some peridural anesthetics, can alter respiration by blocking intercostal nerves. Through other mechanisms (see Actions) SUBLIMAZE fentanyl can also alter respiration. When SUBLIMAZE fentanyl is used to supplement these forms of anesthesia, the anesthetist should be familiar with the physiological alterations involved, and be prepared to manage them in the patients selected for these forms of anesthesia. When used with a tranquilizer such as INAPSINE droperidol, blood pressure may be altered and hypotension can occur.

Vital signs should be monitored routinely.

SUBLIMAZE fentanyl should be used with caution in patients with chronic obstructive pulmonary disease, patients with decreased respiratory reserve, and others with potentially compromised respiration. In such patients, narcotics may additionally decrease respiratory drive and increase airway resistance. During anesthesia, this can be managed by assisted or controlled respiration. Postoperatively, respiratory depression caused by narcotic analgesics can be reversed by narcotic antagonists (levallorphan, nalorphine, and naloxone; consult individual prescribing information before using). Should respiration be compromised by muscle rigidity, assisted or controlled respiration and possibly a neuromuscular blocking agent will be required. The occurrence of muscle rigidity is related to the speed of intravenous injection and the incidence can be reduced by slow intravenous injection.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, pulmonary arterial pressure may be decreased. This fact should be considered by those who conduct diagnostic and surgical procedures where interpretation of pulmonary arterial pressure measurements might determine final management of the patient.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, and general anesthetics) will have additive or potentiating effects with SUBLIMAZE fentanyl. When patients have received such drugs, the dose of SUBLIMAZE fentanyl required will be less than usual. Likewise, following administration of SUBLIMAZE fentanyl the dose of other CNS depressant drugs should be reduced.

SUBLIMAZE fentanyl should be administered with caution to patients with liver and kidney dysfunction because of the importance of these organs in the metabolism and excretion of drugs.

SUBLIMAZE fentanyl may produce bradycardia, which may be treated with atropine; however, SUBLIMAZE fentanyl should be used with caution in patients with cardiac bradyarrhythmias.

When SUBLIMAZE fentanyl is used with a tranquilizer such as INAPSINE droperidol, hypotension can occur. If this occurs the possibility of hypovolemia should also be considered and managed with appropriate parenteral fluid therapy. Repositioning the patient to improve venous return to the heart should be considered when operative conditions permit. Care should be exercised in moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus other countermeasures do not correct hypotension, the administration of pressor agents other than epinephrine should be considered. Because of the alpha-adrenergic blocking action of INAPSINE droperidol, epinephrine may paradoxically decrease the blood pressure in patients treated with INAPSINE droperidol.

Adverse Reactions As with other narcotic analgesics, the most common serious adverse reactions reported to occur with SUBLIMAZE fentanyl are respiratory depression, apnea, muscular rigidity, and bradycardia; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Other adverse reactions that have been reported are hypotension, dizziness, blurred vision, nausea, emesis, laryngospasm, and diaphoresis.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, the following adverse reactions can occur: chills and/or shivering, restlessness, and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression); extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have been observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with antiparkinson agents. Postoperative drowsiness is also frequently reported following the use of INAPSINE droperidol.

Overdosage ***Manifestations:*** The manifestations of SUBLIMAZE fentanyl overdosage are an extension of its pharmacologic actions.
Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered and managed with appropriate parenteral fluid therapy. A specific narcotic antagonist such as nalorphine, levallorphan, or naloxone should be available for use as indicated to manage respiratory depression. This does not preclude the use of more immediate countermeasures. Consult the package insert for the individual narcotic antagonists for details about use.

How Supplied SUBLIMAZE® (fentanyl) injection is supplied in 2 cc. (**NDC** 0045-0180-03) and 5 cc. (**NDC** 0045-0180-05) ampuls, in packages of 12.

IMPORTANT: Complete dosage information is available in insert which accompanies each package (or on request). The drug is available only upon direction of a physician.

MOSBY
TIMES MIRROR

Prepare now for those critical moments. . .

Rely on two new Mosby references for the most current techniques, knowledge, and skills of respiratory therapy and clinical respiratory physiology

A New Book! **RESPIRATORY THERAPY IN CRITICAL CARE.** *By Hugh S. Mathewson, M.D.* This concise volume describes the skills and functions required of respiratory therapists in the critical care situation. Emphasizing the team approach to critical care, the author details team organization and allocation of tasks. Special attention is given to the functions of therapists. The second section of the book discusses the procedures required in many specific critical care situations and covers particular problems in patient management. Diagnostic respiratory function tests are included. September, 1976. Approx. 176 pp., 14 illus. **About $6.95.**

New 3rd Edition! **RESPIRATORY PHYSIOLOGY.** *By N. Balfour Slonim, M.D., Ph.D. and Lyle H. Hamilton, Ph.D.* Now in paperback, this clinically oriented book continues to present basic respiratory physiology in a brief and clear manner. Specialty areas, such as respiratory physiology in lung disease, respiration of the newborn, and respiration in altered environments are thoroughly discussed. New material examines factors affecting oxygen transport by hemoglobin, tests used to detect small airway disease, and mechanically assisted and controlled ventilation. June, 1976. 255 pp., 89 illus. **Price, $9.75.**

Update an old friend.

With the new universal SLICK™ STYLETTE endotracheal tube guide.

The old familiar way of intubating is not necessarily the better way. The better way to prepare for the unexpected during the critical period of induction and to increase the rate of successful first attempt intubations is to routinely use SLICK STYLETTE. Its non-friction coating eliminates the need for additional lubrication, and the stop-lock controls the extent of its advancement into the endotracheal tube. These features, plus its versatility and malleability reduce the difficulties encountered with normal anatomical variations, such as a small mouth, protruding teeth or bull neck as well as pathological obstacles.

Why not update your procedure with the addition of the SLICK STYLETTE as a standard part of your intubation pack—so it's always there when you need it?

Disposable Slick Stylette is packaged in a sterile Tyvek Mylar peel-away package. Fits all sizes and types of tubes from 3.5mm pediatric to 10.5mm adult.

Reg. U.S. Pat. Off.

Evaluation sample and literature on request.

The anesthesia system without compromises is the one you design for yourself. Including Ohio keepables and disposables!

VORTEX® Respiration Monitor measures tidal volumes continuously, totalizes to obtain minute volume.

Disposable Endotracheal Tubes, new, uncuffed or with anatomically designed cuffs for gentle seal. Unique inflation and pilot balloon assembly.

Disposable Anesthesia Breathing Circuit with conductive, cushioned masks in three sizes. Our bacteria filter-pathogen trap fits most anesthesia circuits.

OHIO Critical Care Ventilator with intermittent mandatory ventilation "engineered in." Assists ventilation in any interval from 5 to 100 seconds.

Anesthesia Ventilator, fluidically controlled for less maintenance. Precise and reliable. With a built-in gas evacuator. Ohio can also customize a gas evacuation interface to accommodate your disposal system.

O_2 Monitor with visual and audio alarms.

One system designed to suit all can't really satisfy veryone. Because somewhere along the line you have ɔ compromise. Each of you has your own ideas about ıow best to provide excellence in patient care in your ›wn operating theater. And each OR has its unique ıeeds.

Most new systems begin with one of the four OHIO® ınesthesia machines. Rugged. Practical. Versatile. Functional. Delivering your preference in anesthetic ıgents with accuracy and safety.

Then, your system grows to support your skills and echniques, as you add accessories and options from Ohio: Vaporizers, ventilators and absorbers, monitors, disposables, medical gases, and gas evacuation ;ystems. And we always have more on the way.

You can depend on over 100 factory-trained Ohio servicemen and six service centers in the U.S. and Canada to keep your anesthesia equipment performing. Plus a knowledgeable sales staff.

Send for information. Or send for your salesman. Ohio will help you develop a reliable, sophisticated anesthesia system. One you can build on when future technologies develop. So, you'll never have to compromise in caring for your patients.

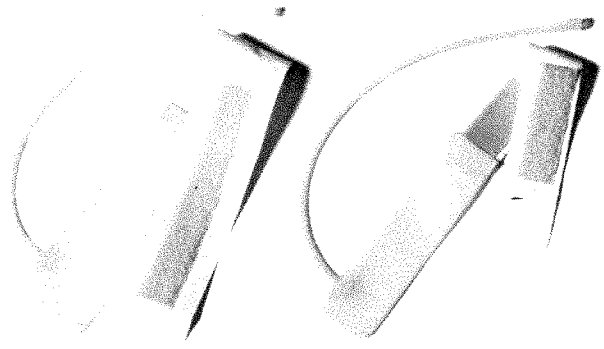
New Trace Gas Analyzer detects and measures the concentration of nitrous oxide in the operating room atmosphere; alerting OR personnel to leak sources.

The tender touch



These soft, pliable blood pressure cuffs are ideal for use on newborns and infants. Incorporating a Latex bladder, minimizing any chances for skin irritation, and Silicon wrap-around with 12-inch inflating tube. They are secured by the Velcro hook and pile method, with no eyes to hook nor ends to tuck in. They are instantly peeled apart for easy removal.

Cuffs are available in two sizes:
22080 - 1⅜ x 5" (new born)
22081 - 2¼ x 6" (infant)

For additional information write for brochure number 27.

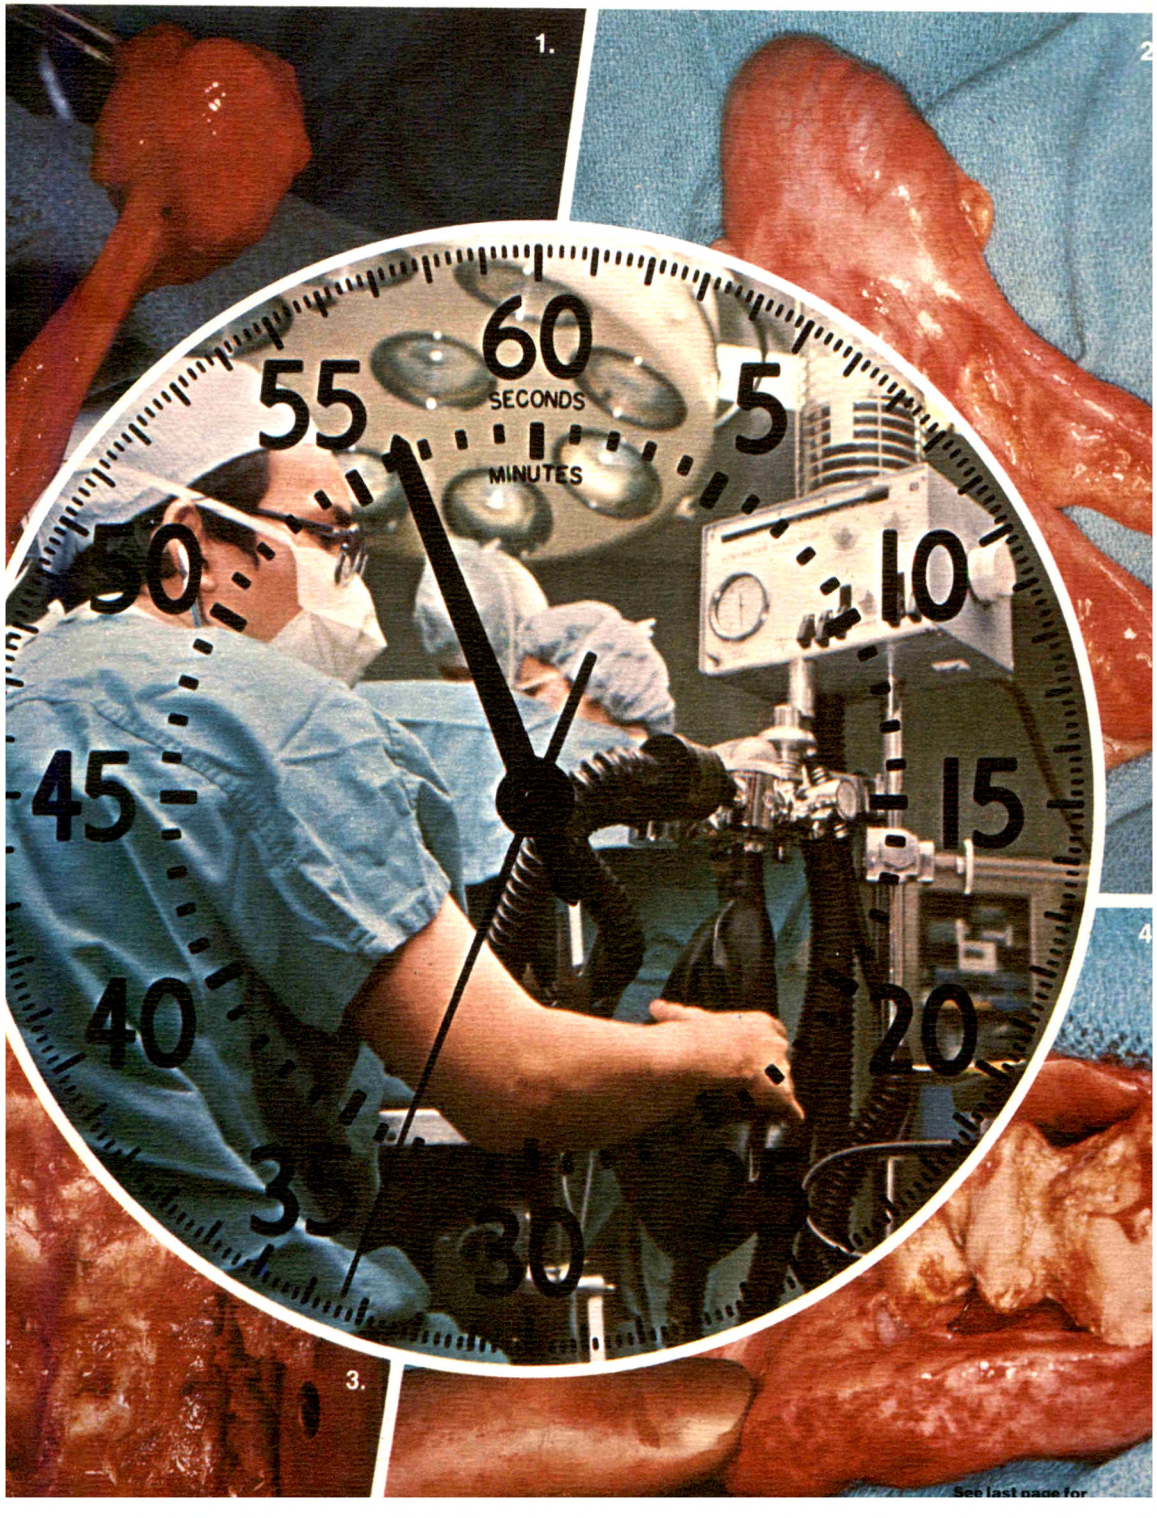
If the Procedure Takes 40 Minutes or More...

You Can Proceed with PAVULON®

pancuronium bromide

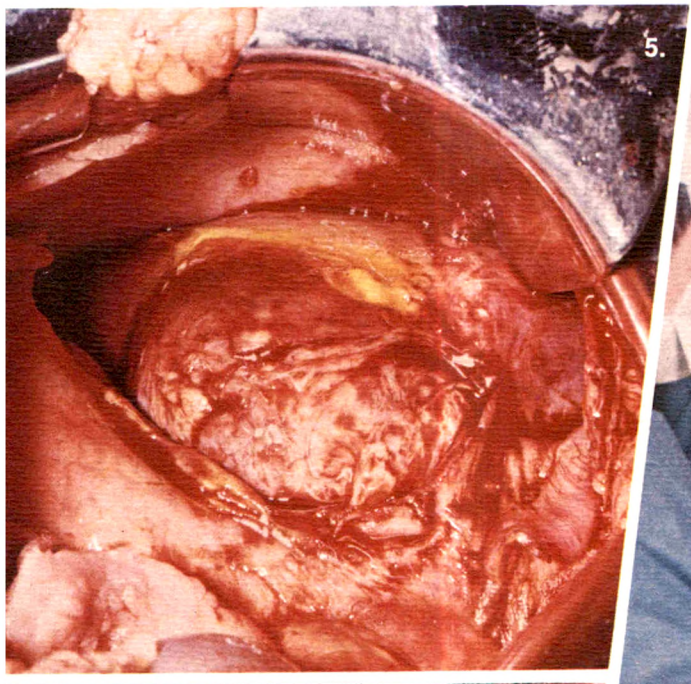


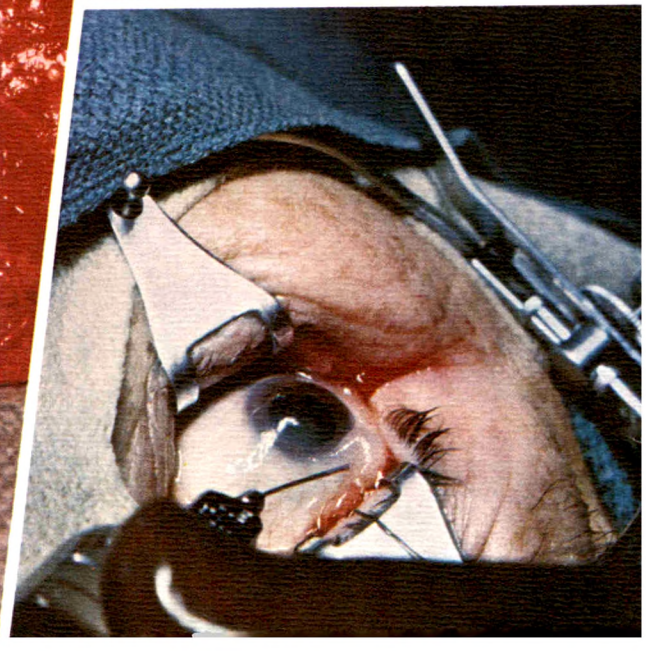
See last page for

Proceed with PAVULON

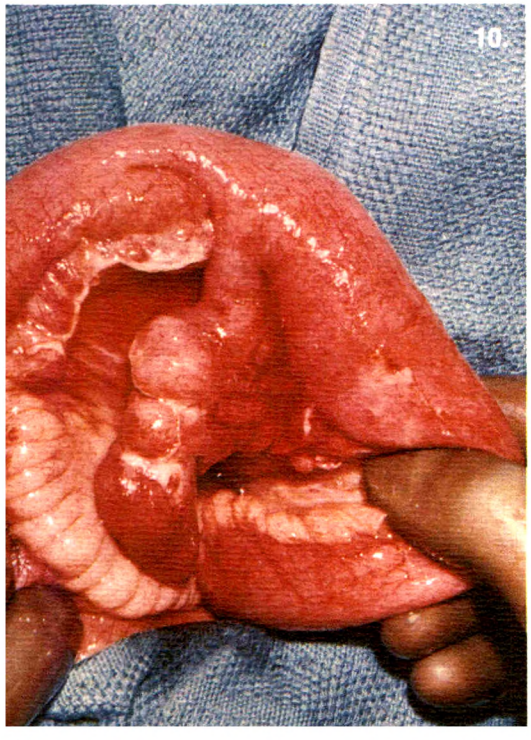
pancuronium bromide

for optimal neuromuscular blockade





No matter where the surgeon's incision



—whatever the part of the body, or the age of the patient, or the cause of surgery, or the system or systems involved —there's a good chance that Pavulon can provide easy, uncomplicated, optimal, neuromuscular blockade.

Initial doses of Pavulon, given to facilitate endotracheal intubation, take effect in approximately 45 seconds and reach their peak at about 2-3 minutes. Once effective blockade is established, it can be maintained with incremental doses of 1 mg or less.

Pavulon is well tolerated, even in the very old, the very young and the very fragile. Histamine release rarely, if ever, occurs; there is little, if any, ganglionic blockade and little effect upon the circulatory system other than an occasional slight rise in pulse rate and blood pressure. There is no muscle pain, no known effects on consciousness, pain threshold or cerebration.

With proper procedure, reversal of Pavulon is relatively simple and generally uneventful. An appropriate antagonist, such as pyridostigmine bromide, can be used. With adequate dosage of the reversal agent, there is relatively little risk of recurarization. In cases of prolonged respiratory depression, other factors (drug interaction, acidosis, hypokalemia, etc.) should be considered.

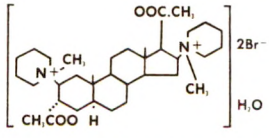
Proceed with PAVULON®

pancuronium bromide

clinically proven nondepolarizing muscle relaxant

THIS DRUG SHOULD ONLY BE ADMINISTERED BY ADEQUATELY TRAINED INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS, AND HAZARDS.

DESCRIPTION: Pavulon (pancuronium bromide) is the aminosteroid 2 beta, 16 beta-dipiperidine-5 alpha-androstane-3 alpha, 17-beta-diol diacetate dimethobromide. It has the following structural formula:



ACTIONS: Pavulon is a non-depolarizing neuromuscular blocking agent possessing all of the characteristic pharmacological actions of this class of drugs (curariform) on the myoneural junction.

Pavulon is approximately 5 times as potent as d-tubocurarine chloride.

The onset and duration of action of Pavulon is dose dependent. With the administration of 0.04 mg. per kg. the onset of action, as measured by a peripheral nerve stimulator, is usually within 45 seconds, and its peak effect is usually within 4½ minutes; recovery to 90% of control twitch height usually takes place in less than one hour. Larger doses, more suitable for endotracheal intubation, such as 0.08 mg. per kg. of Pavulon have an onset of action of about 30 seconds, and a peak effect within 3 minutes. Supplemental incremental doses of Pavulon, following the initial dose, slightly increase the magnitude of blockade, and significantly increase the duration of the blockade.

Pavulon has little effect upon the circulatory system. The most frequently reported observation is a slight rise in pulse rate.

Human histamine assays, and clinical observations, as well as in *vivo* guinea pig testing, and in *vitro* mast cell testing, indicate that histamine release rarely, if ever, occurs.

Pavulon (pancuronium bromide) is antagonized by acetylcholine, anticholinesterases, and potassium ion. Its action is increased by inhalational anesthetics such as halothane, diethyl ether, enflurane and methoxyflurane, as well as quinine, magnesium salts, hypokalemia, some carcinomas, and certain antibiotics such as neomycin, streptomycin, clindamycin, kanamycin, gentamicin and bacitracin. The action of Pavulon may be altered by dehydration, electrolyte imbalance, acid-base imbalance, renal disease, and concomitant administration of other neuromuscular agents.

Pavulon has no known effect on consciousness, the pain threshold, or cerebration.

INDICATIONS: Pavulon is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may also be employed to facilitate the management of patients undergoing mechanical ventilation.

CONTRAINDICATIONS: Pavulon is contraindicated in patients known to be hypersensitive to the drug or to the bromide ion.

WARNINGS: PAVULON SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS, WHO ARE FAMILIAR WITH ITS ACTIONS AND THE POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND REVERSAL AGENTS ARE IMMEDIATELY AVAILABLE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR CONTROL RESPIRATION.

In patients who are known to have myasthenia gravis small doses of Pavulon may have profound effects. A peripheral nerve stimulator is especially valuable in assessing the effects of Pavulon in such patients.

USAGE IN PREGNANCY: The safe use of pancuronium bromide has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards.

Pavulon may be used in operative obstetrics (Cesarean section), but reversal of pancuronium may be unsatisfactory in patients receiving magnesium sulfate for toxemia of pregnancy, because magnesium salts enhance neuromuscular blockade. Dosage should usually be reduced, as indicated, in such cases.

PRECAUTIONS: Although Pavulon has been used successfully in many patients with pre-existing pulmonary, hepatic, or renal disease, caution should be exercised in these situations. This is particularly true of renal disease since a major portion of administered Pavulon is excreted unchanged in the urine.

ADVERSE REACTIONS: Neuromuscular: the most frequently noted adverse reactions consist primarily of an extension of the drug's pharmacological actions beyond the time period needed for surgery and anesthesia. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle relaxation resulting in respiratory insufficiency or apnea. Inadequate reversal of the neuromuscular blockade by anticholinesterase agents has also been observed with Pavulon (pancuronium bromide) as with all curariform drugs. These adverse reactions are managed by manual or mechanical ventilation until recovery is judged adequate.

Cardiovascular: A slight increase in pulse rate is frequently noted.

Gastrointestinal: Salivation is sometimes noted during very light anesthesia, especially if no anticholinergic premedication is used.

Skin: An occasional transient rash is noted accompanying the use of Pavulon.

Respiratory: One case of wheezing, responding to deepening of the inhalational anesthetic, has been reported.

DRUG INTERACTION: The intensity of blockade and duration of action of Pavulon is increased in patients receiving potent volatile inhalational anesthetics such as halothane, diethyl ether, enflurane and methoxyflurane. No increase in intensity of blockade or duration of action of Pavulon is noted from the use of thiobarbiturates, narcotic analgesics, nitrous oxide, or droperidol.

Prior administration of succinylcholine, such as that used for endotracheal intubation, enhances the relaxant effect of Pavulon and the duration of action. If succinylcholine is used before Pavulon, the administration of Pavulon should be delayed until the succinylcholine shows signs of wearing off.

DOSAGE AND ADMINISTRATION: Pavulon should be administered only by or under the supervision of experienced clinicians. DOSAGE MUST BE INDIVIDUALIZED IN EACH CASE. The dosage information which follows has been derived from dose-response studies based on body weight and is intended to serve as a guide only. Since potent inhalational agents or prior administration of succinylcholine enhance the intensity of blockade and duration of Pavulon (see DRUG INTERACTION), these factors should be taken into consideration in selection of initial and incremental dosage.

In adults the initial intravenous dosage range is 0.04 to 0.1 mg. per kg. Later incremental doses starting at 0.01 mg. per kg. may be used. These increments slightly increase the magnitude of the blockade, and significantly increase the duration of blockade, because a significant number of myoneural junctions are still blocked when there is clinical need for more drug.

If Pavulon is used to provide skeletal muscle relaxation for endotracheal intubation, doses of 0.06 to 0.1 mg. per kg. are recommended. Conditions satisfactory for intubation are usually present within 2 to 3 minutes. The ability of the anesthetist to intubate with Pavulon improves with experience.

Dosage in Children: Dose response studies in children indicate that, with the exception of neonates, dosage requirements are the same as for adults. Neonates are especially sensitive to non-depolarizing neuromuscular blocking agents, such as Pavulon, (pancuronium bromide) during the first month of life. It is recommended that a test dose of 0.02 mg. per kg. be given first in this group to measure responsiveness.

Cesarean Section: The dosage to provide relaxation for intubation and operation is the same as for general surgical procedures. The dosage to provide relaxation, following usage of succinylcholine for intubation (see DRUG INTERACTION), is the same as for general surgical procedures.

MANAGEMENT OF PROLONGED NEUROMUSCULAR BLOCKADE: Residual neuromuscular blockade beyond the time period needed for surgery and anesthesia may occur with Pavulon as with other neuromuscular blockers. This may be manifested by skeletal muscle weakness, decreased respiratory reserve, low tidal volume or apnea. A peripheral nerve stimulator may be used to assess the degree of residual neuromuscular blockade. Under such circumstances the primary treatment is manual or mechanical ventilation and maintenance of a patent airway until complete recovery of normal respiration is assured. Regonol (pyridostigmine bromide) or neostigmine, in conjunction with atropine, will usually antagonize the skeletal muscle relaxant action of Pavulon. These should be accompanied by or preceded by injection of atropine sulfate to minimize the incidence of cholinergic side effects, notably excessive secretions and bradycardia. Satisfactory reversal can be judged by adequacy of skeletal muscle tone, and by adequacy of respiration. A peripheral nerve stimulator may also be used to monitor restoration of twitch height. Failure of prompt reversal (within 30 minutes) may occur in the presence of extreme debilitation, carcinomatosis, and with concomitant use of certain broad spectrum antibiotics, or anesthetic agents and adjuncts which enhance neuromuscular blockade or cause respiratory depression of their own. Under such circumstances the management is the same as that of prolonged neuromuscular blockade; ventilation must be supported by artificial means until the patient has resumed control of his respiration. Prior to the use of reversal agents, reference to the specific package insert of the reversal agents should be made.

CAUTION: Federal law prohibits dispensing without prescription.

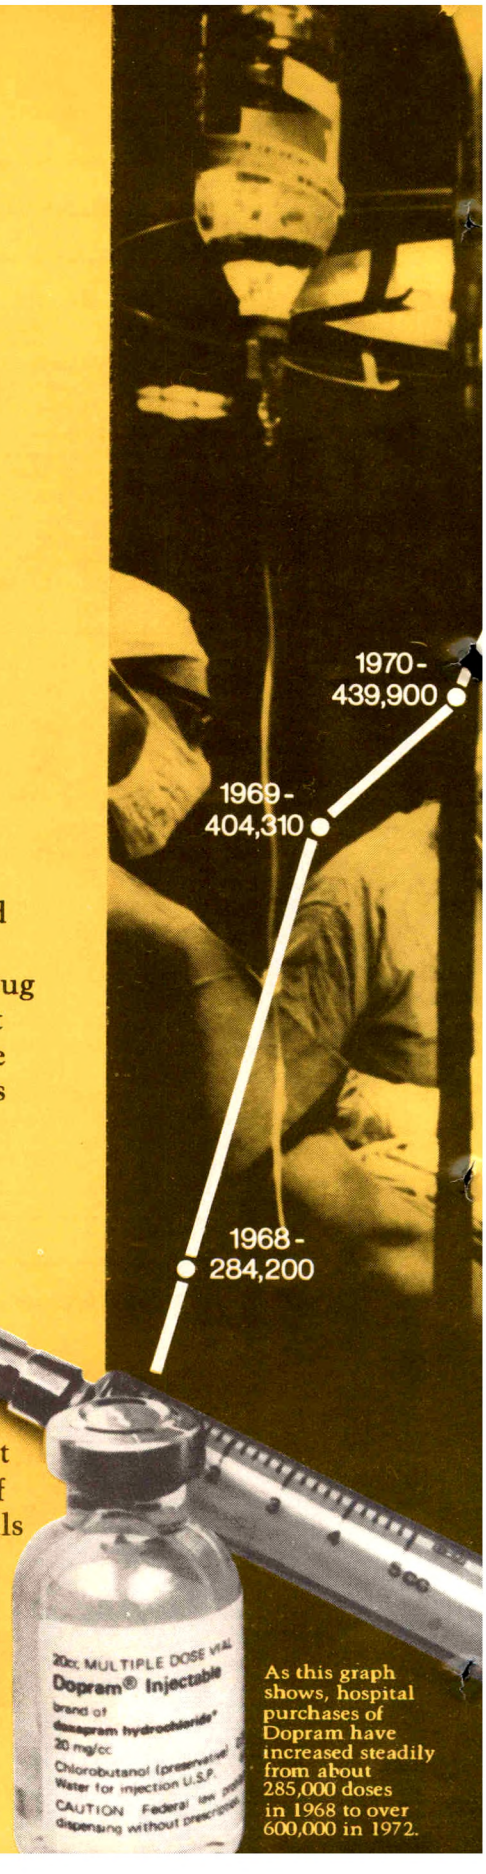
n all types of hospitals
ross the United States,
s usage grows–

Dopram®
njectable
doxapram HCl)

Seven years ago, A. H. Robins introduced Dopram, a unique respiratory stimulant developed in the company's research laboratories. What made this drug so useful to the anesthesiologist was its ability to rapidly restore the respiratory drive in patients with drug-induced post anesthetic depression.

Usage of Dopram has been steadily increasing each year, until today it has become a very important drug in the armamentarium of more than 1,500 hospitals of all types in all 50 states, the District of Columbia, and a number of foreign countries. These hospitals purchased more than 600,000 doses in 1972 alone.

Dopram–an important drug in anesthesiology. Try it for sighs!



As this graph shows, hospital purchases of Dopram have increased steadily from about 285,000 doses in 1968 to over 600,000 in 1972.

...imulate respiration in patients with drug induced post-anesthetic respiratory depression or apnea other than that due to muscle relaxant drugs.
2. To pharmacologically stimulate deep breathing in the so-called "stir-up" regimen in the post-operative patient. Simultaneous administration of oxygen is desirable.
3. To hasten arousal and return of protective pharyngeal and laryngeal reflexes.
4. To aid in the differential diagnosis of post-anesthetic respiratory depression. Failure to adequately stimulate respiration suggests residual muscle relaxant effect.
5. To stimulate respiration, hasten arousal and to encourage the return of laryngopharyngeal reflexes in patients with mild to moderate respiratory and CNS depression due to drug overdosage.

Contraindications—Epilepsy and other convulsive states: incompetence of the ventilatory mechanism due to muscle paresis, flail chest, pneumothorax, airway obstruction, and extreme dyspnea; severe hypertension and cerebrovascular accidents; hypersensitivity.

Doxapram is not recommended for patients 12 years of age or under because studies to evaluate its safety and efficacy have not been performed.

Warnings—Doxapram is an analeptic agent; it is neither an antagonist to muscle relaxant drugs nor a specific narcotic antagonist. Since doxapram has an acid pH, it should not be mixed with alkaline solutions such as thiopental sodium.

Since narcosis may recur after stimulation with doxapram, care should be taken to maintain close observation until the patient has been fully alert for 1/2 to 1 hour. (Duration of drug 5-12 minutes.)

Doxapram is an adjunct to well-accepted supportive measures and resuscitative techniques. It may not stimulate adequate spontaneous breathing or provide sufficient arousal in patients who are severely depressed with CNS depressant drugs.

When doxapram is administered to postoperative patients or to patients in a state of narcosis with chronic pulmonary insufficiency, oxygen should be administered concomitantly. Failure to do so may result in further oxygen debt and more severe dyspnea due to the increased work of breathing.

Doxapram should be administered with great care and only under close supervision to patients with cerebral edema, bronchial asthma, severe tachycardia, cardiac arrhythmia, cardiac disease, hyperthyroidism and pheochromocytoma.

Usage in pregnancy

No adequate clinical studies have been performed to determine the safe use of doxapram in pregnancy. Until further clinical experience has been obtained, the physician must weigh the need against possible risks in using the drug in pregnant patients or in women of child-bearing potential.

Precautions—Recommended dosages of doxapram should be employed and maximum total dosages should not be exceeded. In patients with advanced pulmonary disease with hypoxemia, marked respiratory stimulation increases the work of breathing and may, thus, increase oxygen consumption and carbon dioxide production.

With excessive dosage, hyperventilation induced by doxapram may lead to respiratory alkalosis and hypocapnia with tetany and, theoretically, apnea.

An adequate airway is essential. In order to avoid side effects, it is advisable to use the minimum effective dosage. Monitoring of the blood pressure and deep tendon reflexes is recommended to prevent overdosage.

It is desirable that blood gases (P_{O_2} P_{CO_2} O_2 saturation) be monitored to assess the effectiveness of respiratory stimulation.

Intravenous barbiturates, oxygen and resuscitative equipment should be readily available to manage overdosage manifested by excessive central nervous system stimulation. Slow administration of the drug and careful observation of the patient during administration and for some time subsequently are advisable to insure restoration of the protective reflexes. The possibility of post-[illegible] depression must be kept in mind. In patients who have been lightly curarized, doxapram may temporarily mask the residual effects of muscle relaxant drugs.

Doxapram should be administered cautiously to patients receiving sympathomimetic or monoamine oxidase inhibiting drugs, since a synergistic pressor effect may occur. It should likewise be used with care in post-operative patients with marked dyspnea due to obstructive pulmonary emphysema, acute or chronic asthma, profound metabolic disorders, severe to moderately severe hypertension, increased cerebrospinal fluid pressure, head injury and acute agitation.

Since doxapram may stimulate basal gastric secretion, it should be used with care in patients with peptic ulcer disease and in patients undergoing gastric surgery.

Vascular extravasation or use of a single injection site over an extended period should be avoided since either may lead to thrombophlebitis.

Hypocapnia accompanying forced ventilation is a potent stimulus to cerebral vasoconstriction; it may be postulated that some element of risk may exist from reduced cerebral blood flow following prolonged and intensive hyperventilation.

Since an increase in epinephrine release has been noted with doxapram, it is recommended that initiation of therapy with this respiratory stimulant be delayed for at least 10 minutes following the discontinuance of anesthetics known to sensitize the myocardium to catecholamines, such as halothane and cyclopropane.

As with other intravenous preparations, all precautions should be taken during administration of doxapram to insure that injection is made directly into a suitable vein; extravasation, and inadvertent intra-arterial injection should be avoided.

Adverse reactions—The following adverse reactions have been reported: *Central and Autonomic Nervous Systems.* Hyperactivity feeling of warmth, sweating, muscle tremor, clonus, increased deep tendon reflexes, dizziness, muscle spasticity, pyrexia, confusion, paresthesia, pupillary dilatation, pilomotor erection, headache, bilateral babinski, fasciculation and carpopedal spasm. A grand mal seizure occurred 95 minutes after drug administration in a known epileptic patient who was on anticonvulsant medication.

Respiratory. Cough, dyspnea, laryngospasm bronchospasm and hiccough.

Cardiovascular. Hypertension, sinus tachycardia, bradycardia, extrasystoles, lower T-waves, premature ventricular contractions, irregular heart rhythm, tightness in chest. Although a mild to moderate increase in blood pressure is not infrequent, such an increase may occasionally be of concern in hypertensive patients.

Gastrointestinal. Nausea and/or vomiting, salivation, stimulation of lower bowel, sour taste.

Genitourinary. Urinary retention, stimulation of urinary bladder with spontaneous voiding.

Miscellaneous. Pruritus, thrombophlebitis.

Laboratory Determinations. A decrease in hemoglobin, hematocrit, or red blood cell count has been observed in postoperative patients. In the presence of pre-existing leukopenia, a further decrease in WBC was observed following anesthesia and treatment with doxapram hydrochloride. Elevation of BUN and albuminuria have been observed.

In some of the cases cited above, the patients had received multiple drugs concomitantly, thus preventing an absolute judgment as to the role of doxapram in these reactions.

Dosage—For complete information concerning dosage and administration see package insert.

Supply—Dopram (doxapram hydrochloride) is available in 20 cc rubber-stoppered vials containing 20 mg/cc, with chlorobutanol 0.5% as the preservative.

A. H. Robins Company
Richmond, Virginia 23220

A·H·ROBINS

ANECTINE®
(succinylcholine chloride)
For controlled muscle relaxation adjunctive to anesthesia:

FLO-PACK® for prolonged relaxation

- instant-mix sterile powder interfaces with all major parenteral systems (vacuum or nonvacuum)
- each unit complete—no needle or syringe needed
- retains potency indefinitely
- no refrigeration required
- unbreakable, sterile plastic injection units of 500 and 1,000 mg

INJECTION for short-term relaxation

- a product of choice for intubation and other short procedures
- unique square bottle and bright yellow label for positive identification
- ready for immediate use
- 20 mg per cc . . . in 10 cc multidose vials
- flip-top cap for easy opening
- single or multiple use

ANECTINE®
(succinylcholine chloride)
THE LONG AND SHORT of surgical muscle relaxation

THIS DRUG SHOULD BE USED ONLY BY INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS AND HAZARDS.

DESCRIPTION: Anectine brand Succinylcholine Chloride is an ultra short-acting depolarizing type muscle relaxant. Chemically it is a di-quaternary base consisting of the di-chloride salt of the di-choline ester of succinic acid. It is a white, odorless, slightly bitter powder and very soluble in water. The drug is unstable with alkaline solutions, but relatively stable in acid solutions depending upon the concentration of the solution and the storage temperature. While solutions of succinylcholine chloride are sterilized by autoclaving, they should, nevertheless, be stored under refrigeration to preserve their potency.

INDICATIONS: Succinylcholine chloride is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may be employed to reduce the intensity of muscle contractions of pharmacologically or electrically induced convulsions.

CONTRAINDICATIONS: Succinylcholine is contraindicated for persons with a known hypersensitivity to the drug.

WARNINGS:

WARNING: SUCCINYLCHOLINE SHOULD BE USED ONLY BY THOSE SKILLED IN THE MANAGEMENT OF ARTIFICIAL RESPIRATION AND ONLY WHEN FACILITIES ARE INSTANTLY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND FOR PROVIDING ADEQUATE VENTILATION OF THE PATIENT, INCLUDING THE ADMINISTRATION OF OXYGEN UNDER POSITIVE PRESSURE AND THE ELIMINATION OF CARBON DIOXIDE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR TO CONTROL RESPIRATION.

Succinylcholine should not be mixed with short-acting barbiturates in the same syringe, or administered simultaneously during intravenous infusion through the same needle. Solutions of succinylcholine have an acid pH whereas those of barbiturates are alkaline in reaction. Depending upon the resultant pH of a mixture of solutions of these drugs, either free barbituric acid may be precipitated or succinylcholine hydrolyzed.

Usage in Pregnancy. The safe use of succinylcholine has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards.

PRECAUTIONS: Low levels of, or abnormal variants of plasma cholinesterase may be associated with prolonged respiratory depression or apnea following the use of succinylcholine. Low levels of plasma cholinesterase may occur in patients with severe liver disease or cirrhosis, severe anemia, malnutrition, severe dehydration, changes in body temperature, exposure to neurotoxic insecticides or those receiving antimalarial drugs. Succinylcholine should be administered with extreme care to such patients and dosage should be minimal. If low plasma cholinesterase activity is suspected, a small test dose of from 5 to 10 mg of succinylcholine may be administered, or relaxation may be produced by the cautious administration of a 0.1% solution of the drug by intravenous drip. Drugs which either inhibit plasma cholinesterase, such as neostigmine or phospholine iodide, or compete with succinylcholine for the enzyme, as does intravenous procaine, should not be given concurrently with succinylcholine.

Succinylcholine should be administered with great caution to patients with severe burns, those recovering from severe trauma, those suffering from electrolyte imbalance, those receiving quinidine, those who have been digitalized recently or who may have digitalis toxicity as serious cardiac arrhythmias or cardiac arrest may result. Great caution should be observed also in patients with pre-existing hyperkalemia or who are paraplegic, have suffered spinal neuraxis injury, or have degenerative or dystrophic neuromuscular disease, or such patients tend to become severely hyperkalemic when succinylcholine is given.

When succinylcholine is given over a prolonged period of time, the characteristic depolarization block of the myoneural junction may change to a non-depolarizing block which results in prolonged respiratory depression or apnea. Under such circumstances, small repeated doses of neostigmine may possibly act as an antagonist. A peripheral nerve stimulator (e.g., the Wellcome Peripheral Nerve Stimulator) may be used to ascertain the type of neuromuscular blockade. If a depolarization block is present both fast (tetanic) and slow (twitch) rates of nerve stimulation are well sustained, and post-tetanic facilitation is absent. If a non-depolarizing block is present there is post-tetanic facilitation and "fade" of successive stimuli on both fast (tetanic) and slow (twitch) rates of nerve stimulation.

Succinylcholine should be used with caution during ocular surgery and in patients with glaucoma. The drug should be employed with caution in patients with fractures or muscle spasm as the muscle fasciculations may cause additional trauma. Muscle fasciculations and hyperkalemia may be reduced by administering a small dose of a non-depolarizing relaxant. If other relaxants are to be used during the same procedure, the possibility of a synergistic or antagonistic effect should be considered.

During the past few years, reports have called attention to a fulminant syndrome, malignant hyperthermia, observed during anesthesia. Its etiology is not fully understood. Malignant hyperthermia occurs in genetically prone individuals of all ages and both sexes receiving potent anesthetics such as halothane, methoxyfluorothane, cyclopropane and diethyl ether. It appears to develop irrespective of the concomitant use of a muscle relaxant, but may be triggered by succinylcholine. Because of the seriousness of this syndrome and the need for early effective treatment of the patient, it is suggested that the continuous monitoring of the temperature will serve as an aid to the early recognition of malignant hyperthermia.

ADVERSE REACTIONS: Adverse reactions consist primarily of an extension of the drug's pharmacological actions. Profound and prolonged muscle relaxation may occur, resulting in respiratory depression to the point of apnea. Hypersensitivity to the drug may exist in rare instances.

The following adverse reactions have been reported: bradycardia, tachycardia, hypertension, hypotension, arrhythmias, cardiac arrest, prolonged respiratory depression or apnea, hyperthermia, increased intraocular pressure, muscle fasciculation, postoperative muscle pain, myoglobinemia and excessive salivation.

MANAGEMENT OF ADVERSE REACTIONS: Apnea or prolonged muscle paralysis should be treated with controlled respiration.

The use of neostigmine to reverse a non-depolarization block is a medical decision which must be made upon the basis of the individual clinical pharmacology and the experience and judgment of the clinician. When neostigmine is used atropine should also be administered.

SUPPLIED: Injection, Multi-dose vials, 20 mg/cc, 10 cc, boxes of 12 vials. Flo-Pack® Sterile Powder 500 mg and 1,000 mg, boxes of 12.

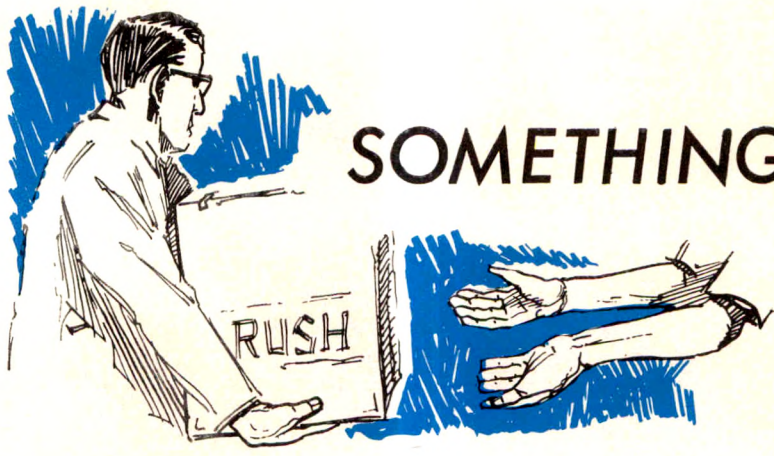
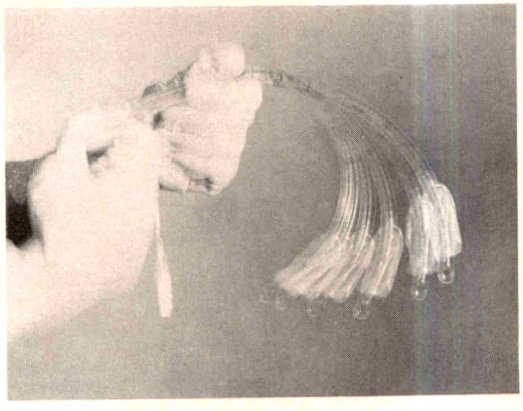
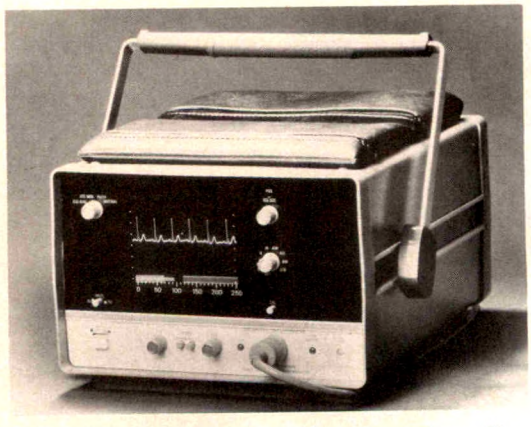
Wellcome
Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709





National Catheter Corporation, Argyle, New York, has available the ENDOTROL, an endotracheal tube designed to provide directional tip control for difficult nasal and/or oral intubations. This tube features the hi-lo® cuff to minimize tracheal damage, a Murphy tip and eye with x-ray marker, a pilot balloon and mechanical self-sealing valve. A 15 mm connector is included.

★ ★ ★



Hewlett-Packard, Waltham, Massachusetts, has available two new portable and battery-operated ECG Monitors for operating rooms and monitoring patients in transit, which offer maximum patient and operator protection and minimize display interference from electrosurgery equipment .

The monitors have single-channel, nonfade displays of ECG, pulse or arterial pressure waveforms and bargraph displays of heart rate.

In operating rooms, interference by electrosurgery devices with the monitors' displays are minimized. Special filtering and circuit shielding reject both conducted and radiated energy associated with such radio-frequency (RF) equipment. It is claimed that the likelihood of RF burns at the site of patient electrodes—has been sharply reduced with a special filter in the patient cable.

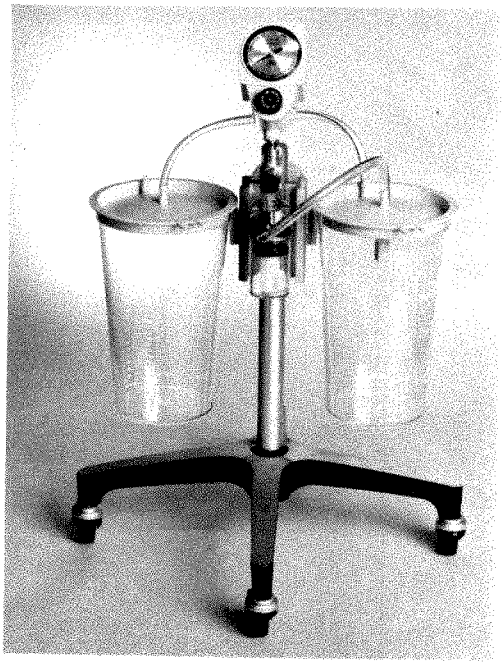
Ohio Medical Products, Madison, Wisconsin, has introduced the OMNI-LAB, a completely automated and self-contained pulmonary function laboratory. The unit tests and computes results to provide accurate and reproducible respiratory diagnostic information.

The integrated Spirometry Module in the OMNI-LAB System has been completely automated to measure and record the patient's Spirogram, Forced Expiratory Vital Capacity (FEVC), Forced Inspiratory Vital Capacity (FIVC) and Maximum Voluntary Ventilation (MVV).

A built-in computer performs all the necessary calculations and calibrations automatically.

An Operator Display provides visual cues to the operator on the appropriate procedures to be followed for each test, and thereby helps insure the proper sequencing of each test. A Patient Display reinforces all operator cues through visual patient instructions. The Patient Display Panel has been incorporated because accurate test results in pulmonary function testing procedures often depend upon the patient's comprehension of precisely what is expected of him.

★ ★ ★



Ohio Medical Products has introduced a Floor Model Suction Bottle Stand for use with the hospital pipeline vacuum systems.

The OHIO Overflow Safety Trap Assembly features a splash deflector to direct incoming fluids to the bottom of the jar, and to act as a seat for the shut-off float for positive overflow protection.

In line with current environmental thinking, Medishield is proud to announce the completion of a totally compatible and comprehensive system which makes pollution-free anaesthesia a reality.

Vital to the concept is the newly-developed Medishield pollution control system. Competitively priced, it features the now well-established anti-pollution valve.

1 Medishield Pollution control system

Precision-engineered to achieve very low resistance to flow, the Medishield anti-pollution system introduces no new anaesthesia technique yet enables waste gases to be safely ducted clear of the theatre. All main components are autoclavable and the system includes a unique feature which gives audible indication of patient respiration.

2 Medishield Manley Servovent

The definitive answer to closed and partial rebreathing circuit techniques. Servo gas consumption is a small fraction of minute volume ventilation while the totally independent servo and patient circuits enable any oil-free available drive gas to be used. The patient circuit can be simply removed in its entirety for sterilization.

A built-in patient safety feature enables spontaneous breathing to take place. The unique fluid logic and patient circuitry give an unprecedented degree of control over tidal volume, inspiratory flow and expiratory time. Any deficiency in gases is automatically compensated by atmospheric air.

3 Medishield Circle Absorber

Utilizing reversible canisters or disposable pre-packs, the Circle Absorber is widely regarded as the finest available. The unique Visidisk system gives at-a-glance confirmation that the valve discs are correctly in place. The absorber is designed for mounting on alternative positions on Boyle tables.

Medishield Boyle International

Now the standard anaesthesia table in many countries of the world, the Boyle International forms a compact, economical foundation for the complete closed-circuit pollution-free anaesthesia station.

When to use the word Phär'mə·sēal.

For components, features, "performance" in single-use anesthesia trays, just say the word.

The trays you've counted on from the start now offer you even more to go on.

Back in 1963 we introduced the world's first single-use, regional anesthesia trays.

Today, with a record of safe performance difficult to equal, we offer you an even wider selection of components and features — just as difficult to match — in spinal, caudal and epidural trays.

All with our all-new spinal needle. The needle that's been called the cleanest spinal needle yet. The one with a cannula with almost uncanny smoothness, a cartridge pack with an exceptional point protector, a matched-ground point, metal hub and more.

Trays that offer you a new fenestrated drape with its own adhesive tabs.

A large, moisture-resistant hospital wrap with a new "wrinkle" for better procedure.

Plus, a specially designed introducer needle, a clear 5-cc. Stylex® syringe, a unique aseptic transfer carton...and a variety of other first-quality components and drugs.

But see for yourself what we're talking about. See the trays with performance you can count on. For samples, just call or write.

You know the word to use.

f You're Confused About O.R. Pollution, Cut It Out.

et a compilation of data on the roblems of trace anesthetic gas nd OR pollution control. Send for ur Positive Response Program.

esides reports and studies to elp you put the problem in erspective, our "PRP" plan of ction provides an up-to-date ook at our products which help ou detect and scavenge trace as in your OR. Key to our pro-ram is the Foregger 410 N_2O race Gas Monitor, a basic equirement for any efficient ace gas monitoring program. 's designed to provide rapid nd continuous sampling of the R air you breathe.

he machine has two sensing odes—Monitor (0-100 ppm) nd Leak Test (0-1,000 ppm). he first mode continuously onitors the ambient air through e gas inlet of the machine. he second permits probing of cal concentrations and sounds repetitive burst alarm as the as concentration increases.

In short, the Foregger 410 N_2O Trace Gas Monitor is a logical first step in solving your OR pollution problem. And there's more. The Scaveng-OR™ Gas Evacuator System, the Protect-OR™ Filter, Wall Suction Systems, and Air-CARE™ Preventive Maintenance Service.

Based on current data, it's likely that routine monitoring of pollution levels and scavenging of waste anesthetic gases will soon be standard Operating Room procedure. We're ready to help you now.

Fill out this ad coupon or ask our Representative for a Foregger PRP Folder. You'll get the problem in perspective and a plan of action to help correct it.

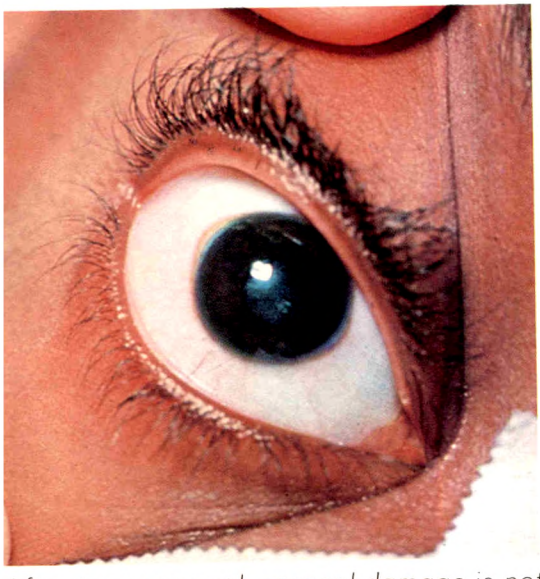
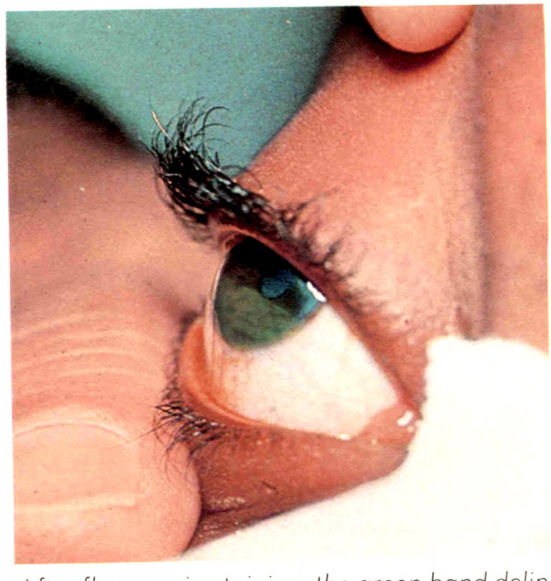
THE UNPROTECTED EYE THAT WAS "PROTECTED" WITH TAPE.



After tape removal, corneal damage is not evident on gross inspection.



After fluorescein staining, the green band delineates area of epithelial injury.

Corneal abrasion...the most common ocular complication of general anesthesia.[1,2] It is painful, may progress to inflammation of the uveal tract, and in the presence of contamination may lead to a serious infection.[1]

This patient's eyes were taped shut and monitored throughout a surgical procedure that lasted several hours. No ocular lubricant was used.[3] The cause of the corneal abrasion is unknown...but it might have been prevented if Lacri-Lube® sterile ophthalmic ointment had been used as an added precaution before the tape was applied.

Lacri-Lube. The first sterile, nonmedicated ophthalmic ointment designed solely to lubricate the eye and protect it against the risk of chemical insult, dehydration, or corneal abrasion.

Whether you tape or not, make Lacri-Lube a part of your standard procedures to minimize the risks of general anesthesia.

LACRI-LUBE®
sterile ophthalmic ointment

In 16 years of use in the United States, FLUOTHANE (halothane) has been administered over 100 million times in a wide variety of surgical procedures. 100 million ...extensive usage and evaluation that attests to FLUOTHANE as the most widely used inhalant anesthetic.

Since it was first introduced, over 4,000 papers worldwide have been published, ranging from review articles to in-depth studies. 4,000 papers... a bibliographic record of note on the most widely used inhalant anesthetic.

In a continuing program of informational services on anesthesiology, Ayerst provides printed and audiovisual aids reflecting the opinions and experiences of recognized authorities in the field. These include the highly regarded series on *Anesthesia Rounds* and *Clinical Aspects of Anesthesiology*, as well as several films of educational value—all available through your Ayerst Representative.

FLUOTHANE® (HALOTHANE) ...OVER 100 MILLION ADMINISTRATIONS

- nonflammable, nonexplosive
- permits use of high concentrations of oxygen
- allows free use of cautery for more adequate control of bleeding
- minimal odor facilitates smooth, rapid induction, reduces patient distress
- early obtundation of pharyngeal and laryngeal reflexes facilitates intubation
- lessens airway problems
- permits rapid adjustment of depth of anesthesia
- emergence is rapid and tranquil with quick recovery of protective reflexes
- minimal nausea and vomiting, shorter recovery room stay

Ayerst

See last page of advertisement for prescribing information.

FLUOTHANE®

brand of halothane

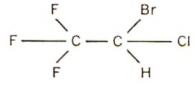
the most widely used inhalant anesthetic

from Ayerst

for precision, experience, quality, and service

(Complete text of package circular.)

Description. FLUOTHANE, brand of halothane, is an inhalation anesthetic. It is 2-bromo-2-chloro-1, 1, 1-trifluoroethane and has the following structural formula:



The specific gravity is 1.872-1.877 at 20° C., and the boiling point (range) is 49° C.-51° C. at 760 mm. Hg. The vapor pressure is 243 mm. Hg at 20° C. The blood/gas coefficient is 2.5 at 37° C., and the olive oil/water coefficient is 220 at 37° C. Vapor concentrations within anesthetic range are nonirritating and have a pleasant odor. FLUOTHANE is nonflammable, and its vapors mixed with oxygen in proportions from 0.5 to 50 per cent (v/v) are not explosive.

FLUOTHANE does not decompose in contact with warm soda lime. When moisture is present, the vapor attacks aluminum, brass, and lead, but not copper. Rubber, some plastics, and similar materials are soluble in FLUOTHANE; such materials will deteriorate rapidly in contact with FLUOTHANE vapor or liquid. Stability of FLUOTHANE is maintained by the addition of 0.01 per cent thymol (w/w), and storage is in amber colored bottles.

FLUOTHANE should not be kept indefinitely in vaporizer bottles not specifically designed for its use. Thymol does not volatilize along with FLUOTHANE, and therefore accumulates in the vaporizer, and may, in time, impart a yellow color to the remaining liquid or to wicks in vaporizers. The development of such discoloration may be used as an indicator that the vaporizer should be drained and cleaned, and the discolored FLUOTHANE (halothane) discarded. Accumulation of thymol may be removed by washing with diethyl ether. After cleaning a wick or vaporizer, make certain all the diethyl ether has been removed before reusing the equipment to avoid introducing ether into the system.

Actions. FLUOTHANE is an inhalation anesthetic. Induction and recovery are rapid and depth of anesthesia can be rapidly altered. FLUOTHANE progressively depresses respiration. There may be tachypnea with reduced tidal volume and alveolar ventilation. FLUOTHANE is not an irritant to the respiratory tract, and no increase in salivary or bronchial secretions ordinarily occurs. Pharyngeal and laryngeal reflexes are rapidly obtunded. It causes bronchodilation. Hypoxia, acidosis, or apnea may develop during deep anesthesia.

FLUOTHANE reduces the blood pressure, and frequently decreases the pulse rate. The greater the concentration of the drug, the more evident these changes become. Atropine may reverse the bradycardia. FLUOTHANE does not cause the release of catecholamines from adrenergic stores. FLUOTHANE also causes dilation of the vessels of the skin and skeletal muscles.

Cardiac arrhythmias may occur during FLUOTHANE anesthesia. These include nodal rhythm, AV dissociation, ventricular extrasystoles and asystole. FLUOTHANE sensitizes the myocardial conduction system to the action of epinephrine and norepinephrine, and the combination may cause serious cardiac arrhythmias. FLUOTHANE increases cerebral spinal fluid pressure. FLUOTHANE produces moderate muscular relaxation. Muscle relaxants are used as adjuncts in order to maintain lighter levels of anesthesia. FLUOTHANE augments the action of nondepolarizing relaxants and ganglionic blocking agents. FLUOTHANE is a potent uterine relaxant.

Indications. FLUOTHANE (halothane) is indicated for the induction and maintenance of general anesthesia.

Contraindications. FLUOTHANE is not recommended for obstetrical anesthesia except when uterine relaxation is required.

Warnings. When previous exposure to FLUOTHANE was followed by unexplained jaundice, consideration should be given to the use of other agents.

FLUOTHANE should be used in vaporizers that permit a reasonable approximation of output, and preferably of the calibrated type. The vaporizer should be placed out of circuit in closed circuit rebreathing systems; otherwise overdosage is difficult to avoid. The patient should be closely observed for signs of overdosage, *i.e.*, depression of blood pressure, pulse rate, and ventilation, particularly during assisted or controlled ventilation.

Usage in Pregnancy: Safe use of FLUOTHANE has not been established with respect to possible adverse effects upon fetal development. Therefore, FLUOTHANE should not be used in women where pregnancy is possible and particularly during early pregnancy, unless, in the judgment of the physician, the potential benefits outweigh the unknown hazards to the fetus.

Precautions. The uterine relaxation obtained with FLUOTHANE, unless carefully controlled, may fail to respond to ergot derivatives and oxytocic posterior pituitary extract.

FLUOTHANE increases cerebrospinal fluid pressure. Therefore, in patients with markedly raised intracranial pressure, if FLUOTHANE is indicated, administration should be preceded by measures ordinarily used to reduce cerebrospinal fluid pressure. Ventilation should be carefully assessed, and it may be necessary to assist or control ventilation to insure adequate oxygenation and carbon dioxide removal.

Epinephrine or norepinephrine should be employed cautiously, if at all, during FLUOTHANE (halothane) anesthesia since their simultaneous use may induce ventricular tachycardia or fibrillation.

Nondepolarizing relaxants and ganglionic blocking agents should be administered cautiously, since their actions are augmented by FLUOTHANE.

Adverse Reactions. The following adverse reactions have been reported: hepatic necrosis, cardiac arrest, hypotension, respiratory arrest, cardiac arrhythmias, hyperpyrexia, shivering, nausea, and emesis.

Dosage and Administration. FLUOTHANE may be administered by the nonrebreathing technic, partial rebreathing, or closed technic. The induction dose varies from patient to patient. The maintenance dose varies from 0.5 per cent to 1.5 per cent.

FLUOTHANE may be administered with either oxygen or a mixture of oxygen and nitrous oxide.

How Supplied. No. 3125—Unit packages of 125 cc. and 250 cc. of halothane stabilized with 0.01% thymol (w/w).

7647

Ayerst **AYERST LABORATORIES**
New York, N.Y. 10017

It works like a magnet; not just a strainer.

lew electrostatic filter element ttracts, traps and holds over 99% f the pathogens found in the nesthesia system. Not just acteria, but viruses as well, *egardless of size.* Tests* prove hat the patented Nicholes "99" is he most practical and effective lter available, affording pro- ection against both infections nd malpractice suits. It is light- veight and multi-directional, and hay be interposed in different ositions within the anesthesia ystem. Its unique filter trap with inimal air resistance eases atient breathing even under ad- erse respiratory conditions or igh relative humidity.

The Complete Circuit.
The finest conductive, disposable anesthesia circuit, it is manufactured to the highest medical standards, at low, competitive prices.

The complete circuit includes two flexible, lightweight breathing tubes, a 3-litre breathing bag and a specially-engineered swivel wye piece for maximum compactness and mobility. Plus the amazingly efficient disposable Nicholes 99 Bacterial and Viral Retentive Filter. Filters and individual components may be ordered separately. Available from your surgical or hospital supply dealer, or call K&G for name of nearest supplier. Dealer inquiries invited. Mail the coupon now.

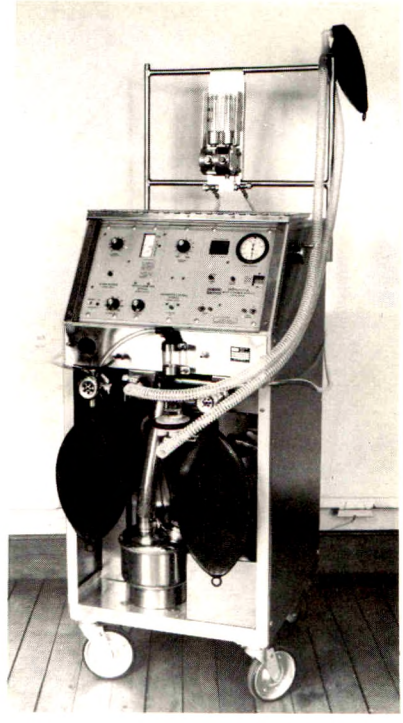
EMERSON IMV *Ventilator*

Intermittent Mandatory Ventilation



Continuous-flow voluntary ventilation, with intermittent forced breaths, is an alternative to assisted or controlled respiration. It has been found especially valuable for infants and for use in "weaning" adults as they improve.

Air fully humidified (and usually enriched with oxygen) flows continuously to a reservoir bag, and is available for unobstructed inspiration by the patient. A slight expiratory back-pressure (PEEP) may be added, to keep the lungs expanded. At intervals the ventilator delivers a "mandatory" breath, which supplements the patient's own breathing activity and increases minute volume. The machine does not have to "take over". The patient maintains his own homeostasis, without interference from drugs or hyperventilation.[1]

At first the ventilator is generally set to supply mandatory breaths at a normal controlled rate. This controlled respiration is then gradually changed, by lengthening the interval between breaths (a second or two at a time) as the patient's condition improves. Eventually mandatory breaths are spaced so far apart that the patient scarcely relies on them at all — and "weaning" is completed.[2]

VERSUS ASSIST

Triggering an assistor has often been a problem, particularly for infants, since their rates are rapid and their inspiratory impulses are slight. If synchronization is less than perfect, the patient inhales (at least part of the time) with no fresh gas available. Under such circumstances, blood levels of CO_2 rise, as noted by Kirby and associates.[1]

VERSUS CONTROL

For apneic patients, control is obviously needed. But to take over, when a patient is breathing spontaneously, drugs have to be used or the patient has to be hyperventilated. Either procedure has drawbacks. Paralytic or sedative agents may obscure signs of neurological or metabloic disorders. Lowered muscle tone may impair venous return, and hence cardiac output. The effects of such drugs are particularly hard to predict in infants.

Hyperventilation (often used to suppress spontaneous breathing efforts) has drawbacks, too. The resultant alkalosis reduces cerebral blood flow. Blood levels of calcium and magnesium are altered. Airway resistance increases and pulmonary compliance decreases with hypocarbia.[3] Finally, there is evidence of a shift in the carbon dioxide response curve, which makes weaning more difficult.

All of these pit-falls can be avoided by using continuous-flow IMV.

CALIBRATION ...is a must

NEW! tec-care™ SERVICE AGREEMENT

Cleaning of FLUOTEC and other TEC type vaporizers is frequently confused with *calibration* of these units.

Proper calibration to factory specifications, essential for safe operation, can only be accomplished by using a complex optical system — The Refractometer.

Vaporizers should be calibrated with a Refractometer *at least* once a year.

HARRIS-LAKE now offers a new preventive maintenance contract (TEC-CARE™), a low-cost service contract that will assure factory service at the *proper* time to the *proper* vaporizer with the *proper* equipment— with *guaranteed* calibration/verification.

PEOPLE and PLACES

Intensive Care sponsored by the Department of Anesthesiology University of Miami School of Medicine will be presented on a Caribbean Cruise aboard S/S Doric, January 6-15, 1977. Contact: **Sonja Auxier,** Department of Anesthesiology, University of Miami School of Medicine, P.O. Box 540875, Biscayne Annex, Miami, Florida 33152.

★ ★

The Second International Symposium on Malignant Hyperthermia, sponsored by the Department of Anesthesiology and the University of Colorado School of Medicine will be held at the University of Colorado Medical Center on April 1, 2, 3, 1977. For further information write: **J. Antonio Aldrete, M.D.,** University of Colorado Medical Center, Box B113, Denver, Colorado 80262.

★ ★

Annual Meeting, Society for Obstetric Anesthesia and Perinatology. Edgewater Inn, Seattle, Washington, will be held April 14-17, 1977.

For more information, write: **David Ralston, M.D.,** Department of Anesthesia, University of Washington, School of Medicine, Seattle, Washington 98105.

★ ★

The Department of Anesthesia, Boston Hospital for Women and Harvard Medical School, Boston, Massachusetts, will present a course entitled "Obstetric Analgesia and Anesthesia," May 6-7, 1977.

This course is designed to present a review and update on obstetric anesthetic management.

Course directors: **Gerard W. Ostheimer, M.D.,** and **Milton H. Alper, M.D.**

For more information write: Department of Continuing Education, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115.

★ ★

The First Colorado Anesthesiology Symposium sponsored by the Colorado Society of Anesthesiologists and the Office of Postgraduate Education and the Department of Anesthesiology of the University of Colorado School of Medicine will be held at the Broadmoor Hotel in Colorado Springs on July 30-31, 1977. The seminar will deal with anesthesiology and the cardiac patient. Further details may be obtained from **Dr. J. Antonio Aldrete,** University of Colorado Medical Center, Box B113, Denver, Colorado 80262.

The best anesthesia system without compromises is the one you design for yourself. Including Ohio keepables and disposables!

VORTEX™ Respiration Monitor measures tidal volumes continuously, totalizes to obtain minute volume.

Disposable Endotracheal Tubes, new, uncuffed or with anatomically designed cuffs for gentle seal. Unique inflation and pilot balloon assembly.

Disposable Anesthesia Breathing Circuit with conductive, cushioned masks in three sizes. Our bacteria filter-pathogen trap fits most anesthesia circuits.

OHIO Critical Care Ventilator with intermittent mandatory ventilation "engineered in." Assists ventilation in any interval from 5 to 100 seconds.

Anesthesia Ventilator, fluidically controlled for less maintenance. Precise and reliable. With a built-in gas evacuator. Ohio can also customize a gas evacuation interface to accommodate your disposal system.

O_2 Monitor with visual and audio alarms.

One system designed to suit all can't really satisfy everyone. Because somewhere along the line you have to compromise. Each of you has your own ideas about how best to provide excellence in patient care in your own operating theater. And each OR has its unique needs.

Most new systems begin with one of the four OHIO® anesthesia machines. Rugged. Practical. Versatile. Functional. Delivering your preference in anesthetic agents with accuracy and safety.

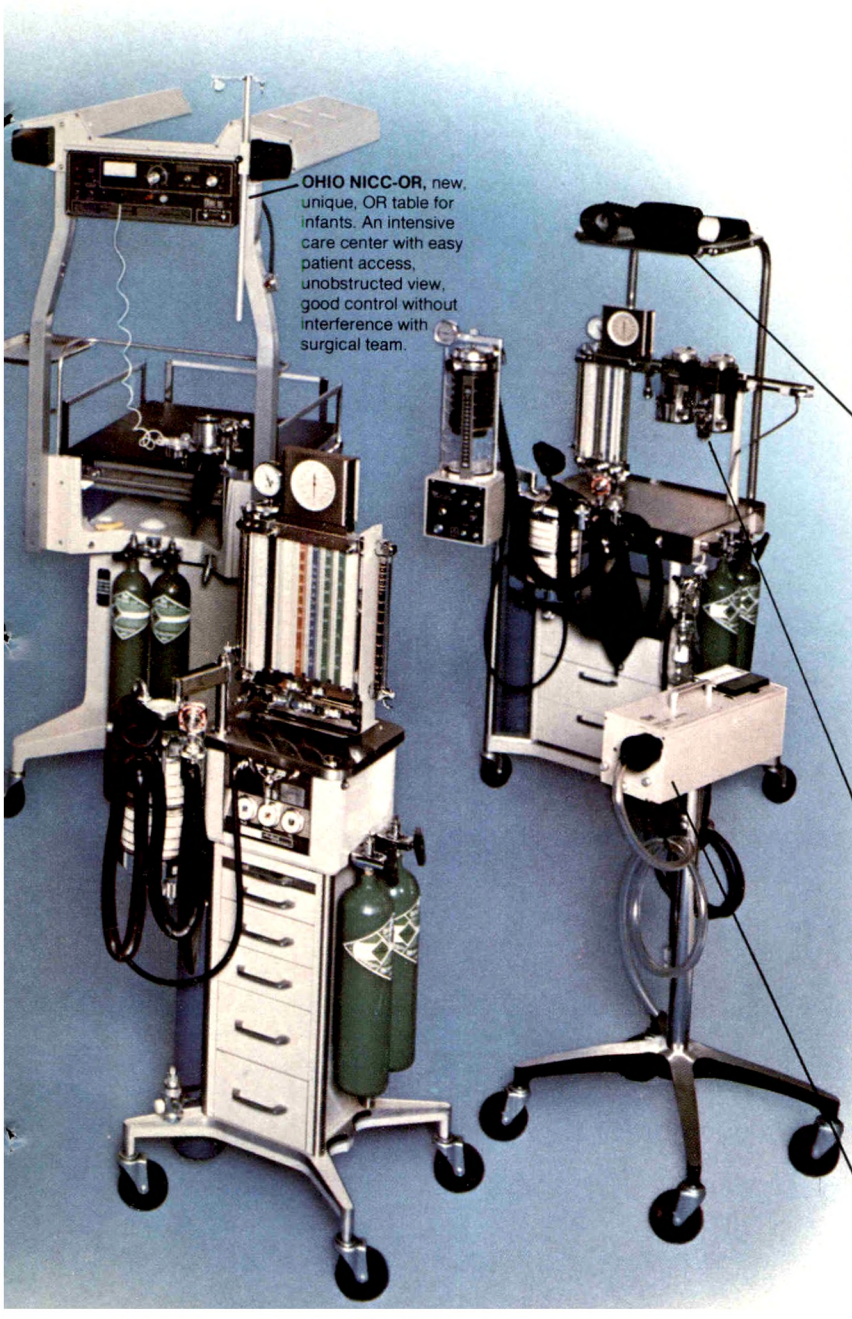
Then, your system grows to support your skills and techniques, as you add accessories and options from Ohio: Vaporizers, ventilators and absorbers, monitors, disposables, medical gases, and gas evacuation systems. And we always have more on the way.

You can depend on over 100 factory-trained Ohio servicemen and six service centers in the U.S. and Canada to keep your anesthesia equipment performing. Plus a knowledgeable sales staff.

Send for information. Or send for your salesman. Ohio will help you develop a reliable, sophisticated anesthesia system. One you can build on when future technologies develop. So, you'll never have to compromise in caring for your patients.

Ohio Medical Products AIRCO®

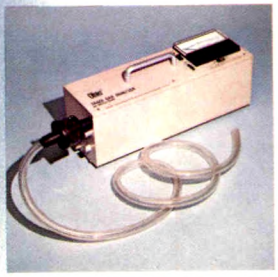
3030 Airco Drive, P.O. Box 7550, Dept. 305
Madison, Wisconsin 53707



OHIO NICC-OR, new, unique, OR table for infants. An intensive care center with easy patient access, unobstructed view, good control without interference with surgical team.

HOPE® II resuscitator with a new valve and the facility to administer enriched oxygen concentrations.

OHIO Calibrated Vaporizer, new, easy-to-use, temperature and flow compensated with excellent low-flow performance.



New Trace Gas Analyzer detects and measures the concentration of nitrous oxide in the operating room atmosphere; alerting OR personnel to leak sources.

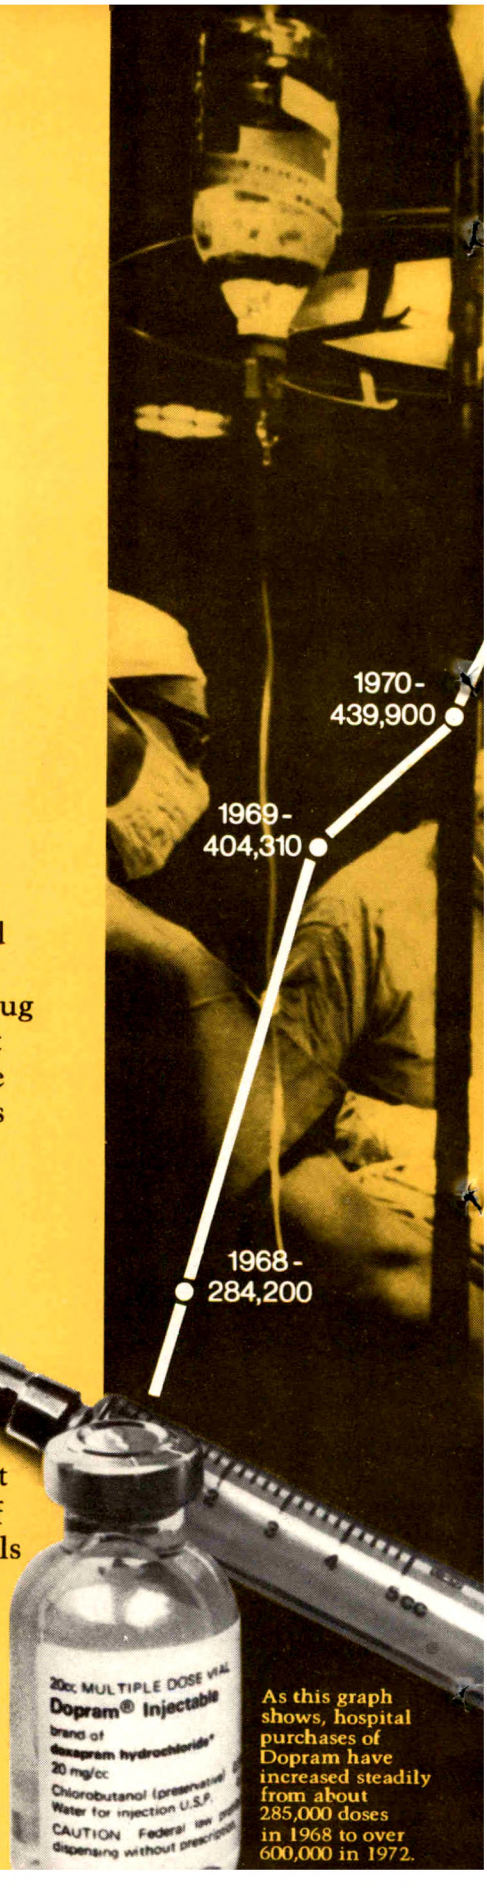
In all types of hospitals across the United States, its usage grows–

Dopram®
Injectable
(doxapram HCl)

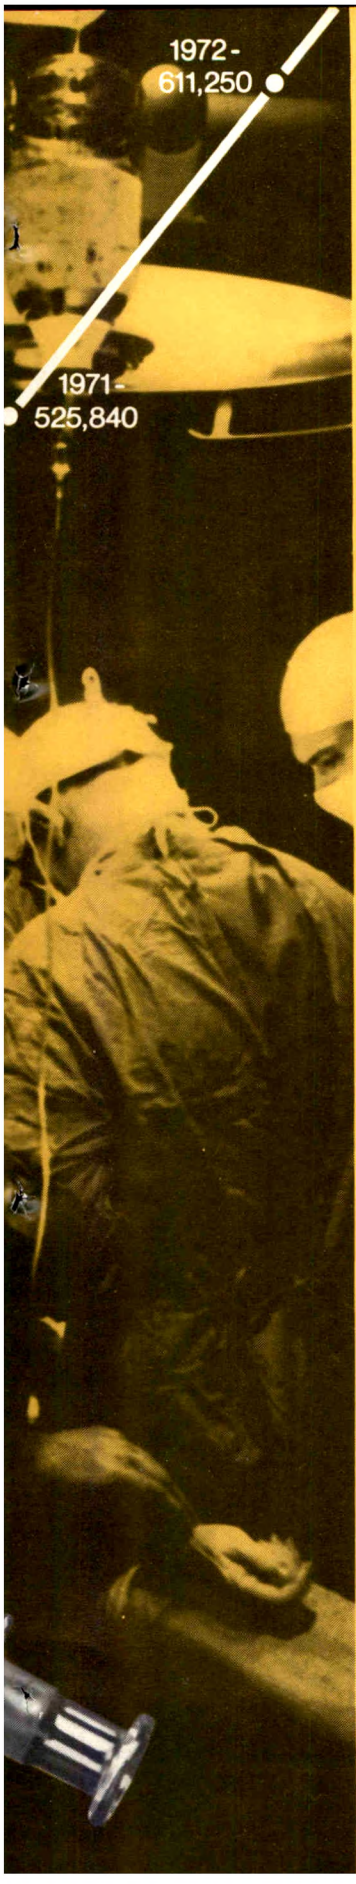
Seven years ago, A. H. Robins introduced Dopram, a unique respiratory stimulant developed in the company's research laboratories. What made this drug so useful to the anesthesiologist was its ability to rapidly restore the respiratory drive in patients with drug-induced post anesthetic depression.

Usage of Dopram has been steadily increasing each year, until today it has become a very important drug in the armamentarium of more than 1,500 hospitals of all types in all 50 states, the District of Columbia, and a number of foreign countries. These hospitals purchased more than 600,000 doses in 1972 alone.

Dopram–an important drug in anesthesiology. Try it for sighs!



As this graph shows, hospital purchases of Dopram have increased steadily from about 285,000 doses in 1968 to over 600,000 in 1972.



Indications

1. To stimulate respiration in patients with drug induced post-anesthetic respiratory depression or apnea other than that due to muscle relaxant drugs.
2. To pharmacologically stimulate deep breathing in the so-called "stir-up" regimen in the post-operative patient. Simultaneous administration of oxygen is desirable.
3. To hasten arousal and return of protective pharyngeal and laryngeal reflexes.
4. To aid in the differential diagnosis of post-anesthetic respiratory depression. Failure to adequately stimulate respiration suggests residual muscle relaxant effect.
5. To stimulate respiration, hasten arousal and to encourage the return of laryngopharyngeal reflexes in patients with mild to moderate respiratory and CNS depression due to drug overdosage.

Contraindications—Epilepsy and other convulsive states: incompetence of the ventilatory mechanism due to muscle paresis, flail chest, pneumothorax, airway obstruction, and extreme dyspnea; severe hypertension and cerebrovascular accidents; hypersensitivity.

Doxapram is not recommended for patients 12 years of age or under because studies to evaluate its safety and efficacy have not been performed.

Warnings—Doxapram is an analeptic agent; it is neither an antagonist to muscle relaxant drugs nor a specific narcotic antagonist. Since doxapram has an acid pH, it should not be mixed with alkaline solutions such as thiopental sodium.

Since narcosis may recur after stimulation with doxapram, care should be taken to maintain close observation until the patient has been fully alert for 1/2 to 1 hour. (Duration of drug 5-12 minutes.)

Doxapram is an adjunct to well-accepted supportive measures and resuscitative techniques. It may not stimulate adequate spontaneous breathing or provide sufficient arousal in patients who are severely depressed with CNS depressant drugs.

When doxapram is administered to postoperative patients or to patients in a state of narcosis with chronic pulmonary insufficiency, oxygen should be administered concomitantly. Failure to do so may result in further oxygen debt and more severe dyspnea due to the increased work of breathing.

Doxapram should be administered with great care and only under close supervision to patients with cerebral edema, bronchial asthma, severe tachycardia, cardiac arrhythmia, cardiac disease, hyperthyroidism and pheochromocytoma.

Usage in pregnancy

No adequate clinical studies have been performed to determine the safe use of doxapram in pregnancy. Until further clinical experience has been obtained, the physician must weigh the need against possible risks in using the drug in pregnant patients or in women of child-bearing potential.

Precautions—Recommended dosages of doxapram should be employed and maximum total dosages should not be exceeded. In patients with advanced pulmonary disease with hypoxemia, marked respiratory stimulation increases the work of breathing and may, thus, increase oxygen consumption and carbon dioxide production.

With excessive dosage, hyperventilation induced by doxapram may lead to respiratory alkalosis and hypocapnia with tetany and, theoretically, apnea.

An adequate airway is essential. In order to avoid side effects, it is advisable to use the minimum effective dosage. Monitoring of the blood pressure and deep tendon reflexes is recommended to prevent overdosage.

It is desirable that blood gases (P_{O_2}, P_{CO_2} O_2 saturation) be monitored to assess the effectiveness of respiratory stimulation.

Intravenous barbiturates, oxygen and resuscitative equipment should be readily available to manage overdosage manifested by excessive central nervous system stimulation. Slow administration of the drug and careful observation of the patient during administration and for some time subsequently are advisable to insure restoration of the protective reflexes. The possibility of post-stimulation respiratory depression must be kept in mind. In patients who have been lightly curarized, doxapram may temporarily mask the residual effects of muscle relaxant drugs.

Doxapram should be administered cautiously to patients receiving sympathomimetic or monoamine oxidase inhibiting drugs, since a synergistic pressor effect may occur. It should likewise be used with care in post-operative patients with marked dyspnea due to obstructive pulmonary emphysema, acute or chronic asthma, profound metabolic disorders, severe to moderately severe hypertension, increased cerebrospinal fluid pressure, head injury and acute agitation.

Since doxapram may stimulate basal gastric secretion, it should be used with care in patients with peptic ulcer disease and in patients undergoing gastric surgery.

Vascular extravasation or use of a single injection site over an extended period should be avoided since either may lead to thrombophlebitis.

Hypocapnia accompanying forced ventilation is a potent stimulus to cerebral vasoconstriction; it may be postulated that some element of risk may exist from reduced cerebral blood flow following prolonged and intensive hyperventilation.

Since an increase in epinephrine release has been noted with doxapram, it is recommended that initiation of therapy with this respiratory stimulant be delayed for at least 10 minutes following the discontinuance of anesthetics known to sensitize the myocardium to catecholamines, such as halothane and cyclopropane.

As with other intravenous preparations, all precautions should be taken during administration of doxapram to insure that injection is made directly into a suitable vein; extravasation, and inadvertent intra arterial injection should be avoided.

Adverse reactions—The following adverse reactions have been reported: *Central and Autonomic Nervous Systems.* Hyperactivit feeling of warmth, sweating, muscle tremor clonus, increased deep tendon reflexes, dizziness, muscle spasticity, pyrexia, confusion, paresthesia, pupillary dilatation pilomotor erection, headache, bilateral babinski, fasciculation and carpopedal spasm. A grand mal seizure occurred 95 minutes after drug administration in a known epileptic patient who was on anticonvulsant medication.

Respiratory. Cough, dyspnea, laryngospasr bronchospasm and hiccough.

Cardiovascular. Hypertension, sinus tachycardia, bradycardia, extrasystoles, lower T-waves, premature ventricular contractions, irregular heart rhythm, tightness in chest. Although a mild to moderate increase in blood pressure is not infrequent, such an increase may occasionally be of concern in hypertensive patients.

Gastrointestinal. Nausea and/or vomiting salivation, stimulation of lower bowel, sour taste.

Genitourinary. Urinary retention, stimulation of urinary bladder with spontaneous voiding.

Miscellaneous. Pruritus, thrombophlebitis

Laboratory Determinations. A decrease in hemoglobin, hematocrit, or red blood cell count has been observed in postoperative patients. In the presence of pre-existing leukopenia, a further decrease in WBC wa observed following anesthesia and treatment with doxapram hydrochloride. Elevation of BUN and albuminuria have been observed.

In some of the cases cited above, the patients had received multiple drugs concomitantly, thus preventing an absolute judgment as to the role of doxapram in these reactions.

Dosage—For complete information concerning dosage and administration see package insert.

Supply—Dopram (doxapram hydrochloride) is available in 20 cc rubber stoppered vials containing 20 mg/cc, with chlorobutanol 0.5% as the preservative.

A·H·ROBINS

ANECTINE®
(succinylcholine chloride)
For controlled muscle relaxation adjunctive to anesthesia:

FLO-PACK® for prolonged relaxation

- instant-mix sterile powder interfaces with all major parenteral systems (vacuum or nonvacuum)
- each unit complete—no needle or syringe needed
- retains potency indefinitely
- no refrigeration required
- unbreakable, sterile plastic injection units of 500 and 1,000 mg

INJECTION for short-term relaxation

- a product of choice for intubation and other short procedures
- unique square bottle and bright yellow label for positive identification
- ready for immediate use
- 20 mg per cc . . . in 10 cc multidose vials
- flip-top cap for easy opening
- single or multiple use

ANECTINE®
(succinylcholine chloride)
THE LONG AND SHORT of surgical muscle relaxation

THIS DRUG SHOULD BE USED ONLY BY INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS AND HAZARDS.

DESCRIPTION: Anectine brand Succinylcholine Chloride is an ultra short-acting depolarizing type muscle relaxant. Chemically it is a di-quaternary base consisting of the di-chloride salt of the di-choline ester of succinic acid. It is a white, odorless, slightly bitter powder and very soluble in water. The drug is unstable with alkaline solutions, but relatively stable in acid solutions depending upon the concentration of the solution and the storage temperature. While solutions of succinylcholine chloride are sterilized by autoclaving, they should, nevertheless, be stored under refrigeration to preserve their potency.

INDICATIONS: Succinylcholine chloride is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may be employed to reduce the intensity of muscle contractions of pharmacologically or electrically induced convulsions.

CONTRAINDICATIONS: Succinylcholine is contraindicated for persons with a known hypersensitivity to the drug.

WARNINGS:

WARNING: SUCCINYLCHOLINE SHOULD BE USED ONLY BY THOSE SKILLED IN THE MANAGEMENT OF ARTIFICIAL RESPIRATION AND ONLY WHEN FACILITIES ARE INSTANTLY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND FOR PROVIDING ADEQUATE VENTILATION OF THE PATIENT, INCLUDING THE ADMINISTRATION OF OXYGEN UNDER POSITIVE PRESSURE AND THE ELIMINATION OF CARBON DIOXIDE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR TO CONTROL RESPIRATION.

Succinylcholine should not be mixed with short-acting barbiturates in the same syringe, or administered simultaneously during intravenous infusion through the same needle. Solutions of succinylcholine have an acid pH whereas those of barbiturates are alkaline in reaction. Depending upon the resultant pH of a mixture of solutions of these drugs, either free barbituric acid may be precipitated or succinylcholine hydrolyzed.

Usage in Pregnancy The safe use of succinylcholine has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards.

PRECAUTIONS: Low levels of, or abnormal variants of plasma cholinesterase may be associated with prolonged respiratory depression or apnea following the use of succinylcholine. Low levels of plasma cholinesterase may occur in patients with severe liver disease or cirrhosis, severe anemia, malnutrition, severe dehydration, changes in body temperature, exposure to neurotoxic insecticides or those receiving antimalarial drugs. Succinylcholine should be administered with extreme care to such patients and dosage should be minimal. If low plasma cholinesterase activity is suspected, a small test dose of from 5 to 10 mg of succinylcholine may be administered, or relaxation may be produced by the cautious administration of a 0.1% solution of the drug by intravenous drip. Drugs which either inhibit plasma cholinesterase, such as neostigmine or phospholine iodide, or compete with succinylcholine for the enzyme, as does intravenous procaine, should not be given concurrently with succinylcholine.

Succinylcholine should be administered with great caution to patients with severe burns, those recovering from severe trauma, those suffering from electrolyte imbalance, those receiving quinidine, those who have been digitalized recently or who may have digitalis toxicity as serious cardiac arrhythmias or cardiac arrest may result. Great caution should be observed also in patients with pre-existing hyperkalemia or who are paraplegic, have suffered spinal neuraxis injury, or have degenerative or dystrophic neuromuscular disease, as such patients tend to become severely hyperkalemic when succinylcholine is given.

When succinylcholine is given over a prolonged period of time, the characteristic depolarization block of the myoneural junction may change to a non-depolarizing block which results in prolonged respiratory depression or apnea. Under such circumstances, small repeated doses of neostigmine may possibly act as an antagonist. A peripheral nerve stimulator (e.g., the Wellcome Peripheral Nerve Stimulator) may be used to ascertain the type of neuromuscular blockade. If a depolarization block is present both fast (tetanic) and slow (twitch) rates of nerve stimulation are well sustained, and post-tetanic facilitation is absent. If a non-depolarizing block is present there is post-tetanic facilitation and "fade" of successive stimuli on both fast (tetanic) and slow (twitch) rates of nerve stimulation.

Succinylcholine should be used with caution during ocular surgery and in patients with glaucoma. The drug should be employed with caution in patients with fractures or muscle spasm as the muscle fasciculations may cause additional trauma. Muscle fasciculations and hyperkalemia may be reduced by administering a small dose of a non-depolarizing relaxant. If other relaxants are to be used during the same procedure, the possibility of a synergistic or antagonistic effect should be considered.

During the past few years, reports have called attention to a fulminant syndrome, malignant hyperthermia, observed during anesthesia. Its etiology is not fully understood. Malignant hyperthermia occurs in genetically prone individuals of all ages and both sexes receiving potent anesthetics such as halothane, methoxyfluothane, cyclopropane and diethyl ether. It appears to develop irrespective of the concomitant use of a muscle relaxant, but may be triggered by succinylcholine. Because of the seriousness of this syndrome and the need for early effective treatment of the patient, it is suggested that the continuous monitoring of the temperature will serve as an aid to the early recognition of malignant hyperthermia.

ADVERSE REACTIONS: Adverse reactions consist primarily of an extension of the drug's pharmacological actions. Profound and prolonged muscle relaxation may occur, resulting in respiratory depression to the point of apnea. Hypersensitivity to the drug may exist in rare instances.

The following adverse reactions have been reported: bradycardia, tachycardia, hypertension, hypotension, arrhythmias, cardiac arrest, prolonged respiratory depression or apnea, hyperthermia, increased intraocular pressure, muscle fasciculation, postoperative muscle pain, myoglobinemia and excessive salivation.

MANAGEMENT OF ADVERSE REACTIONS: Apnea or prolonged muscle paralysis should be treated with controlled respiration.

The use of neostigmine to reverse a non-depolarization block is a medical decision which must be made upon the basis of the individual clinical pharmacology and the experience and judgment of the clinician. When neostigmine is used atropine should also be administered.

SUPPLIED: Injection, Multi-dose vials, 20 mg cc, 10 cc, boxes of 12 vials. Flo-Pack® Sterile Powder 500 mg and 1,000 mg, boxes of 12.

LIQUI-SEAL™ ALLOWS CONTROL OF MOST HAZARDOUS PRESSURE PROBLEMS

U.S. Pat. No. 3766927
Other Pat. pending

Dupaco's new Liqui-Seal™ Systems solves pressure problems associated with air filled Tracheal Tube cuffs by eliminating air itself. This is accomplished by filling the cuff with saline solution from a self-contained reservoir. Since the fluid in the cuff system is incompressable, as compared with air, the pressure on the tracheal mucosa will vary directly with the height of the top of the fluid reservoir above the cuff at the time the cuff inflation valve is closed. The use of Liqui-Seal™ System gives the following advantages:

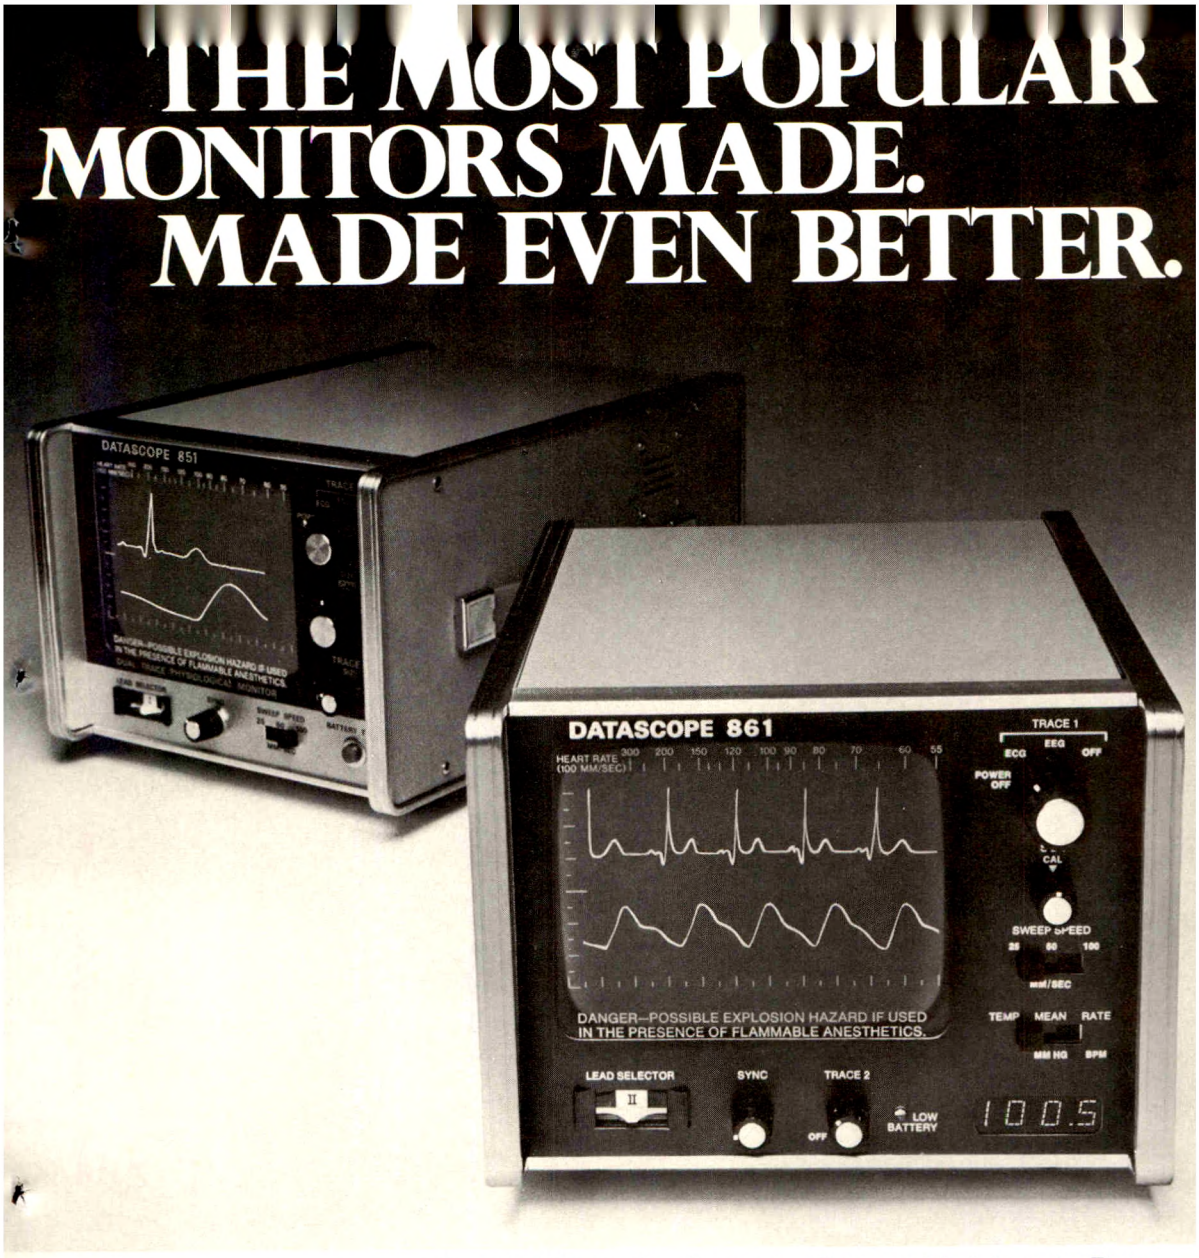
1. Positive seal at extremely low pressure.
2. Safe for prolonged use without periodic cuff deflation.
3. Cuff pressure readily regulated.
4. Cuff pressure constant during N_2O anesthesia.
5. No change in cuff pressure due to altitude changes (air evacuation).
6. Maximum pressure obtainable approx. 40cm H_2O.
7. One hand operation.

Liqui-Seal™ Tracheal Tubes are available in five sizes, have Murphy eye and are sterile packaged in convenient peel packages with appropriate connector.

DUPACO
INCORPORATED

P.O. Box 98, San Marcos, CA 92069

THE MOST POPULAR MONITORS MADE. MADE EVEN BETTER.



For some time now, our monitors have been selected for use in surgery by more medical people than any other battery-powered monitors in the world. Because we give you more of what you want in a monitor than any other monitors in the world.

However, this didn't stop us from improving them.

Our new Datascope 851 and 861 will now give you heart rate not only from ECG, but also from pulse or blood pressure.

And both monitors will give you 2 traces. So you can monitor ECG (or EEG) and pulse simultaneously.

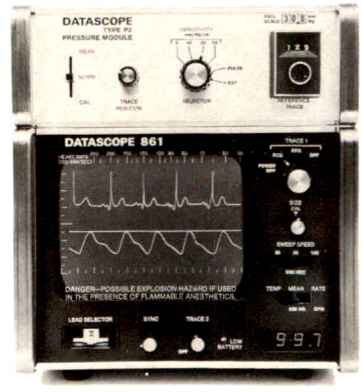
And both give you beat by beat synchronization†. So a single ECG complex shows up with each full sweep.

The 861 does even more. It monitors body temperature. On a digital read-out. And this same digital display will give you heart rate when you want it; or mean blood pressure when you are using the 861 with our Pressure Module.

For all the things our 851 and 861 do, they're surprisingly portable. And they offer longer battery-operating time than any other monitors. In some cases, actually twice as long.

Will they continue to be the most popular monitors made? More so.

For further information about our new 851, 861, or our Pressure Module, write Datascope Corp., 580 Winters Ave., Paramus, NJ 07652.



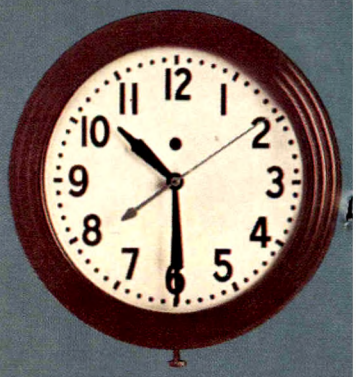
The 861 with Pressure Module.

THE DATASCOPE 851/861

†U.S. PATENT NO. 3457452

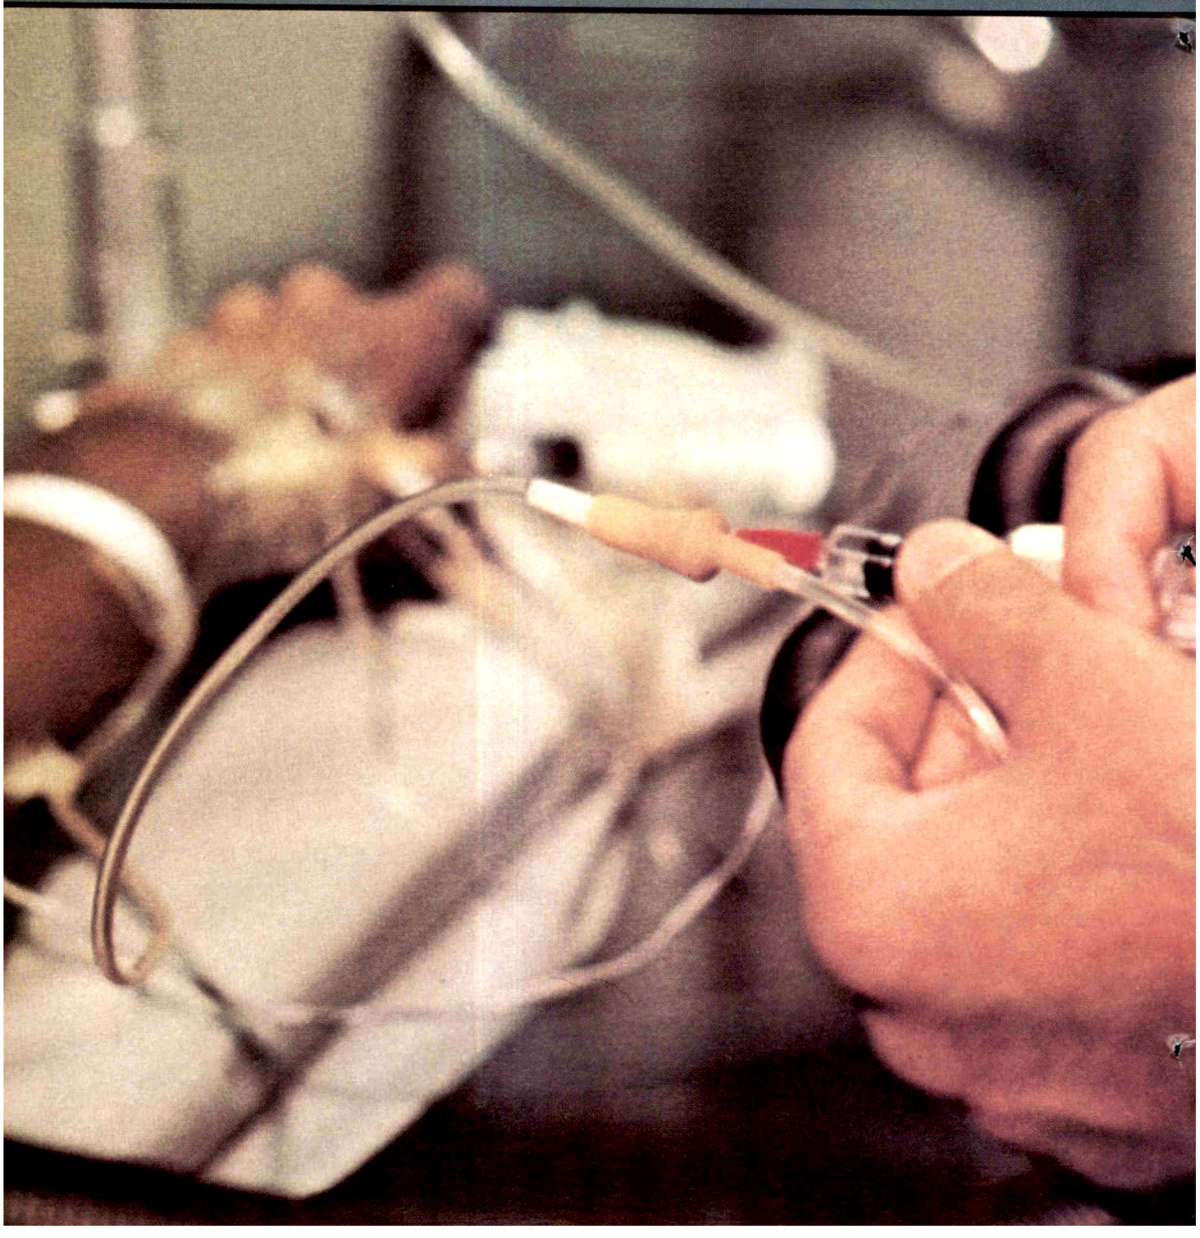
SUBLIMAZE® (fentanyl) has a uniquely short duration of analgesic action—for more precise control and minimal risk of prolonged narcotic effects.

Within 5 minutes I.V., SUBLIMAZE® (fentanyl) reaches its peak analgesic effect.



Within 30 to 60 minutes I.V., the analgesic effect of SUBLIMAZE® (fentanyl) is almost completely dissipated.†

† Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with larger doses, multiple doses or use of postoperative narcotic analgesics.



For potent narcotic analgesic action with rapid onset and short duration:

SUBLIMAZE fentanyl provides profound analgesia without hypnosis and with little or no sedation. With this analgesia as a foundation, it is possible to use light general anesthesia in most cases.

SUBLIMAZE fentanyl is particularly suited for maintenance of analgesia after INNOVAR® injection* has been used for induction. It may also be used preoperatively, during surgery with any common general or regional anesthetic agent, and in the immediate postoperative period whenever the need for potent analgesic action arises.

SUBLIMAZE fentanyl is available both alone and as a component of INNOVAR injection.*

*INNOVAR injection is composed of a 50:1 mixture of droperidol 2.5 mg./cc. and fentanyl 0.05 mg./cc., with lactic acid for adjustment of pH to 3.5 ± 0.3.

SUBLIMAZE® (fentanyl) offers:

☐ Almost immediate analgesia—peak effect within 5 minutes I.V., 8 minutes I.M.

☐ Short duration of analgesic action—30 to 60 minutes with a single I.V. dose of up to 0.1 mg. (Respiratory depressant effects may las longer than the analgesia and are increased an prolonged with larger doses, multiple doses or use of postoperative narcotic analgesics.)

☐ No evidence of liver, heart, or kidney toxicity—expecially valuable in poor-risk patients However, the drug should be administered cautiously in the presence of liver or kidney dysfunction or cardiac arrhythmias, and the dose should be appropriately reduced in poor-risk patients.

☐ Immediate reversibility by narcotic antagonists.

☐ Little or no histamine release—decreasing the risk of cardiovascular instability.

☐ Minimal emetic effect—has been used successfully to prepare nonfasting patients for awake intubation.

☐ Prevention or reversal of emergence delirium and tachypnea.

SUBLIMAZE® Ⓒ (fentanyl) injection

0.05 mg./cc. as the citrate.
Warning: May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0—7.5

INNOVAR® injection and SUBLIMAZE® (fentanyl) injection are available for use only upon direction of a physician. For information relating to Contraindications, Warnings, Precautions and Adverse Reactions for SUBLIMAZE fentanyl, please turn page.

© McNeil Laboratories, Inc., 1974

SUBLIMAZE® (fentanyl) injection

Description
Each cc. contains:
Fentanyl as the citrate ..... 0.05 mg.
Warning—May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0-7.5
FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY.

Actions SUBLIMAZE fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. SUBLIMAZE fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. SUBLIMAZE fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays and skin wheal testing in man, as well as *in vivo* testing in dogs, indicate that histamine release rarely occurs with SUBLIMAZE fentanyl.

SUBLIMAZE fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of SUBLIMAZE fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours.

Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics it may be considerably longer than the analgesic effect.

Indications SUBLIMAZE fentanyl is indicated:
—for analgesic action of short duration during the anesthetic periods, premedication, induction, and maintenance, and in the immediate postoperative period (recovery room) as the need arises.
—for use as a narcotic analgesic supplement in general or regional anesthesia.
—for administration with a neuroleptic such as INAPSINE® (droperidol) injection as an anesthetic premedication, for the induction of anesthesia and as an adjunct in the maintenance of general and regional anesthesia.

Contraindications SUBLIMAZE fentanyl is contraindicated in patients who are hypersensitive to the drug.

Warnings PATIENTS WHO HAVE RECEIVED *SUBLIMAZE* FENTANYL SHOULD HAVE APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

If SUBLIMAZE fentanyl is administered with a tranquilizer such as INAPSINE droperidol, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action. In addition, when such a combination is used *fluids and other countermeasures to manage hypotension should be available.*

As with other potent narcotics, the respiratory depressant effect of SUBLIMAZE fentanyl persists longer than the measured analgesic effect. The total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, should be used in reduced doses initially, as low as 1/4 to 1/3 those usually recommended. A neuromuscular blocking agent compatible with the patient's condition may be required to control muscle rigidity which may develop with the use of SUBLIMAZE fentanyl.

Drug Dependence: SUBLIMAZE fentanyl can produce drug dependence of the morphine type and therefore has the potential for being abused.

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl in this regard has not been established, the use of SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: SUBLIMAZE fentanyl should be used with caution in patients who may be particularly susceptible to respiratory depression, such as comatose patients who may have a head injury or brain tumor. In addition, SUBLIMAZE fentanyl may obscure the clinical course of patients with head injury.

Usage in Children: The safety of SUBLIMAZE fentanyl in children younger than two years of age has not been established.

Usage in Pregnancy: The safe use of SUBLIMAZE fentanyl has not been established with respect to possible adverse effects upon fetal development. Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects; therefore, safety for the infant in obstetrics has not been established.

Precautions *The initial dose of SUBLIMAZE fentanyl should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and some peridural anesthetics, can alter respiration by blocking intercostal nerves. Through other mechanisms (see Actions) SUBLIMAZE fentanyl can also alter respiration. When SUBLIMAZE fentanyl is used to supplement these forms of anesthesia, the anesthetist should be familiar with the physiological alterations involved, and be prepared to manage them in the patients selected for these forms of anesthesia. When used with a tranquilizer such as INAPSINE droperidol, blood pressure may be altered and hypotension can occur.

Vital signs should be monitored routinely.

SUBLIMAZE fentanyl should be used with caution in patients with chronic obstructive pulmonary disease, patients with decreased respiratory reserve, and others with potentially compromised respiration. In such patients, narcotics may additionally decrease respiratory drive and increase airway resistance. During anesthesia, this can be managed by assisted or controlled respiration. Postoperatively, respiratory depression caused by narcotic analgesics can be reversed by narcotic antagonists (levallorphan, nalorphine, and naloxone; consult individual prescribing information before using). Should respiration be compromised by muscle rigidity, assisted or controlled respiration and possibly a neuromuscular blocking agent will be required. The occurrence of muscle rigidity is related to the speed of intravenous injection and the incidence can be reduced by slow intravenous injection.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, pulmonary arterial pressure may be decreased. This fact should be considered by those who conduct diagnostic and surgical procedures where interpretation of pulmonary arterial pressure measurements might determine final management of the patient.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, and general anesthetics) will have additive or potentiating effects with SUBLIMAZE fentanyl. When patients have received such drugs, the dose of SUBLIMAZE fentanyl required will be less than usual. Likewise, following administration of SUBLIMAZE fentanyl the dose of other CNS depressant drugs should be reduced.

SUBLIMAZE fentanyl should be administered with caution to patients with liver and kidney dysfunction because of the importance of these organs in the metabolism and excretion of drugs.

SUBLIMAZE fentanyl may produce bradycardia, which may be treated with atropine; however, SUBLIMAZE fentanyl should be used with caution in patients with cardiac bradyarrhythmias.

When SUBLIMAZE fentanyl is used with a tranquilizer such as INAPSINE droperidol, hypotension can occur. If this occurs the possibility of hypovolemia should also be considered and managed with appropriate parenteral fluid therapy. Repositioning the patient to improve venous return to the heart should be considered when operative conditions permit. Care should be exercised in moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus other countermeasures do not correct hypotension, the administration of pressor agents other than epinephrine should be considered. Because of the alpha-adrenergic blocking action of INAPSINE droperidol, epinephrine may paradoxically decrease the blood pressure in patients treated with INAPSINE droperidol.

Adverse Reactions As with other narcotic analgesics, the most common serious adverse reactions reported to occur with SUBLIMAZE fentanyl are respiratory depression, apnea, muscular rigidity, and bradycardia; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Other adverse reactions that have been reported are hypotension, dizziness, blurred vision, nausea, emesis, laryngospasm, and diaphoresis.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, the following adverse reactions can occur: chills and/or shivering, restlessness, and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression); extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have been observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with antiparkinson agents. Postoperative drowsiness is also frequently reported following the use of INAPSINE droperidol.

Overdosage ***Manifestations:*** The manifestations of SUBLIMAZE fentanyl overdosage are an extension of its pharmacologic actions.
Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered and managed with appropriate parenteral fluid therapy. A specific narcotic antagonist such as nalorphine, levallorphan, or naloxone should be available for use as indicated to manage respiratory depression. This does not preclude the use of more immediate countermeasures. Consult the package insert for the individual narcotic antagonists for details about use.

How Supplied SUBLIMAZE® (fentanyl) injection is supplied in 2 cc. (**NDC** 0045-0180-03) and 5 cc. (**NDC** 0045-0180-05) ampuls, in packages of 12.

IMPORTANT: Complete dosage information is available in insert which accompanies each package (or on request). The drug is available only upon direction of a physician.

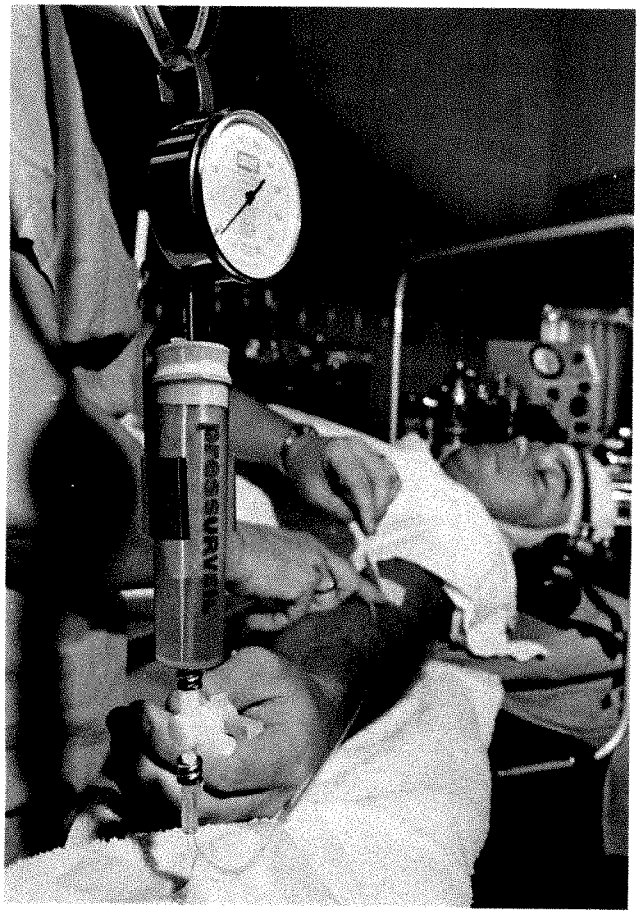
What's even easier than Pressurveil™ for continuous blood pressure monitoring? The Pressurveil Kit.



Cat. No. 6700	PRESSURVEIL	$50 box of 10
Cat. No. 6710	Venous Pressure Gauge (0-50 cm H_2O)	$65 each
Cat. No. 6715	Mean Arterial Gauge (20-300 mm Hg)	$45 each
Cat. No. 6720	Dual Reading Gauge for CVP, PAP, PWP (0-45 mm Hg or 0-60 cm H_2O)	$69 each
Cat. No. 6725	**PRESSURVEIL Kit**	**$75 box of 10**

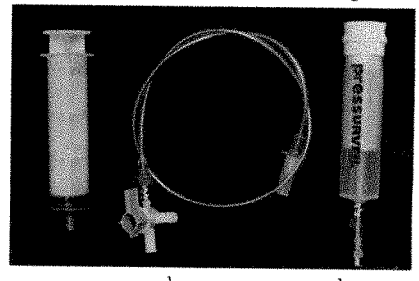
We put ideas to work.

12707 U.S. Highway 19 South
Clearwater, Florida 33516

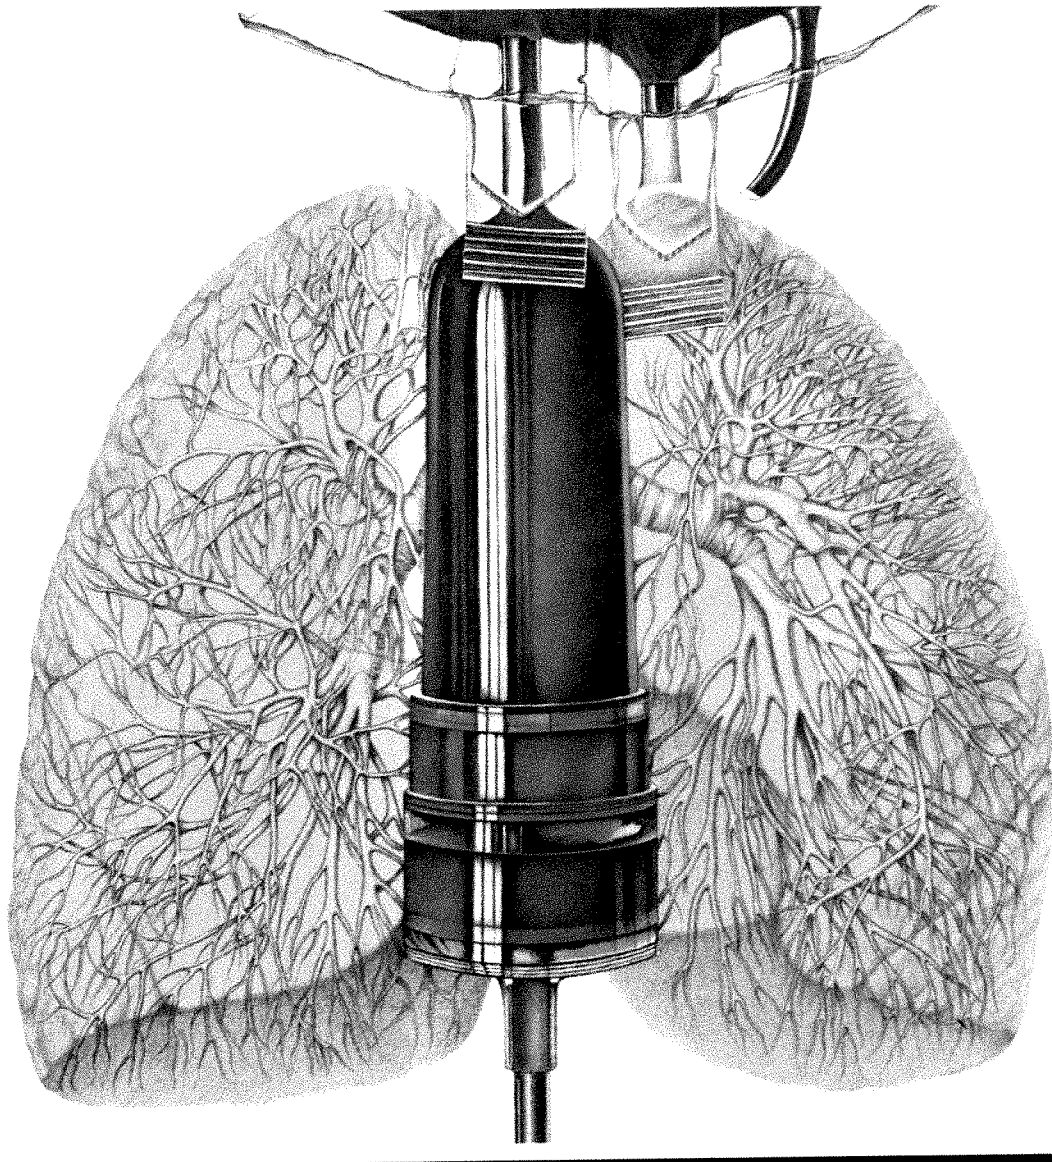
concept INC.

We put an idea to work.

To make your job even easier, we've packaged PRESSURVEIL in a convenient, three-piece disposable kit. Included is the PRESSURVEIL unit, a syringe and a connecting tube with stopcock. It's all in one place. Sterile. Ready-to-use. Just follow the simple instructions. In seconds, you can select the proper gauge and begin monitoring blood pressure continuously, with confidence — whether it's central venous, mean arterial, pulmonary



mean or pulmonary wedge pressure. And, since PRESSURVEIL is portable, you can monitor patients regardless of where they are, or where they're going. PRESSURVEIL minimizes danger of alignment shift and eliminates electric shock hazard. You probably know that with PRESSURVEIL, reliable, continuous blood pressure surveillance is easy. Now, the PRESSURVEIL KIT makes it even easier.



For routine filtration of stored blood the Swank Transfusion Filter, utilizing the principle of Dacron® wool filtration, offers these important advantages:

- **Removes Microaggregates Down to 10-Micron Range**—the vast majority of the amorphous debris in stored blood is less than 30 microns in diameter and will not be removed by a standard screen filter.
- **Adsorptive Filtration**—highly efficient—degenerative blood elements are inherently adhesive and adhere to the Dacron wool fibers.
- **Flow Rate**—the Swank Transfusion Filter will efficiently remove microemboli from stored blood at a flow rate greater than 100cc per minute under gravity.
- **Multiple Unit Capacity**—the Swank Transfusion Filter will maintain efficiency through multiple-unit usage. The exact number of units will vary with blood age.

Now available: Swank Transfusion Filter with integral administration set.

PI Peripheral Nerve Stimulator

Monitors Muscle Relaxants

The PI Peripheral Nerve Stimulator monitors effects of skeletal muscle relaxants on the neuromuscular junction, detects abnormal response to muscle relaxants and distinguishes between depolarizing and non-depolarizing blockade.

Model NS-2

The NS-2 is now in use in many hospitals throughout the U. S. and abroad. It is designed primarily for use during surgery and delivers stimuli automatically at 5-second intervals. One or fifty pulses-per-second may be selected by momentary push-button switches. Output is a monophasic square wave pulse. Amplitude of the pulse is linearly adjustable. A flashing red light indicates low battery voltage. The NS-2 is solid state, rugged, battery powered, portable and lightweight.

Model NS-3

The NS-3 represents the latest in solid state technology. Use of integrated circuits has made it possible to build a very compact and versatile stimulator. Its miniature size makes the NS-3 more convenient for preoperative and postoperative testing. It delivers stimili at one second intervals when the rocker switch is depressed to the TWITCH position. A fifty-pulses-per-second rate may be selected by depressing the rocker switch to the momentary TETANUS position. Output is a monophasic square wave pulse. Amplitude of the pulse is linearly adjustable. The NS-3 also has a low-battery-voltage indicator.

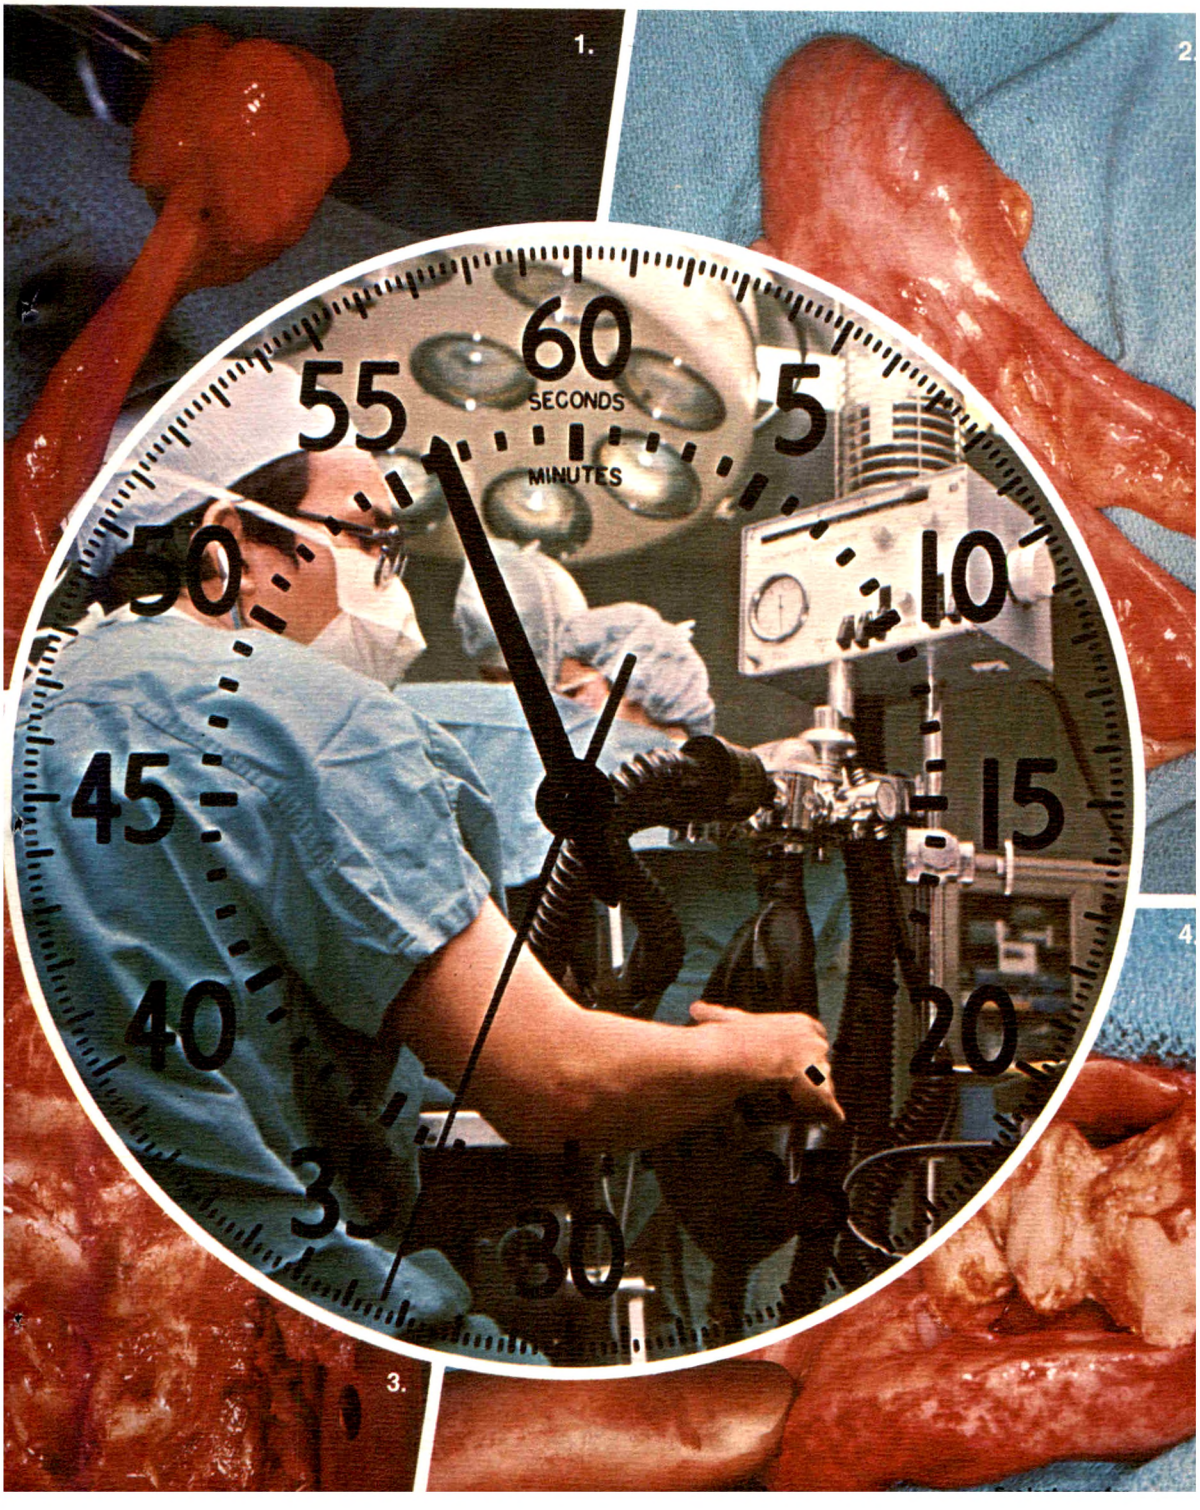
Professional Medical and Scientific Instrumentation

If the Procedure Takes 40 Minutes or More...

You Can Proceed with PAVULON®

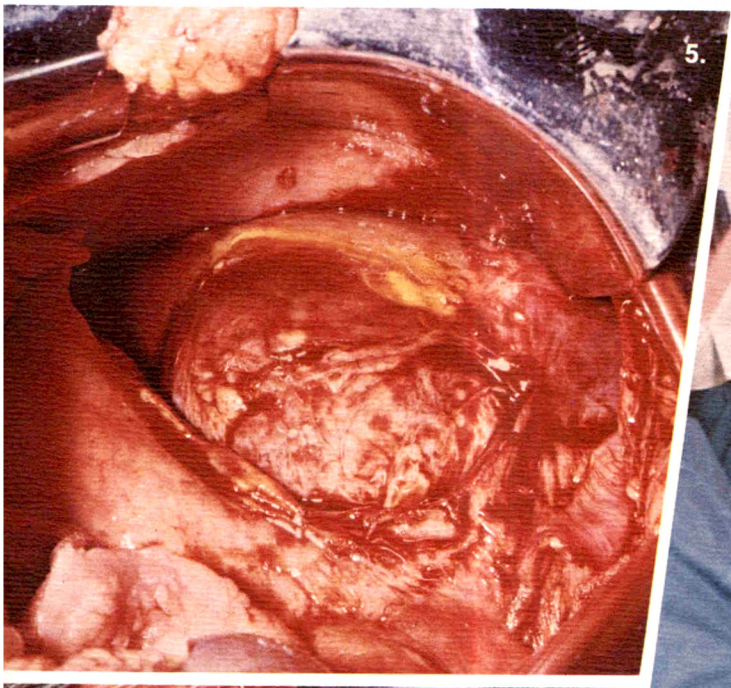
pancuronium bromide

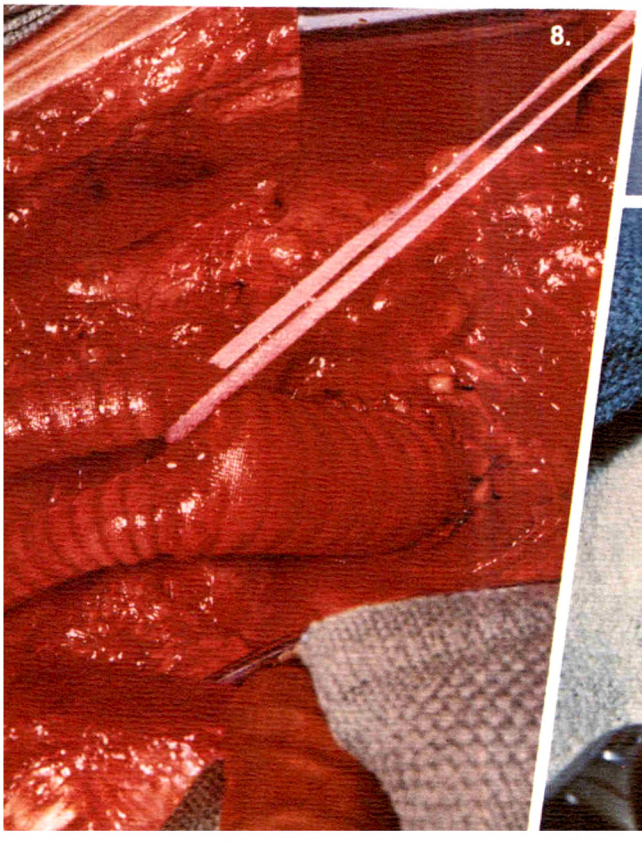


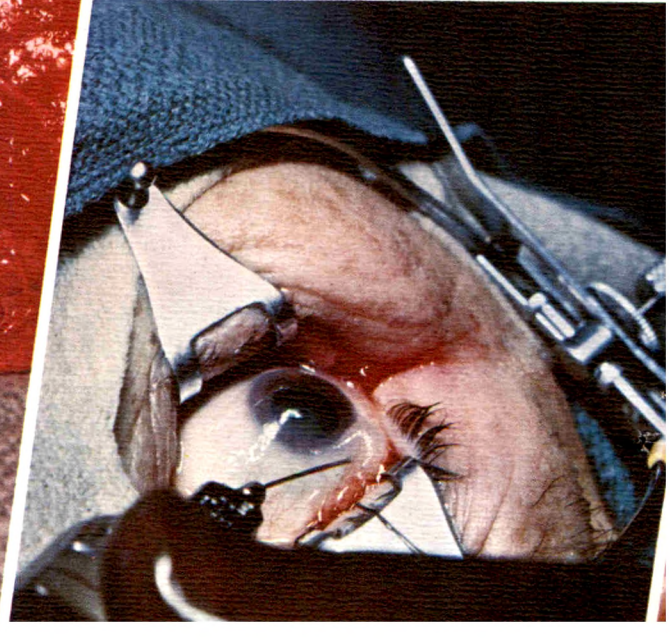
Proceed with PAVULON

pancuronium bromide

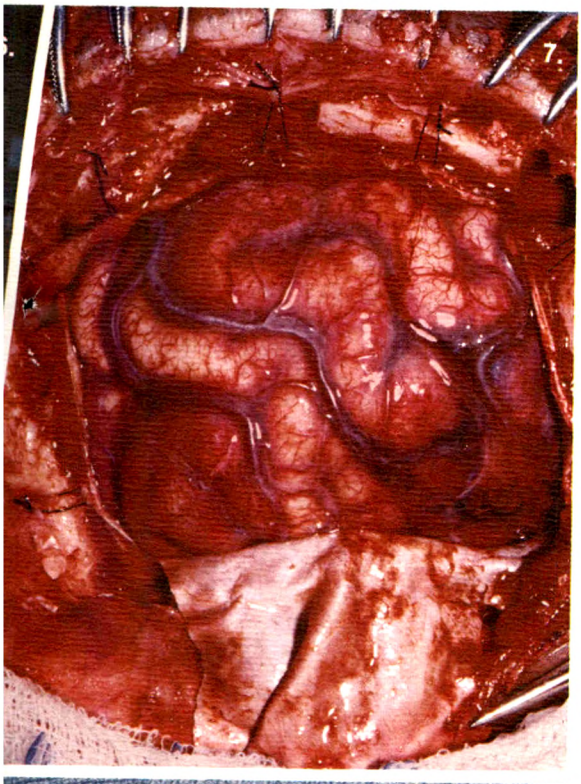
for optimal neuromuscular blockade

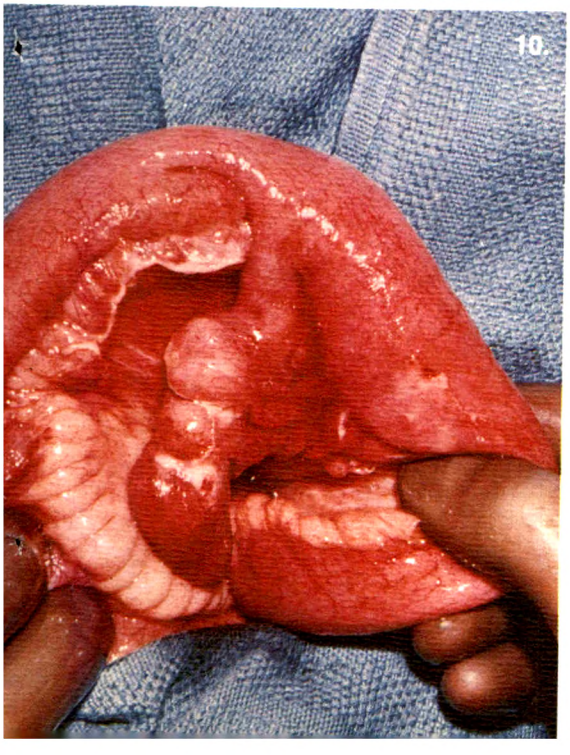






No matter where the surgeon's incision





—whatever the part of the body, or the age of the patient, or the cause of surgery, or the system or systems involved —there's a good chance that Pavulon can provide easy, uncomplicated, optimal, neuromuscular blockade.

Initial doses of Pavulon, given to facilitate endotracheal intubation, take effect in approximately 45 seconds and reach their peak at about 2-3 minutes. Once effective blockade is established, it can be maintained with incremental doses of 1 mg or less.

Pavulon is well tolerated, even in the very old, the very young and the very fragile. Histamine release rarely, if ever, occurs; there is little, if any, ganglionic blockade and little effect upon the circulatory system other than an occasional slight rise in pulse rate and blood pressure. There is no muscle pain, no known effects on consciousness, pain threshold or cerebration.

With proper procedure, reversal of Pavulon is relatively simple and generally uneventful. An appropriate antagonist, such as pyridostigmine bromide, can be used. With adequate dosage of the reversal agent, there is relatively little risk of recurarization. In cases of prolonged respiratory depression, other factors (drug interaction, acidosis, hypokalemia, etc.) should be considered.

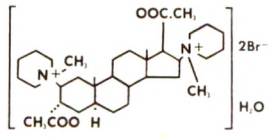
Proceed with PAVULON®

pancuronium bromide

clinically proven nondepolarizing muscle relaxant

THIS DRUG SHOULD ONLY BE ADMINISTERED BY ADEQUATELY TRAINED INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS, AND HAZARDS.

DESCRIPTION: Pavulon (pancuronium bromide) is the aminosteroid 2 beta, 16 beta-dipiperidine-5 alpha-androstane-3 alpha, 17-beta-diol diacetate dimethobromide. It has the following structural formula:



ACTIONS: Pavulon is a non-depolarizing neuromuscular blocking agent possessing all of the characteristic pharmacological actions of this class of drugs (curariform) on the myoneural junction.

Pavulon is approximately 5 times as potent as d-tubocurarine chloride.

The onset and duration of action of Pavulon is dose dependent. With the administration of 0.04 mg. per kg. the onset of action, as measured by a peripheral nerve stimulator, is usually within 45 seconds, and its peak effect is usually within 4½ minutes; recovery to 90% of control twitch height usually takes place in less than one hour. Larger doses, more suitable for endotracheal intubation, such as 0.08 mg. per kg. of Pavulon have an onset of action of about 30 seconds, and a peak effect within 3 minutes. Supplemental incremental doses of Pavulon, following the initial dose, slightly increase the magnitude of blockade, and significantly increase the duration of the blockade.

Pavulon has little effect upon the circulatory system. The most frequently reported observation is a slight rise in pulse rate.

Human histamine assays, and clinical observations, as well as in *vivo* guinea pig testing, and in *vitro* mast cell testing, indicate that histamine release rarely, if ever, occurs.

Pavulon (pancuronium bromide) is antagonized by acetylcholine, anticholinesterases, and potassium ion. Its action is increased by inhalational anesthetics such as halothane, diethyl ether, enflurane and methoxyflurane, as well as quinine, magnesium salts, hypokalemia, some carcinomas, and certain antibiotics such as neomycin, streptomycin, clindamycin, kanamycin, gentamicin and bacitracin. The action of Pavulon may be altered by dehydration, electrolyte imbalance, acid-base imbalance, renal disease, and concomitant administration of other neuromuscular agents.

Pavulon has no known effect on consciousness, the pain threshold, or cerebration.

INDICATIONS: Pavulon is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may also be employed to facilitate the management of patients undergoing mechanical ventilation.

CONTRAINDICATIONS: Pavulon is contraindicated in patients known to be hypersensitive to the drug or to the bromide ion.

WARNINGS: PAVULON SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS, WHO ARE FAMILIAR WITH ITS ACTIONS AND THE POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND REVERSAL AGENTS ARE IMMEDIATELY AVAILABLE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR CONTROL RESPIRATION.

In patients who are known to have myasthenia gravis small doses of Pavulon may have profound effects. A peripheral nerve stimulator is especially valuable in assessing the effects of Pavulon in such patients.

USAGE IN PREGNANCY: The safe use of pancuronium bromide has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards.

Pavulon may be used in operative obstetrics (Cesarean section), but reversal of pancuronium may be unsatisfactory in patients receiving magnesium sulfate for toxemia of pregnancy, because magnesium salts enhance neuromuscular blockade. Dosage should usually be reduced, as indicated, in such cases.

PRECAUTIONS: Although Pavulon has been used successfully in many patients with pre-existing pulmonary, hepatic, or renal disease, caution should be exercised in these situations. This is particularly true of renal disease since a major portion of administered Pavulon is excreted unchanged in the urine.

ADVERSE REACTIONS: Neuromuscular: the most frequently noted adverse reactions consist primarily of an extension of the drug's pharmacological actions beyond the time period needed for surgery and anesthesia. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle relaxation resulting in respiratory insufficiency or apnea. Inadequate reversal of the neuromuscular blockade by anticholinesterase agents has also been observed with Pavulon (pancuronium bromide) as with all curariform drugs. These adverse reactions are managed by manual or mechanical ventilation until recovery is judged adequate.

Cardiovascular: A slight increase in pulse rate is frequently noted.

Gastrointestinal: Salivation is sometimes noted during very light anesthesia, especially if no anticholinergic premedication is used.

Skin: An occasional transient rash is noted accompanying the use of Pavulon.

Respiratory: One case of wheezing, responding to deepening of the inhalational anesthetic, has been reported.

DRUG INTERACTION: The intensity of blockade and duration of action of Pavulon is increased in patients receiving potent volatile inhalational anesthetics such as halothane, diethyl ether, enflurane and methoxyflurane. No increase in intensity of blockade or duration of action of Pavulon is noted from the use of thiobarbiturates, narcotic analgesics, nitrous oxide, or droperidol.

Prior administration of succinylcholine, such as that used for endotracheal intubation, enhances the relaxant effect of Pavulon and the duration of action. If succinylcholine is used before Pavulon, the administration of Pavulon should be delayed until the succinylcholine shows signs of wearing off.

DOSAGE AND ADMINISTRATION: Pavulon should be administered only by or under the supervision of experienced clinicians. DOSAGE MUST BE INDIVIDUALIZED IN EACH CASE. The dosage information which follows has been derived from dose-response studies based on body weight and is intended to serve as a guide only. Since potent inhalational agents or prior administration of succinylcholine enhance the intensity of blockade and duration of Pavulon (see DRUG INTERACTION), these factors should be taken into consideration in selection of initial and incremental dosage.

In adults the initial intravenous dosage range is 0.04 to 0.1 mg. per kg. Later incremental doses starting at 0.01 mg. per kg. may be used. These increments slightly increase the magnitude of the blockade, and significantly increase the duration of blockade, because a significant number of myoneural junctions are still blocked when there is clinical need for more drug.

If Pavulon is used to provide skeletal muscle relaxation for endotracheal intubation, doses of 0.06 to 0.1 mg. per kg. are recommended. Conditions satisfactory for intubation are usually present within 2 to 3 minutes. The ability of the anesthetist to intubate with Pavulon improves with experience.

Dosage in Children: Dose response studies in children indicate that, with the exception of neonates, dosage requirements are the same as for adults. Neonates are especially sensitive to non-depolarizing neuromuscular blocking agents, such as Pavulon, (pancuronium bromide) during the first month of life. It is recommended that a test dose of 0.02 mg. per kg. be given first in this group to measure responsiveness.

Cesarean Section: The dosage to provide relaxation for intubation and operation is the same as for general surgical procedures. The dosage to provide relaxation, following usage of succinylcholine for intubation (see DRUG INTERACTION), is the same as for general surgical procedures.

MANAGEMENT OF PROLONGED NEUROMUSCULAR BLOCKADE: Residual neuromuscular blockade beyond the time period needed for surgery and anesthesia may occur with Pavulon as with other neuromuscular blockers. This may be manifested by skeletal muscle weakness, decreased respiratory reserve, low tidal volume or apnea. A peripheral nerve stimulator may be used to assess the degree of residual neuromuscular blockade. Under such circumstances the primary treatment is manual or mechanical ventilation and maintenance of a patent airway until complete recovery of normal respiration is assured. Regonol (pyridostigmine bromide) or neostigmine, in conjunction with atropine, will usually antagonize the skeletal muscle relaxant action of Pavulon. These should be accompanied by or preceded by injection of atropine sulfate to minimize the incidence of cholinergic side effects, notably excessive secretions and bradycardia. Satisfactory reversal can be judged by adequacy of skeletal muscle tone, and by adequacy of respiration. A peripheral nerve stimulator may also be used to monitor restoration of twitch height. Failure of prompt reversal (within 30 minutes) may occur in the presence of extreme debilitation, carcinomatosis, and with concomitant use of certain broad spectrum antibiotics, or anesthetic agents and adjuncts which enhance neuromuscular blockade or cause respiratory depression of their own. Under such circumstances the management is the same as that of prolonged neuromuscular blockade; ventilation must be supported by artificial means until the patient has resumed control of his respiration. Prior to the use of reversal agents, reference to the specific package insert of the reversal agents should be made.

CAUTION: Federal law prohibits dispensing without prescription.

ANTILIRIUM
(Physostigmine Salicylate)

REVERSES MOST POST-OPERATIVE DELIRIUM AND PROLONGED SOMNOLENCE

Before prescribing, please consult complete product information, a summary of which follows:

ACTION: ANTILIRIUM (physostigmine salicylate) is a salicylic acid derivative of an alkaloid extracted from seeds of Physostigma Venenosum (calabar bean). The action of the parasympathetic nerves is intermediated by the formation of acetylcholine at the peripheral end of these nerves. Physostigmine inhibits the destructive action of cholinesterase and thereby prolongs and exaggerates the effect of the acetylcholine.

Physostigmine contains a tertiary amine and easily crosses the blood brain barrier, while neostigmine contains a quaternary amine and is not capable of crossing the structure. This may explain why neostigmine does not cause reversal of anticholinergic-induced delirium while physostigmine does.

INDICATIONS: TO REVERSE THE TOXIC EFFECTS UPON THE CENTRAL NERVOUS SYSTEM CAUSED BY DRUGS IN CLINICAL OR TOXIC DOSAGES CAPABLE OF PRODUCING ANTICHOLINERGIC POISONING.

SEVERE ANTICHOLINERGIC POISONING MAY PRODUCE: COMA, MEDULLARY PARALYSIS AND DEATH.

CENTRAL TOXIC EFFECTS MAY INCLUDE: HALLUCINATIONS, DELIRIUM, DISORIENTATION, ANXIETY AND HYPERACTIVITY.

Dramatic reversal within minutes of coma, hallucinations, and other signs can be expected if the diagnosis is correct and the patient has not suffered anoxia or other insult. Therapeutic doses may be necessary at intervals as life-threatening signs recur. Physostigmine is destroyed in the body in 60 to 120 minutes.

CONTRAINDICATIONS: Physostigmine should not be used in the presence of asthma, gangrene, diabetes, cardiovascular disease, mechanical obstruction of the intestines or urogenital tract or any vagotonic state, and in patients receiving choline esters or depolarizing neuromuscular blocking agents.

WARNING: If excessive symptoms of salivation, emesis, urination and defecation occur, the use of ANTILIRIUM should be terminated. If excessive sweating or nausea occur, the dosage should be reduced.

Intravenous administration should be at a slow, controlled rate, no more than 1 mg. per minute (see dosage). Rapid administration can cause bradycardia, hypersalivation leading to respiratory difficulties and possibly convulsions.

An overdosage of ANTILIRIUM can cause a cholinergic crisis.

PRECAUTIONS: Because of the possibility of hypersensitivity in an occasional patient, atropine sulfate injection should always be at hand since it is an antagonist and antidote for physostigmine.

ADMINISTRATION AND DOSAGE: The usual adult dose of ANTILIRIUM is 0.5 to 2.0 mg. intramuscularly or intravenously. Intravenous administration should be at a slow, controlled rate of no more than 1 mg. per minute. It may be necessary to repeat dosages of 1 mg. to 4 mg. at intervals as life threatening signs such as arrhythmias, convulsions and deep coma recur.

IN ALL CASES OF POISONING, THE USUAL SUPPORTIVE MEASURES SHOULD BE UNDERTAKEN.

SUPPLIED: 2 ml. ampules containing: PHYSOSTIGMINE SALICYLATE 1 mg. per ml. Packed 12 ampules per box.

NDC 0456-1037-12

CAUTION: Federal law prohibits dispensing without prescription.

Arterial and Venous Plasma Levels of Bupivacaine Following Peripheral Nerve Blocks

DANIEL C. MOORE, MD*
LAURENCE E. MATHER, PhD†
L. DONALD BRIDENBAUGH, MD‡
ROBERT I. BALFOUR, MD§
DONALD F. LYSONS, MD‖
WILLIAM G. HORTON, MD**
Seattle, Washington††

Mean arterial plasma (MAP) and peripheral mean venous plasma (MVP) levels of bupivacaine were ascertained in 3 groups of 10 patients each for: (1) intercostal nerve block, 400 mg; (2) block of the sciatic, femoral, and lateral femoral cutaneous nerves, with or without block of the obturator nerve, 400 mg; and (3) supraclavicular brachial plexus block, 300 mg. MAP levels were consistently higher than simultaneously sampled MVP levels, the highest levels occurring from bilateral intercostal nerve block. No evidence of systemic toxicity was observed. The results suggest that bupivacaine has a much wider margin of safety in humans than is now stated.

BUPIVACAINE, like all local anesthetic agents, is used in varying concentrations and volumes, depending on the peripheral nerve-block technic to be employed and on the type of procedure for which it is being performed—surgery, obstetrics, diagnosis, or therapy. If there is no need for rapid establishment of sensory anesthesia, and if complete motor blockade is not required or desired, as for diagnostic or therapeutic peripheral nerve block, 0.25 percent bupivacaine can be employed.[1,2] However, to assure rapid onset of sensory anesthesia and complete motor blockade for surgical procedures after peripheral nerve block, 0.5 percent bupivacaine is required.[1,2]

The purpose of this paper is to report plasma levels of bupivacaine following the use of concentrations, volumes, and milligram doses adequate for all peripheral nerve-block technics.

METHOD OF STUDY

Blocks Studied and Selection of Patients.—Mean arterial plasma (MAP) and mean venous plasma (MVP) levels of bupivacaine were ascertained following: (1) supraclavicular brachial plexus block, in 10 patients; (2) bilateral intercostal nerve block, in 10 patients; and (3) sciatic, femoral, and lateral femoral cutaneous nerve blocks, with or

LIBRARY

without obturator nerve block, in 10 patients. Patients were not screened but were chosen consecutively, depending on the operating room schedule and the number of patients that could be studied on any specific day. Written informed consent, as approved by the Human Rights Committee of the Virginia Mason Research Center, was obtained from every patient for: (1) block technic; (2) arterial and venous sampling; and (3) bupivacaine dosage.

Premedication.—Premedication was the choice of the resident involved. Patients who had supraclavicular brachial plexus blocks, as well as those given sciatic, femoral, and lateral femoral cutaneous nerve blocks, with or without obturator nerve block, received no sedation other than the premedication, until the surgical procedure began. The 10 patients given bilateral intercostal nerve blocks received 100 to 150 mg of 0.2 percent methohexital solution IV before and during block administration, in addition to the premedication, so that they would not remember being blocked. Methohexital administration was stopped before completion of the block, so patients were able to respond to questions within 10 minutes after block completion.

Dosage of Bupivacaine and Block Technic.—For supraclavicular brachial plexus block, 60 ml of 0.5 percent bupivacaine (300 mg) with 0.25 mg of epinephrine (1:240,000) was injected. For the bilateral block of the 6th through the 12th intercostal nerves, 80 ml of 0.5 percent bupivacaine (400 mg) with 0.25 mg of epinephrine (1:320,000) was administered—5 ml to each of the 14 nerves, or a total of 70 ml plus 10 ml for skin wheals and infiltration. Because we wanted to complete the intercostal nerve blocks in less than 5 minutes, 2 anesthesiologists worked simultaneously (1 on each side). For sciatic, femoral, and lateral femoral cutaneous nerve blocks, with or without obturator nerve block, 80 ml of 0.5 percent bupivacaine (400 mg) with 0.25 mg of epinephrine (1:320,000) was employed. For sciatic nerve block 30 ml was used and the remainder equally distributed among the other nerves to be blocked. Technics were as previously described.[3]

Blood Sampling and Plasma Analysis.—For arterial sampling, a 20-gauge, 3.8-cm Teflon catheter needle was inserted percutaneously into the radial artery. For venous sampling, a 16-gauge, 6.4-cm Teflon catheter needle was inserted in the largest available vein in the cubital fossa of the same arm. IV anesthetics were administered through a 16-gauge, 6.4-cm Teflon catheter inserted in a vein in the opposite hand.

The blocks were performed in a central induction room where the patient remained for at least 30 minutes after completion of the block. In no case was the surgical procedure begun until after the 45-minute sample was drawn. Blood samples were drawn simultaneously from the artery and vein at 0 (control), and then at 5, 10, 15, 20, 25, 30, 45, 60, and 120 minutes from the start of the block by raising of the skin wheal. Plasma levels of bupivacaine were determined by gas chromatography.[4]

Time Determinations.—Elapsed time was calculated to the closest minute. All timing, including sampling times, was determined by stopwatches.

Analysis of Data.—All data were analyzed by the Conversational Computer Statistical System and significance was determined by the test of bivariant correlations.[5]

RESULTS

All 30 blocks produced satisfactory surgical anesthesia, indicating that the solutions of bupivacaine had been placed correctly and in adequate volume and concentration.

Supraclavicular Brachial Plexus Blocks With 60 ml of 0.5 Percent Bupivacaine (300 mg) Containing Epinephrine 1:240,000.—Six of these blocks were completed within 5 minutes, 2 within 7 minutes, and 2 within 8 minutes, with a mean time of 5.5 (SD ± 1.8) minutes for the 10 blocks.

The mean peak arterial and venous plasma levels in 6 men and 4 women, 20 to 69 years of age, weighing 53 kg or more, and undergoing upper extremity surgery, were 1.71 (range 1.05 to 2.40) mcg/ml and 1.55 (range 0.94 to 2.25) mcg/ml, respectively.* They occurred 30 to 35 minutes after injection of the agent (fig 1).

Bilateral Intercostal Nerve Blocks With 80 ml of 0.5 Percent Bupivacaine (400 mg) Containing Epinephrine 1:320,000.—Nine of these blocks were completed within 5 minutes and 1 in 7 minutes, with a mean time of 4.4 (SD ± 0.97) minutes.

*Mean peak level is the highest microgram level attained in plasma from each of the 10 patients in each group.

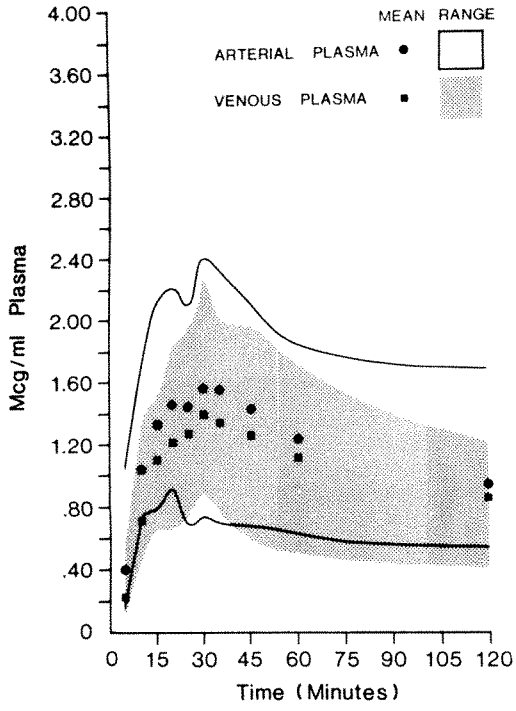

FIG 1. Means and range of arterial and venous plasma levels of 60 ml of bupivacaine 0.5 percent (300 mg) with 1:240,000 epinephrine following supraclavicular block at time intervals of sampling. ● = mean arterial plasma level; black lines = ranges (high and low) of arterial plasma levels; ■ = mean venous plasma level; edges of shaded area = high and low of venous plasma levels.

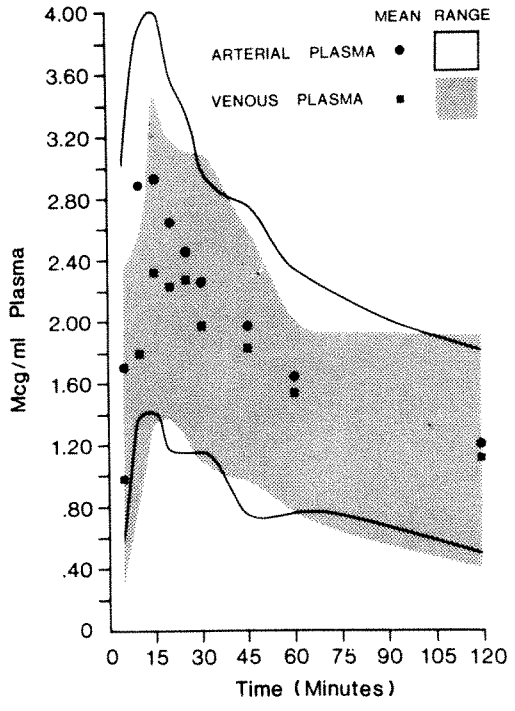

FIG 2. Means and range of arterial and venous plasma levels of 80 ml of bupivacaine 0.5 percent (400 mg) with 1:320,000 epinephrine following bilateral intercostal nerve block at the time intervals of sampling. ● = mean arterial plasma level; black lines = ranges (high and low) of arterial plasma levels; ■ = mean venous plasma level; edges of shaded area = high and low of venous plasma levels.

The mean peak arterial and venous plasma levels in 6 men and 4 women, 20 to 72 years of age, weighing 49 kg or more, undergoing upper intraabdominal surgery, were 3.29 (range 1.72 to 4) mcg/ml and 2.52 (range 1.4 to 3.45) mcg/ml, respectively. They occurred 10 to 20 minutes after injection of the agent (fig 2).

Sciatic, Femoral, and Lateral Femoral Cutaneous Nerve Block With or Without Obturator Nerve Block With 80 ml of 0.5 Percent Bupivacaine (400 mg) Containing Epinephrine 1:320,000.—Two of these blocks were completed within 7 minutes, 5 within 8 minutes, 2 within 10 minutes, and 1 within 14 minutes, with a mean time for the 10 patients of 8.8 (± 2.1) minutes.

The mean peak arterial and venous plasma levels in 6 male and 4 female patients, 14 to 79 years of age, 1 weighing 39 kg and the others 60 kg or more, for lower extremity surgery, were 1.89 (range 1.0 to 3.16) mcg/ml and 1.6 (range 0.84 to 2.73) mcg/ml, respectively. They occurred within 15 minutes after injection of the agent, these levels persisting for up to 60 minutes (fig 3).

DISCUSSION

Selection of Blocks Studied and Dosages of Bupivacaine and Epinephrine.—Peripheral nerve blocks were investigated in this study because: (1) we frequently employ them, particularly in the patient with poor physical status—ASA status III, IV, or V; (2) they may sometimes require a higher volume (60 to 80 ml) of 0.5 percent bupivacaine for rapid establishment of surgical sensory anesthesia and for complete motor blockade; and (3) if systemic toxic reactions are to occur from bupivacaine *absorption* in any block technic, this would most likely be after such blocks.[6] In addition, bilateral intercostal nerve block can usually be completed within a 5-minute period; when it is done rapidly and properly, the plasma levels of local anesthetic agents peak sooner and are higher than with any other regional nerve block studied to date.[7,8]

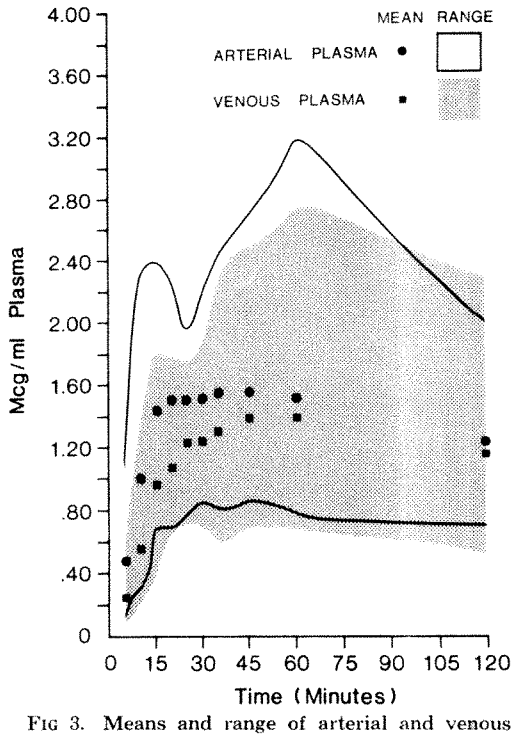

FIG 3. Means and range of arterial and venous plasma levels of 80 ml of bupivacaine 0.5 percent (400 mg) with 1:320,000 epinephrine following sciatic, femoral, and lateral femoral cutaneous nerve blocks with or without obturator nerve block at time intervals of sampling. • = mean arterial plasma level; black lines = ranges (high and low) of arterial plasma levels; ■ = mean venous plasma level; edges of shaded area = high and low of venous plasma levels.

The volumes and concentrations for these blocks were chosen because they are the approximate maxima that might be required to result in effective sensory and motor blockade under any circumstance, clinical or teaching. If a volume greater than 80 ml is required—for example, 100 ml for a bilateral intercostal nerve block with celiac plexus block—the necessary volume may be obtained by adding 20 ml of normal saline solution to the 80 ml of 0.5 percent (400 mg) of the bupivacaine solution. This would lower rather than raise plasma levels of bupivacaine because the weaker the concentration, the lower the plasma level of the local anesthetic.[8] Furthermore, the slight reduction in the concentrations of the bupivacaine solutions will not noticeably affect sensory or motor anesthesia.

All solutions in this study contained epinephrine. Epinephrine is added to most local anesthetic solutions because it lowers the blood level of such agents by slowing absorption from the site of injection.[3,9] We seldom exceed a dose of 0.25 mg of epinephrine regardless of volume of the local anesthetic solution injected.[3] Therefore, the solutions used contained epinephrine 1:240,000 (0.25 mg/60 ml) and 1:320,000 (0.25 mg/80 ml), which are considered less than the optimal [1:200,000 (0.1 mg/20 ml)].[3,9-11]

Arterial and Venous Plasma Levels.—Plasma levels were selected rather than whole blood because plasma is easier to analyze and 95 percent of bupivacaine is protein-bound in the plasma.[12]

Arterial levels were compared with peripheral venous levels because they more closely reflect changes in drug levels in well-perfused vital organs and are more sensitive to change in drug absorption and disposition.[13] Venous sampling is more subject to variability and artifact due to local circulatory changes in the sampling site, in which case the resultant blood concentration profile may lead to erroneous conclusions.[14] For these reasons, toxic effects may be more reliably associated with arterial rather than venous levels.*[14]

Following bilateral intercostal nerve block, MAP levels were 20 to 25 percent higher than simultaneously sampled venous plasma levels. They occurred earlier and the arteriovenous differences persisted for approximately 60 minutes after injection (fig 2). Such marked differences did not occur in the arteriovenous plasma levels of the other 2 block technics studied, in which plasma levels peaked later and were significantly lower than those occurring after bilateral intercostal nerve block (fig 1 and 3). In part, this is due to: (1) the lower dose used in brachial plexus block; (2) the longer time needed to execute brachial plexus and sciatic, femoral, and lateral femoral cutaneous nerve blocks; and (3) circulatory differences of the areas.

Systemic Toxicity.—Plasma levels of bupivacaine resulting in convulsions in man have been reported as 4 mcg/ml or higher.[13] In only 1 of our 30 patients did the arterial plasma level peak at 4 mcg/ml in 15 minutes following a bilateral intercostal nerve block. No systemic toxic reactions were observed in any of the 30 patients. We did not expect any such reactions; from 1966 through 1975, we administered 0.25 or 0.5 percent bupivacaine for 3137 peripheral nerve blocks, with and without epinephrine, with no evidence of systemic toxicity. Of these, 2520

	518	501	1501	2520

were the same blocks investigated in this study (table).

Such factors as age, weight, and underlying disease have been said to influence the development of systemic toxic reactions.[3,9,10] The degree of importance of these factors in adults, if any, needs verification. No correlations between these factors and maximum plasma levels were found in our previous study of bupivacaine or of mepivacaine, whose chemical structure closely resembles that of bupivacaine (bupivacaine contains a butyl radical where mepivacaine contains a methyl radical[8,15]). Likewise, in the small patient population reported herein, the bivariant correlations between predictor variables (sex, age, height, weight, and physical status) and each of the various plasma-level criteria were of no significance.

In the sciatic, femoral, and lateral femoral cutaneous nerve block group of 10 patients, the 79-year-old woman weighed 39 kg, was 157 cm tall, with a physical status of ASA II. Her block took 7 minutes to execute, and peak arterial and venous levels were 2.38 mcg/ml and 1.80 mcg/ml, respectively, in 15 minutes. These levels were not the highest in the ranges and may further indicate that age and weight are of little significance in determining dosage.

The principal factor in determining nontoxic dosage in adults is probably the specific regional block technic, considering (1) the area of the body injected; (2) its vascularity; and (3) the possibility of an intravascular injection from a needle whose position is not changed during injection of a large dose of the local anesthetic agent, as in epidural (peridural) block. In our peripheral nerve blocks, it is unlikely that a large bolus would be injected intravascularly, for the position of the needle is seldom fixed in a single position during the entire block procedure.[3]

Although premedication may mask, ameliorate, or prevent systemic toxic reaction, it is doubtful that this occurred in our 30 patients. Nineteen received meperidine (50 to 125 mg), while 11 received morphine (8 to 15 mg). Eight patients received no other premedication. The remaining patients received along with the IM narcotic: (1) atropine 0.4 mg (n = 15); (2) scopolamine 0.4 mg (n = 2); (3) diazepam 10 mg (n = 4); or (4) atropine 0.4 mg with hydroxyzine 75 mg (n = 1).* Perhaps the methohexital administered during bilateral intercostal nerve block could have prevented recognition of a systemic toxic reaction, but this is doubtful because the dose was minimal.

Shivering.—Shivering has been cited as possible evidence of a mild systemic toxic reaction after bupivacaine administration.[1,2,16] Therefore, this sign was carefully observed, both in the induction room, where all blocks were performed and the temperatures were 23.3° C or above, and in the operating rooms, where the temperatures were 21.1° C or less. In the induction room, where the patient remained for at least 30 minutes after block completion, none of the patients shivered. In the operating rooms, shivering occurred in 3 of the 10 patients given bilateral intercostal nerve blocks, but in none of the patients in whom the extremity was blocked. In a previous study of parturients, shivering was higher with 0.25 percent than with 0.5 percent solutions of bupivacaine.[16] In both instances, shivering occurred when temperatures in the rooms were between 18.3 and 21.1° C. Shivering may result from a number of variables such as room temperature or degree of block of the sympathetic nervous system, the least influential of which may be the local anesthetic agent.

Systemic Toxicity and Package Inserts.—In countries other than the USA, the dosage of 0.25 and 0.5 percent concentrations of bupivacaine is 2 mg/kg, with the maximum of 100 mg without epinephrine and 150 mg

*n = number of patients.

with epinephrine 1:200,000.* In the USA, maximum doses of such concentrations have not been determined, and the package insert states: (a) "Most experience to date is with single doses of Marcaine up to 225 mg with epinephrine 1:200,000, and 175 mg without epinephrine; more or less drug may be used depending on the individualization of each case;" and (b) "In clinical studies to date, total daily doses have been up to 400 mg. Until further experience is gained, this dose should not be exceeded in 24 hours."† However, some physicians misinterpret point (a) to mean that these doses stated represent maximum total dosage.

From our clinical experiences with bupivacaine and peripheral nerve block from 1966 through March 1975, involving 3137 patients, of whom 1863 received in excess of 150 mg and at least 836 in excess of 225 mg (table), as well as from the plasma studies reported herein, such restrictions appear unnecessarily stringent and in need of revision because bupivacaine apparently has a much greater margin of safety in humans than the package insert indicates, and dosages as stated in the inserts of other countries markedly limit the use of this versatile, long-acting local anesthetic agent in single-dose peripheral nerve blocks.

A Word of Caution.—Readers are cautioned that the 0.75 percent solution of bupivacaine available in the USA was developed for use in single-dose epidural or caudal block *only*—not for peripheral nerve-block technics.[1,2] If this concentration is used for peripheral nerve block in the dosages described above, systemic toxic reactions might occur, because the higher the concentration of a local anesthetic in the same milligram dose, the higher the blood level of the agent.[8]

ACKNOWLEDGMENT

The authors thank Gayle DeBay for determination of plasma levels in the gas chromatograph laboratory at the University of Washington School of Medicine, Department of Anesthesiology, under the directorship of Laurence E. Mather, Ph.D. Also for programming and analysis of data appreciation is expressed to Jeri Kronmal and James Hayes, Ph.D.

Advantages of Infant Ventilators Over Adapted Adult Ventilators in Pediatrics

ROBERT E. BINDA, JR, MD*
DAVID R. COOK, MD†
CARL G. FISCHER, MD‡
Pittsburgh, Pennsylvania§

A lung simulator with variable compliance and resistance components was used to evaluate the dynamic compliance of the Bournes, Babybird, and Pediatric Emerson postoperative ventilators. With increase in airway pressure from combined changes in compliance and resistance, the internal compliance of the Bournes was lowest and the internal compliance of the Emerson was highest. With low constant airway resistance (50 cm/L/sec), the Babybird exhibited tidal volume losses similar to those of the Bournes in the face of decreased lung compliance. With constant lung compliance (10 ml/cm H_2O) and increasing airway resistance, the Babybird had marked volume losses at higher volumes. Under all simulated conditions, internal compliance of the Emerson, although large, was relatively constant and the Bournes had the smallest internal compliance.

WHEN mechanical ventilators are used for infants and small children, significant volumes of gas may be lost to the patient as airway pressure increases as a result of (1) compression of gas in the internal volume of the ventilator and (2) distention of the flexible tubing that connects ventilator and patient. As airway pressure rises from either a decrease in lung compliance or an increase in airway resistance, there will be a decrease in delivered volume. These volume losses may have significant effects on the minute volume and hence gas exchange in infants.[1]

We compared the volume losses from increased airway pressure in an adult ventilator adapted for pediatric use and in 2 ventilators specificially designed for infants. In addition, we evaluated the difference between volume losses when the increase in airway pressure was first produced by a decrease in compliance and second by an increase in airway resistance.

MATERIAL AND METHODS

Three infant ventilators were compared: the Emerson postoperative with pediatric piston and modified for IMV, a Babybird, and a Bournes. These were selected at random from those used daily in the intensive care unit, and each was studied with a full humidifier in place.[2] All were equipped with Tygon patient tubing.

Ventilator function was tested with a Bournes Infant Lung Simulator, which consists of several 150-ml containers of known

Paper received: 11/10/75
Accepted for publication: 3/15/76

compliance, connected in series by nondistensible Tygon tubing. The containers are filled with finely divided copper wool to ensure that compression of gas within them is isothermal and not adiabatic.[3] Compliance can be varied from 10 to 1 ml/cm H_2O. The simulator also allows changes in airway resistance from 50 to 500 cm H_2O/L/sec by interchanging small metal filters proximal to the compliance component. In all studies, a 3.5-mm OD endotracheal tube was interposed between the ventilator and the lung simulator.[4] Air was used as the gas in all studies.

Peak airway pressure and lung pressure were measured with aneroid manometers connected to the simulator. These pressures were secondarily displayed on an oscilloscope that could be marked for calibration. By knowing the compliance and lung pressure, the simulator could be used as a "pneumatic integrator," the delivered lung volume being the product of compliance (ml/cm H_2O) and lung pressure (cm H_2O).

To test the accuracy of this pneumatic integrator, a 3.5-mm OD endotracheal tube was connected to a Fleisch #0 pneumotachograph. The pressure drop across the resistance of the pneumotachograph was measured by a differential pressure transducer, amplified, integrated, and gas flow and volume recorded on a Grass polychannel recorder. A Hamilton syringe and an oiled glass syringe were used to calibrate the electronic integrator on the Grass recorder for volume. There was linear response in the electronic integrator from 20 to 200 ml tidal volume.

The pneumotachograph head was then interposed between the resistance component and one of the compliance containers. Volume from a piston ventilator was delivered to the lung simulator and resistance varied from 50 to 500 cm H_2O/L/sec. The delivered volumes to the lung calculated from the pneumatic integrator of the Bournes simulator and from the electronic integrator agreed within ± 5 percent. The calculated internal compliance of the ventilator using the two differently derived volumes was essentially the same.

The internal compliance of a ventilator is a measure of the volume lost within a ventilator system following rises in airway pressure during gas flow. The higher the internal compliance of a ventilator system, the greater the amount of gas it can accommodate without transferring this volume to the patient in response to an increase in pressure within the ventilator.

The experiment was divided into 3 parts. In each part, the ventilators were adjusted to provide ± 100, 60, and 40 ml delivered lung volume at the lowest resistance and highest compliance on the lung simulator at a ventilator rate of 20/min.

In part A, compliance was decreased in steps and resistance was increased to give 12 progressive increases in airway pressure. The 12 compliances of the lung and lung pressures were noted at each setting. The delivered volume was then calculated.

In part B, airway resistance was kept constant while compliance was decreased in 4 steps from 10 to 1 ml/cm H_2O, and again delivered volume was calculated.

In part C, compliance was maintained constant at 10 ml/cm H_2O, while airway resistance was increased in 7 steps from 50 to 500 cm/L/sec.

For each volume in all 3 parts, a linear regression equation was derived from the calculated lung volume and airway pressures. The correlation coefficient was calculated. The slope of this regression line is the internal (effective) compliance of the ventilator.

The slope of the calculated regression line is the volume lost/cm H_2O change in pressure. Student's *t*-test was used to determine the significance of slope differences for each ventilator at comparable preset volumes.

RESULTS

In part A of this study, where both airway resistance and lung compliance were varied, the Bournes ventilator had the lowest internal compliance, the Babybird had twice this value, and the Emerson had 5 times this value at the several volumes studied (table 1). The volume losses to the patient as peak airway pressure rises are significantly greater with the Babybird and Emerson than with the Bournes; volume losses with the Emerson were greater than with the Babybird.

When the airway resistance is constant, the Babybird and Bournes have comparable volume losses as airway pressure increases because of decreases in lung compliance (table 2). The Emerson has 4 to 5 times the volume loss of the other two.

DISCUSSION

A lung simulator allows variation in airway resistance and lung compliance separately, approximating the conditions encountered in a patient with pulmonary disease. Such a device provides a method for comparing the performance of various pediatric ventilators. The Bournes simulator is patterned after the simulator suggested by the International Standards Committee.[5]

When airway resistance was increased and lung compliance decreased, the Bournes ventilator had the lowest internal compliance. Lower internal compliance reflects smaller tidal volume losses with increases in airway pressures. The Babybird had approximately twice and the Emerson had approximately 5 times the internal compliance of the Bournes.

When airway resistance was constant, the Babybird improved its performance to the level of the Bournes. However, when increased airway resistance was simulated, the internal compliance of the Babybird was similar to that of the Emerson. Since the tidal volume of a Babybird is flow-generated, as airway resistance is increased, the delivered flow will decrease.

This relation between flow, pressure, and resistance in the airway is generally analogous to the relationship between current, electromotive force, and resistance in an electric circuit, as expressed in Ohm's Law:

$$\text{Current (i)} = \frac{\text{Electromotive force (E)}}{\text{Resistance (R)}}$$

$$\text{Flow (F)} \propto \frac{\text{Pressure (P)}}{\text{Resistance (R)}}$$

Since delivered tidal volumes flow from areas of high pressure (within the ventilator) to areas of relatively low pressure (within the lung) and since this pressure dfferential remains relatively constant, any increase in airway resistance will result in a decrease in delivered flow.

In the Babybird ventilator, which is time cycled, the tidal volume is the product of the flow rate and the inspiratory time. If the delivered flow is decreased because of an increase in airway resistance, the tidal volume delivered is likewise decreased.

No ventilator functions as a true "volume" ventilator when used to ventilate infants. In part, compression and distention volume losses can be compensated for by increasing the preset tidal volume of the ventilator above the required patient tidal volume. This provides an adequate patient tidal volume when airway pressure remains constant. If airway pressure rises, significant tidal volume losses to the infant may occur; in adults this volume loss due to increased airway pressure represents a small fraction of the patient tidal volume.

One of the factors influencing the compression volume loss is the size of the internal volume of the ventilator,[2] the larger the internal volume, the larger the tidal volume losses. Even though compression volume losses in the Emerson can be anticipated and additional tidal volume used to allow for these losses, subsequent changes in airway pressures will result in greater volume losses in the adult ventilators.

Therefore, there is a definite advantage in using infant ventilators (with small internal volumes) for the mechanical ventilation of infants rather than adapting adult ventilators for this purpose.

POSTOPERATIVE RENAL FAILURE. Since acute renal failure (ARF) in the postoperative period has an extremely poor prognosis, it is important to be able to predict preoperatively the patients at risk. A prospective study of 500 consecutive cardiac operations evaluated the incidence, etiology and therapy of postoperative ARF. Thirty-five patients developed ARF. Positive risk factors included age, elevated preoperative renal function tests (BUN, serum creatinine, creatinine clearance) reduced cardiac output preoperatively, duration of cardiopulmonary bypass and duration of aortic cross clamping. Factors that did not correlate with the development of ARF included the type of operation, intraoperative blood pressure or urine output, flow rate during cardiopulmonary bypass, hemoglobinemia or preoperative diuretic therapy. Mortality was 88.8 percent and 100 percent if dialysis was required. Postoperative ARF is better prevented than treated. *(Abel RA, Buckley MJ, Austen WG et al: Etiology, incidence and prognosis of renal failure following cardiac operations. Results of a prospective analysis of 500 consecutive patients. J Thor Cardiovas Surg 71:323-333, 1976)*

Ketamine and Intraocular Pressure in Children

BAIBA AUSINSCH, MD*
ROBERT L. RAYBURN, MD†
EDWIN S. MUNSON, MD‡
NORMAN S. LEVY, MD, PhD§
Gainesville, Florida‖

The effect of ketamine on intraocular pressure (IOP) was studied in 10 children. Control IOP values were determined prior to induction of anesthesia, following premedication with atropine alone or in combination with pentobarbital and meperidine. After the IM injection of 8 mg/kg of ketamine, the IOP was determined at 5, 10, 15, and 20 minutes. Mean (± SD) IOP values before and after ketamine were 22.2 ± 4.8 and 16.7 ± 3.3 torr ($p<0.001$), respectively. The authors believe that the reduction in IOP was not due to ketamine, per se, but rather to lack of patient relaxation and cooperation during control measurements. At the end of 20 minutes, a second dose of ketamine, this time 1 mg/kg IV, was given and measurements were repeated at the same intervals. In 5 patients, the effects on IOP of d-tubocurarine, endotracheal intubation, and N_2O inhalation also were evaluated. A significant increase (6.7 torr) in IOP was observed only after endotracheal intubation. The authors conclude that ketamine does not raise IOP in the healthy pediatric patient and, therefore, can be used for ophthalmic procedures requiring sedation or anesthesia.

KNOWLEDGE of the effect of anesthetic agents on intraocular pressure (IOP) is important in the selection of anesthesia for patients with elevated IOP or open eyeball injuries. While most inhalation anesthetics produce little or no decrease in IOP,[1-3] ketamine has been reported to increase IOP markedly[4,5] or to a mild degree.[6,7] Yet another study[8] in adults reported that ketamine had no effect on IOP.

Furthermore, knowledge of the normal range of IOP associated with the use of ketamine is necessary for the ophthalmologist in the diagnosis and treatment of glaucoma. We therefore evaluated the effects of ketamine on IOP in a group of healthy pediatric patients. The effects on IOP of d-tubocurarine, endotracheal intubation, and N_2O inhalation were also examined.

METHODS

Ten healthy children who showed no evidence of intraocular disease were studied. Ages ranged from 2 to 10 (mean 5.7) years and mean weight was 21.5 ± 8.1 kg. Informed consent was obtained from parents or guardians and the experimental protocol was approved by the University's Committee for the Protection of Human Subjects.

Each patient received 0.02 mg/kg of atropine IM 1 hour before the study, 5 also receiving 1.1 mg/kg of meperidine and 2.2 to 4.4 mg/kg of pentobarbital IM. Studies were conducted in a quiet room adjacent to the operating room. Following corneal application of 0.5 percent proparacaine hydrochloride ophthalmic solution, control measurements of IOP were obtained in both eyes with a MacKay-Marg electronic applanation tonometer.[9] Blood pressure was monitored throughout the study period by standard arm-cuff occlusion. The ECG (lead II) recorded cardiac rate and rhythm.

The protocol was divided into two phases. In phase I, anesthesia was induced in all 10 patients with 8 mg/kg of ketamine IM. IOP measurements were made after 5, 10, 15, and 20 minutes while patients spontaneously breathed room air. Phase II began with the administration of a 2nd dose of 1 mg/kg of ketamine IV, 20 minutes after the initial IM dose. Patients were then randomly divided into 2 equal groups.

In group A (controls), IOP measurements were recorded in 5 patients after 5, 10, and 15 minutes while breathing 100 percent O_2. The other 5 patients received 0.8 mg/kg of d-tubocurarine IV in addition to the 2nd dose of ketamine. They were ventilated with O_2, and 5 minutes later IOP was measured. Muscular response was evaluated by ulnar nerve stimulation at the wrist with a Wellcome peripheral nerve stimulator. The tracheas of these patients then were intubated with the aid of a straight laryngoscope blade and, after a period of 5 minutes, IOP measurements were determined. N_2O-O_2 (70:30) was then administered, and IOP was again measured at 5 minutes in 5 patients and at 10 minutes in 3 patients.

The average pressure in both eyes was used in the tabulations and in statistical analysis of paired data by Student's *t*-test.

RESULTS

Phase I: Mean (± SD) IOP values before and after ketamine (8 mg/kg) were 22.2 ± 4.8 and 16.7 ± 3.3 torr ($p<0.001$), respectively (table 1). The reduction in IOP persisted throughout the 20-minute observation period. Although 5 of 10 children received premedication, only 3 were relaxed and cooperative during control IOP measurements. In the 3 children in whom adequate control measurements were obtained, IOP was 17.5 ± 2.6 torr, a value significantly less ($p<0.05$) than for the 7 uncooperative patients (24 ± 3.5).

†0.8 mg/kg IV.
‡$p<0.05$ from all other values.
§Represents mean (and range) in 3 patients.

No IOP differences after ketamine were observed between premedicated and unpremedicated children. Both systolic blood pressure and heart rate showed a significant ($p<0.05$) increase (10 and 16 percent, respectively) 5 minutes after ketamine administration. These changes were maintained throughout the study period.

Phase II: Mean (± SD) IOP values after IV ketamine (1 mg/kg) in 5 children are shown in table 2. No significant effect on IOP was observed when compared to the 20-minute value after the initial IM ketamine. The administration of a paralyzing dose of d-tubocurarine in the other 5 patients resulted in a small (2.2 torr) but insignificant decrease in IOP (table 3). The

greatest change in IOP occurred after endotracheal intubation, when a 6.7 torr increase ($p<0.05$) was observed. A 10 percent increase ($p<0.05$) in systolic blood pressure also occurred at this time. No change in heart rate was observed. Following N_2O administration, IOP and systolic blood pressure returned to control levels.

DISCUSSION

In contrast to the reports of others,[4-7] our findings show that ketamine anesthesia does not produce an increase in IOP. Mean IOP values during 35 minutes of ketamine anesthesia ranged from 15.4 to 17.5 torr, values similar to those we previously reported for halothane and isoflurane.[1] The presence or absence of narcotic-barbiturate premedication did not affect this response. These observations, and the finding that a paralyzing dose of d-tubocurarine failed to produce further lowering of IOP, indicate that an IOP value of 16 to 17 torr (as determined by applanation tonometry) probably represents a basal pressure in the anesthetized state.

When compared to awake control measurements, we observed a small but significant reduction in IOP after ketamine administration. However, we believe that this reduction was not an effect of ketamine, per se, but rather related to the lack of relaxation and patient cooperation in most children during control measurements. Five of our patients received premedication and adequate cooperation was achieved in only 3. In contrast, sedated control IOP measurements in our previous study of a larger group of children[1] showed an IOP value of 17.4 ± 3.4 torr, which is similar to that observed in our 3 cooperative sedated patients before ketamine, and in all 10 patients after ketamine in this study (table 1).

The observation of a significantly elevated IOP 5 minutes after endotracheal intubation was unanticipated and is not readily explained. However, it does suggest that the finding of an elevated IOP immediately after endotracheal intubation should be viewed with caution in a child with an open eye and anesthetized with ketamine. Similarly, this response may interfere with the evaluation of glaucoma.

Our findings during ketamine anesthesia agree with those of Peuler[8] and of Harris.[10] However, differences in methodology and age distribution do not permit direct quantitative comparisons. Corssen[7] also reported similar IOP values during ketamine anesthesia, but the results of that study represent a small (2 torr), but statistically significant, increase in IOP. The greatest increase in IOP was found by Purschke and Hassouna,[5] who reported an increase of 34 torr 15 minutes after ketamine administration.

The inconsistency of previous studies evaluating ketamine action may be related, in part, to differences in premedication and the methods of tonometry. The MacKay-Marg applanation tonometer is generally considered more accurate than the indentation tonometers used in many of the previous studies.

We conclude that in the absence of endotracheal intubation, ketamine does not raise IOP in the healthy pediatric patient and, therefore, can be used for ophthalmic procedures requiring sedation or anesthesia.

Anesthesia and the Modification of Response to Infection in Mice

PETER G. DUNCAN, MD*
BRUCE F. CULLEN, MD†
NANCY N. PEARSALL, PhD‡
Seattle, Washington§

Anesthetic-induced immunosuppression, if clinically significant, could modify the natural course of infectious diseases *in vivo*. To test this hypothesis, the localized response to IM *Candida albicans* and the mortality following fecal peritonitis were examined in anesthetized mice. Using these 2 models, halothane anesthesia was found not to modify the natural history of local sepsis but to significantly accentuate the mortality associated with the more severe infection. Possible explanations for these results include significant inhibition of reticuloendothelial function or plasma opsonization with relatively minor derangements of peripheral leukocyte capability.

ANESTHESIA and surgery are associated with suppression of various components of the immune response.[1,2] Anesthesia may reduce bacterial phagocytosis and killing, impair lymphocyte transformation, and alter immunoglobulin production in appropriate *in vitro* assay systems. However, the significance of these observed defects to the *in vivo* resistance to infection remains to be determined. The immune system has many effector mechanisms which tend to overlap in the intact individual, thus compensating for an isolated deficiency in a single component. In addition, immune responses are often far greater than needed to control an invading organism, suggesting that the deficiency must be quantitatively large or the infection unusually great before adverse effects will be noted. The present studies were undertaken to determine what role, if any, anesthesia plays in the host response to infection *in vivo*.

We studied the influence of halothane in the pathogenesis of 2 types of infections in mice: (A) *Candida albicans*, injected into the mouse thigh, and (B) suspended colonic contents, injected intraperitoneally (IP). The former produced an easily measured lesion, self-limited over 4 to 6 weeks, the size of the abscess appearing to be dependent upon host vascular and granulocytic responses with little evidence for the participation of specific cell-mediated immune mechanisms.[3] This model thus afforded an accurate assessment of host resistance to a localized infection *in vivo*. In contrast, fecal peritonitis, as previously reported,[4] was associated with a more generalized infection and a high mortality rate.

METHODS AND MATERIALS

A. Candida Albicans Model.—The test organism, *C albicans*, obtained from the Department of Microbiology and Immunology, University of Washington, was passaged regularly on Sabouraud's agar. Organisms to be injected were grown for 24 to 48 hours in Sabouraud's broth at 37° C, centrifuged from the broth, washed 3 times in saline solution, counted, and resuspended in saline at a concentration of 2.5×10^8 viable yeast cells per milliliter.

The left thigh of 78 male outbred Swiss-white mice weighing 25 to 35 gm was injected IM with 25×10^6 organisms/gm body weight, suspended in 0.2 ml of physiologic saline. The right thigh was injected with 0.2 ml saline as a control. Thigh size was measured with sliding calipers daily for the first 10 days as the lesions developed, then at intervals until the lesion had regressed completely. The largest dimension was taken as the thigh size and was recorded as the difference from the control side for each animal.

Test animals were divided into 4 groups:

Group I: Halothane administered for 4 hours immediately before infection (n=14).

Group II: Halothane administered for 4 hours immediately after infection (n=10).

Group III: Halothane administered for 4 hours daily for 4 days before infection (n=9).

Group IV: Halothane administered for 4 hours daily for 4 days after infection (n=20).

One control group, similarly infected and paired for each test group, received 100 percent O_2 according to the same schedule, while a 2nd control group was maintained in air.

Animals were anesthetized in a 30 x 14 x 34-cm plexiglass container. Halothane was administered in 100 percent O_2 at a rate sufficient to maintain ambient halothane concentration at 1.1 ± 0.1 percent. Total gas flow was 3 L/min. Halothane, O_2, and CO_2 concentrations were monitored by a Beckman LB-II infrared gas analyzer, a Beckman DB-2 paramagnetic analyzer, and an Instrumentation Laboratories gas analyzer, respectively. Rectal temperatures were maintained at 37 ± 0.5° C by an overhead heat lamp. A maximum of 20 animals were anesthetized at any one time, and all anesthetics were administered at a similar time of day.

Following anesthesia, the mice were allowed to recover in O_2 until capable of a sustained righting response, after which they were housed in similar cages for the duration of the experiment. Animals were given food and water ad lib; daily weighing indicated no gross metabolic alteration secondary to the anesthetic.

To examine the effect of halothane on *C albicans* itself, cultures prepared with 5×10^8 organisms in Sabouraud's broth were incubated for 4 hours daily for 4 days in either 1 percent halothane, 100 percent O_2, or air. The remainder of the time, the cultures were maintained in air at 37° C. At the end of the 4 days, the yeast cells were counted in a hemocytometer.

B. Fecal Peritonitis Model.—Fecal material was obtained from male Swiss-Webster mice by irrigating the colons with 20 ml of Hank's balanced salt solution (HBSS) immediately after death. The fecal material was homogenized with a tissue grinder and the resulting suspension filtered through surgical gauze. Mice of the same strain were injected IP with 0.7 ml of the fecal suspension, using a 23-gauge needle. Control (noninfected) animals received a similar volume of HBSS without colonic contents. Forty additional mice were injected with a similar preparation which had been heat-sterilized at 100° C for 60 minutes, leaving endotoxin and particulate matter in the suspension.

Infected animals were paired into 2 groups and subjected to either 0.6 to 0.8 percent halothane in O_2 or to 100 percent O_2 for 4 hours by the anesthetic technic described above, with no more than 20 animals treated in a single experiment, to a total of 6 paired studies. Food and water were withheld for 12 hours from both groups upon recovery from anesthesia, to offset any metabolic advantage to the unanesthetized controls.

These mice were distributed into 5 groups:

Group I: Halothane administered for 4 hours after IP injection of fecal suspension (n=48).

Group II: O_2 administered for 4 hours after IP injection of fecal suspension (n=46).

Group III: Halothane administered for 4 hours after IP injection of HBSS (n=20).

Group IV: Halothane administered for 4 hours after IP injection of heat-sterilized fecal suspension (n=20).

Group V: O_2 administered for 4 hours after IP injection of heat-sterilized fecal suspension (n=20).

Mortality was assessed regularly for the next 2 weeks, after which the survivors were sacrificed and gross examination of the peritoneum was made.

Statistics.—Results of the mouse thigh lesion were examined by Student's *t*-test for unpaired data. Mortality in the fecal peritonitis model was evaluated by chi-square with continuity correction.

RESULTS

A. Mouse Thigh Lesion.—The administration of halothane was not associated with any significant alteration in the magnitude of the IM lesion produced by *C albicans*. Similarly, there was no significant alteration in the time course of development or regression of the abscess. Data for group IV (figure) are representative of all other groups. Similar results were obtained with other dosage schedules, none of which demonstrated any significant difference in size of the control thighs with time or within groups; hence, the diameter of the infected side is recorded in absolute figures.

The administration of halothane, even on consecutive days, did not affect the weight of the animals despite apparent lethargy for several hours after anesthesia. Halothane did not affect the growth of *C albicans in vitro*, for cell counts were similar after exposure to the anesthetic gas, O_2, or air.

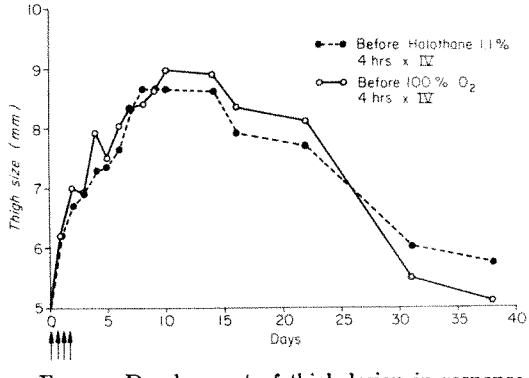

FIGURE. Development of thigh lesion in response to IM *C albicans* in mice of group IV. Similar results were obtained for the other groups in thigh tests.

TABLE 1
Anesthetic Mortality Due to Infection

	HBSS, n = 20	Infected, n = 48	*p*
Deaths	0	3	≤0.1
Percent mortality	0	6	

B. Fecal Peritonitis Model.—The administration of halothane to mice infected with colonic contents was associated with increased mortality during the anesthetic period; hence, 0.6 to 0.8 percent halothane was employed rather than the 1.1 percent concentration used in the mouse thigh model. Although the difference was not statistically significant, mortality during a single exposure to halothane was 6 percent for infected animals as compared to none for control animals anesthetized without infection (table 1).

Since the animals that died during anesthesia appeared to develop copious airway secretions and respiratory obstruction as a terminal event, they were excluded from subsequent calculations, as they did not represent morality directly attributable to the infection. The following data therefore represent only those animals that recovered from anesthesia and survived the acute cardiopulmonary consequences of halothane imposed on septicemia.

Following halothane-O_2 anesthesia, mice with peritonitis exhibited a significantly increased mortality as compared with O_2-treated mice. This was apparent from 24 hours after anesthesia to the end of the study at 14 days (table 2). Mean mortality from 6 paired experiments was 44 percent in O_2 as compared to 81 percent in halothane. Heat sterilization of the colonic contents prevented mortality in O_2-treated mice and greatly reduced mortality in halothane-treated animals (table 3). Thus the effect of halothane was significant only when mice were infected with viable organisms. In both halothane and O_2, the use of viable organisms significantly increased mortality over that observed with endotoxin-containing killed suspensions alone.

The bacterial species isolated from the fecal suspension were predominately *Escherichia coli* and enterococci, as determined by standard isolation technics. Cultures for

strict anaerobes were not performed. Both experimental and control animals received equal aliquots of the fecal suspension. Thus, although the quantity of bacteria per injection was not determined, it was identical for paired anesthetized and control animals.

DISCUSSION

While anesthetic-induced immunosuppression has been demonstrated by *in vitro* technics, the impact of these findings on the prognosis of patients bearing infections has not been well documented. In particular, it is not known whether similar derangements occur *in vivo*. Animal models have been used previously to study infection during anesthesia, but results have been inconclusive.

Bruce[5] demonstrated an accelerated mortality in mice subjected to halothane anesthesia after IP injection of *Salmonella typhimurium*, although the ultimate mortality of his anesthetized animals was similar to control. Goldstein's group,[6] using radiolabeled *Staphylococcus aureus*, found impaired murine pulmonary bactericidal activity following cyclopropane and methoxyflurane administration but not after halothane or pentobarbital. However, their mice were sacrificed immediately after anesthesia, leaving open to question the significance of observed results in the development of pneumonia. Viral pneumonia is more easily produced in mice under ether anesthesia,[7] although this has been attributed to altered host respiratory mechanics rather than to immunosuppression by the anesthetic. Hence, it remains to be demonstrated experimentally that anesthetic agents alone are capable of significantly modifying the morbidity or mortality associated with microbial invasion.

Our studies suggest that halothane anesthesia in the presence of severe infection (peritonitis) is associated with increased mortality, although the precise mechanism remains to be elucidated. On the other hand, localized infection with organisms of low virulence (*C albicans*) does not appear to be significantly modified by halothane anesthesia.

The mouse immune system is very similar to that of man; hence, it affords a reasonable experimental model for the study of infectious diseases. The mouse thigh lesion appears to be a valid *in-vivo* technic for assessment of immune responses to *C albicans*, with the development of the lesion principally a function of the neutrophil response. The modification of the normal response in the thigh lesion by antibiotics and

steroids[8] parallels the clinical picture of candidiasis in animals and man.

Peripheral leukocytes have the primary responsibility in control of local sepsis.[9] Failure of halothane to affect the size of the lesion produced in response to candida suggests that this anesthetic has little effect on the mobilization and deposition of inflammatory cells at an infected site, at least with *C albicans* as the inciting organism. Whether similar responsiveness persists in intact animals subjected to other organisms remains to be determined. Bruce,[5] in contrast, demonstrated reduced mobilization of neutrophils into the peritoneal cavity of mice in response to salmonella infection during halothane anesthesia. His results, however, may be attributed to altered splanchnic blood flow caused by this anesthetic and not necessarily to reduced leukocyte capability.

In contrast to its failure to affect the development of a localized abscess, halothane significantly increased the lethality of fecal peritonitis in the model we employed. Failure of heat-sterilized fecal material to have a similar effect suggests that death was the result of active infection rather than an indirect effect of endotoxin. Since mortality was increased well after anesthesia was discontinued, and since deaths occurring during anesthesia were excluded, it is doubtful that any acute cardiovascular or respiratory effects of the anesthetic can be incriminated.

Before attributing these results to altered host defense mechanisms, it is necessary to rule out effects of the anesthetic on the microorganism's growth characteristics. We were unable to demonstrate any inhibition or stimulation of fungal growth by halothane *in vitro*. Previous authors[10] have documented growth inhibition of bacteria by halothane for species such as *E coli*, but at concentrations achievable only in anesthetic apparatus.[11] In addition, the effects appear to be less significant on moist, protein-rich agar than on dry cellulose-acetate media, suggesting that *in vivo* effects should be minimal at the scene of an inflammatory exudate.[12] The increased O_2 administered with halothane may inhibit anaerobic growth, but this we controlled by using O_2-treated controls. Hence, we conclude that direct antimicrobial effects of halothane should be minimal in our experimental situation.

In response to generalized bacterial infection and septicemia, the phagocytic cells of the reticuloendothelial system (both fixed and circulating) and polymorphonuclear leukocytes control the infectious process.[9] Their activities are promoted by opsonins, circulating proteins which react with bacteria to cause their easier phagocytosis and destruction. Opsonins in serum include natural antibodies, immune antibodies, components of the complement system, and yet-unidentified thermolabile proteins. Certain organisms, such as *E coli*,[13] are relatively resistant to phagocytosis unless they are suitably opsonized.

It is postulated, though by no means proved, that the increased mortality following anesthesia was in part the result of depressed reticuloendothelial phagocytic function, whereas normal host defense mechanisms remained intact in control animals. Surgery in animals is associated with a reduced reticuloendothelial capability,[14] probably due to reduced plasma opsonization.[15] While peripheral leukocytes do not appear to be affected by halothane,[16,17] the phagocytic ability of the reticuloendothelial system is impaired in humans undergoing minor surgery with a variety of anesthetics, including halothane.[18] It may be that the organisms of our model were potentiated by halothane-induced suppression of reticuloendothelial phagocytosis or by modification of normal serum opsonization. Such mechanisms are only speculative at present, to be explored by further studies.

Anesthesia is all too often accompanied by side effects, such as hypoxia, acidosis, and hypothermia, all of which have been shown to diminish bactericidal ability in experimental animals.[6,19] Although our animals were anesthetized in 100 percent O_2 and kept normothermic, some degree of acidosis probably occurs in all anesthetized small animals that must breathe spontaneously.[20] In addition, there is some evidence that infected animals may be abnormally susceptible to the cardiovascular and respiratory-depressant effects of anesthesia.[21] This latter point may explain the increased incidence of respiratory complications in the infected mice and consequent elevated intra-anesthetic mortality.

It is a time-honored impression that patients with infections fare poorly after anesthesia, although firm evidence supporting this contention is lacking. Anesthesia is associated with increased morbidity and mortality in patients bearing the infectious hepatitis virus,[22] an observation paralleled by the increased ease of induction of viral

hepatitis in mice subjected to halothane.[23] Respiratory infections are frequent after both general[24] and topical[25] anesthesia, usually attributed to altered respiratory mechanics and impaired mucociliary clearance. Whether other pathogens can similarly be potentiated by anesthesia remains to be demonstrated.

CONCLUSIONS

We have demonstrated an increased mortality (to 81%) in mice subjected to anesthesia after IP injection of fecal material sufficient to kill 44 percent of control animals. Anesthetic complications were also increased in infected animals. While the localized inflammatory response to *C albicans* IM is not affected by halothane, effects of the anesthetic or complications thereof on other aspects of host defenses, particularly on reticuloendothelial function, remain to be excluded.

ACKNOWLEDGMENT

We thank Marlene Risen for excellent technical assistance during the studies of *Candida albicans*.

The Effects of Stellate Ganglion Block on the Idiopathic Prolongation of the Q-T Interval with Cardiac Arrhythmia (The Romano-Ward Syndrome)

HISASHI YANAGIDA, MD*
CHIYUKI KEMI, MD†
KUNIO SUWA, MD‡

The association of a prolonged Q-T interval, congenital deafness, and syncopal attacks due to ventricular fibrillation following emotional or physical stress is known as the Jervell-Lange-Nielsen syndrome. Absence of the congenital deafness characterizes the otherwise identical Romano-Ward syndrome. Both conditions have a high mortality rate and are recognized as contributing to sudden death in children. Although the pathogenetic factors are not yet completely elucidated, the condition is well enough understood to permit effective treatment. The authors performed a left stellate ganglion block in a 12-year-old girl with a mild form of the Romano-Ward syndrome, shortening the Q-T interval and eliminating the ventricular tachyarrhythmia. The left stellate ganglion block should be considered by anesthesiologists as an emergency measure, effective in interrupting the attack.

THE association of a prolonged Q-T interval, congenital deafness, and syncopal attacks due to ventricular fibrillation following emotional or physical stress is a clinical entity known as the Jervell-Lange-Nielsen syndrome.[1] Absence of the congenital deafness characterizes the otherwise identical "Romano-Ward" syndrome.[2,3] Both conditions (long Q-T syndrome) have a high mortality rate and are recognized as contributing to sudden death in children.[4]

The pathogenesis of long Q-T syndrome is dependent on an imbalance between various components of the cardiac sympathetic innervation. A congenital decreased activity through the right cardiac sympathetic nerves seems the most likely pathogenetic mechanism in the majority of cases.[5-8] Other forms of sympathetic imbalance, including left or even right hyperactivity, are, however, possible in isolated cases.[9]

Beta-blockers, at full blocking dose, represent the therapy of choice and are greatly effective in reducing mortality.[9] If medical therapy is not effective, ablation of the left stellate ganglion along with the first thoracic ganglia is the most rational and specific therapy.[5,6,9,10]

CASE REPORT

We performed a left stellate ganglion block in a 12-year-old girl, diagnosed as having a mild form of Romano-Ward syndrome. She was admitted to the hospital because of attacks of dizziness and cardiac arrhythmia, the latter having been noted since birth. At age 11, she experienced a feeling of sudden fullness in the chest, dizziness, and acute abdominal discomfort for about 2 minutes. Seven months later, she cried out and fell unconscious, although neither cyanosis nor convulsions occurred. Subsequently, she had similar attacks with increasing frequency, often, though not constantly, related to emotional or physical stress. Recovery, after about 2 minutes, was associated with headache and nausea. She felt otherwise well and

her vital signs remained normal. She had not taken any drugs.

Physical examination showed essentially normal findings. The heart was normal on palpation. The heart sounds were normal but the rhythm was irregular. No third or fourth heart sounds or murmur were present. The heart rate was 70 bpm, blood pressure 115/80 torr supine, and 110/85 torr standing. Arterial and venous pulses were normal but irregular. Chest radiography was normal.

Hemodynamic Studies.—Left ventricular systolic time constants were studied with the aid of simultaneous electrocardiogram, phonogram, carotid pulse tracing, and apex cardiogram. The pre-ejection period was 101 msec, the left ventricular ejection time 313 msec, and the isovolumetric relaxation period 106 msec, the heart rate being 54 cycles/min. All these values are within the range considered normal in this laboratory. After these studies, the heart was catheterized, to exclude the remote possibility of silent idiopathic cardiomyopathy. The left ventricular end-diastolic pressure (LVEDP) was 9 torr. No gradient was present in the left ventricular outflow tract or at the aortic valve. The aortic pressure pulse wave was normal. The left ventricular cineangiogram revealed a ventricular cavity of normal size, a ventricular myocardium of normal size and thickness, and a normal synergic pattern of contraction, with normal cardiac and stroke indices.

Other laboratory investigation, which included urinalysis, serum glucose tolerance test, intravenous ethylene-ediaminetetraacid test to exclude hypoparathyroidism, catecholamine, metanephrine, and adrenaline excretion during bed rest and while ambulatory, electroencephalogram, and audiogram revealed no abnormalities.

Family Studies.—Examination of parents and brothers revealed no abnormalities. Cardiac disease had caused the death of the patient's paternal grandmother and one of 6 paternal grand-uncles, but no syncopal attacks were reported. Four of 6 paternal cousins had clinically observable cardiac arrhythmias but showed no Q-T prolongation on the ECG.

Electrocardiographic Studies.—The ECG recorded in the supine position at rest showed normal P waves, P-Q interval, QRS complexes, and a consistently prolonged Q-T (or Q-U) interval, which varied between +38 to +29 percent of the predicted normal value at each heart rate encountered. In the tracing recorded in the supine position, it was not possible to differentiate between the T and U waves, which together produced a common complex (fig 1).

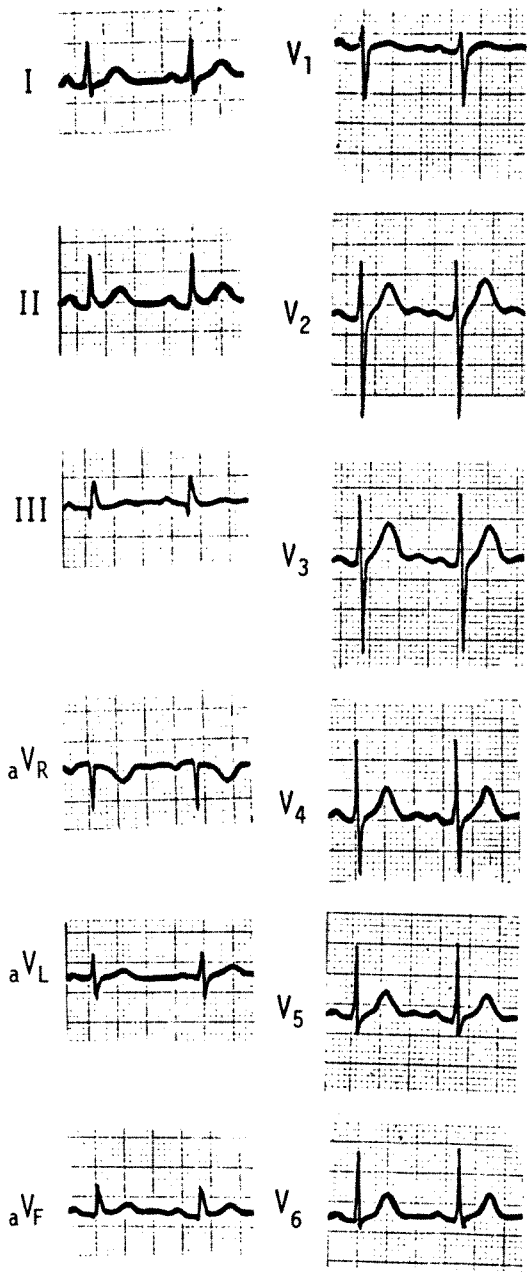

FIG 1. Supine decubitus ECG, heart rate 85 (extremity), 88 (precordial), showing normal P waves, P-Q interval, QRS complex, and S-T segments, and prolonged Q-T interval (0.4 sec versus normal of 0.31 and 0.29 sec).

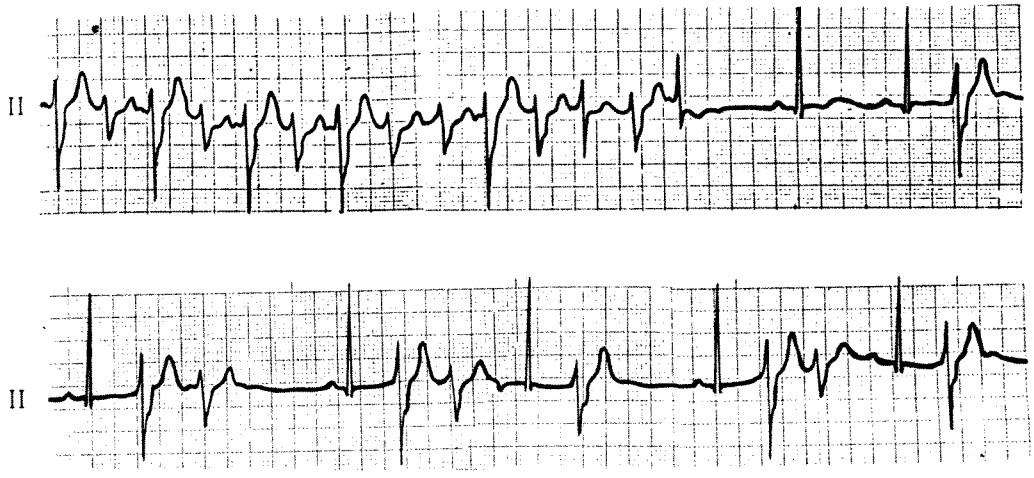

FIG 2. Upper tracing: During attack, supine decubitus ECG, showing paroxysmal ventricular arrhythmias. At that time, patient complained of fullness in the chest. The Q-T interval is prolonged (0.66 sec, upper limit of normal 0.45 sec at heart rate of 61 to 65 bpm). Lower tracing: An exercise ECG showing paroxysmal ventricular arrhythmias.

According to a 12-hour continuous ECG decubitus recording, the sinus rhythm (fig 1) never continued for over 1 minute but showed paroxysmal ventricular arrhythmias (fig 2, upper tracing). The abnormally long Q-T interval persisted (about +47 percent of the predicted normal). At that time she complained of a sense of fullness in the chest. A Master's two-step ECG produced paroxysmal ventricular arrhythmias (fig 2, lower tracing) after 10 seconds. These ventricular arrhythmias with prolongation of Q-T interval did not respond to medical therapy by digitalis, propranolol, atropine, diphenylhydantoin, or phenobarbital.

Left Stellate Ganglion Block. — In the ECG (fig 3A) taken immediately before the left stellate ganglion block, the abnormal Q-T interval can be plainly seen. Block with 5 ml of 1 percent lidocaine shortened the Q-T interval for about 10 minutes and eliminated the ventricular arrhythmia for 35 minutes (fig 3B). By 5 minutes after block, the Q-T interval became minimum. At that time, Horner's syndrome appeared maximum, as did the amplitude of plethysmogram recorded from the left thumb. Table shows the time courses of the changes in Q-T interval after left stellate ganglion block. These effects were reproducible.

DISCUSSION

The association of a prolonged Q-T interval and syncopal attacks following emotional or physical stress represents a dramatic and unmistakable clinical picture. If congenital deafness and/or episodes of alternation of the T wave occur, the diagnosis is even easier. The seriousness of long Q-T syndrome, however, is not the same in all patients: While some patients may have many syncopal attacks per month, others have a few per year, and still others have only one or two episodes in their entire lives.[9]

Moreover, syncope is not always associated with the Romano-Ward syndrome, a mild form of which includes transient palpitations, a feeling of fullness in the chest, apprehension, sweating, guarding of the abdomen, moaning, and crying.[10] Our present case is probably of a mild form in the Romano-Ward syndrome. The possible mode of inheritance has been largely discussed in several papers.[12,13] However, all recognize the finding of patients whose immediate relatives have no deafness or other familial pattern of signs or symptoms.

The long Q-T syndrome is provoked by abrupt increase in the sympathetic activity, which is likely to be nonuniform and mostly mediated through the left sympathetic upper thoracic ganglia.[9] It follows, as already suggested,[9] a double therapeutic line: one less specific consisting of the treatment with beta-blockers, and one more specific consisting of the ablation of left stellate ganglion along with the first thoracic ganglia.

In our present case, propranolol had no effect on the ventricular arrhythmia and Q-T interval, leading to the belief that surgical treatment is the most rational choice. As our patient refused surgical removal of

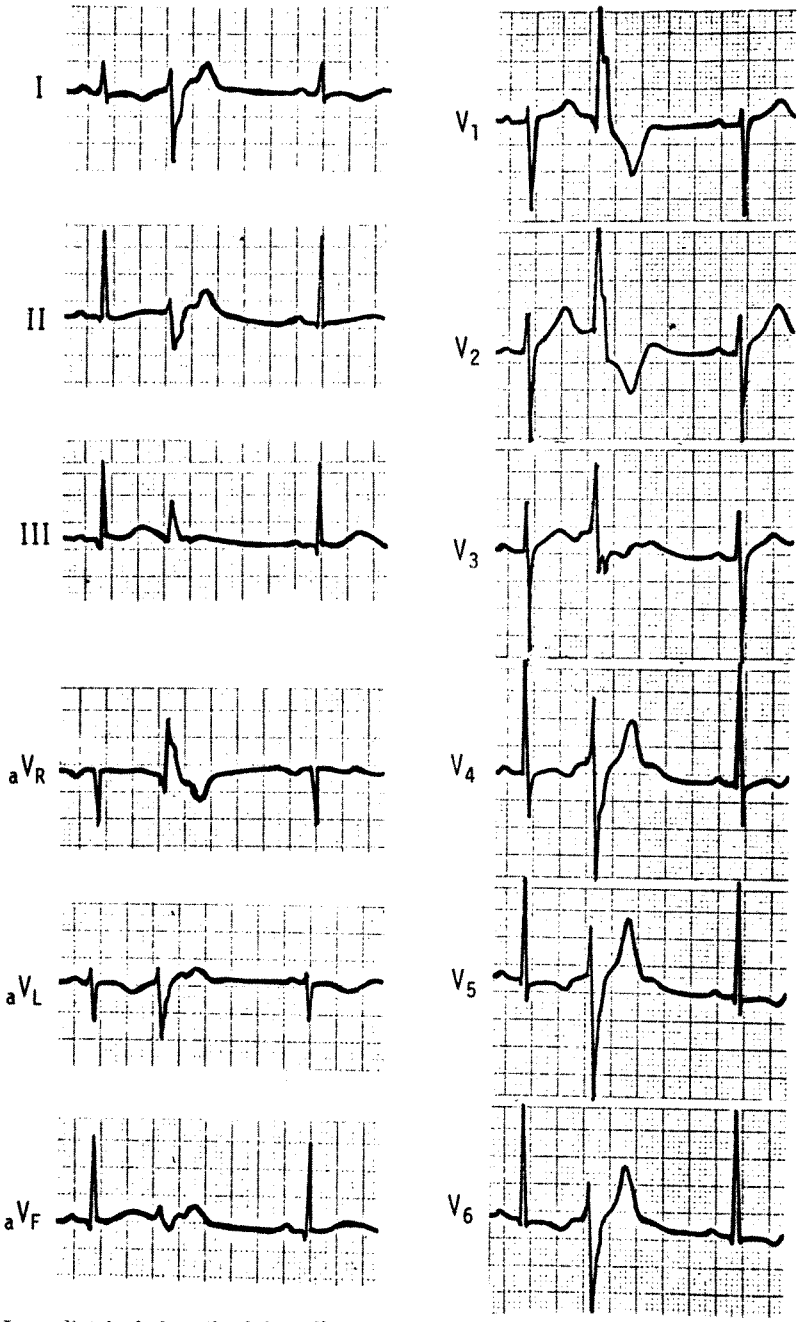

FIG 3. A. Immediately before the left stellate ganglion block, ECG recorded in decubitus supine patient.

the left stellate ganglion, left stellate ganglion block, in place of surgical removal, resulted in a definite shortening of the Q-T interval for about 10 minutes and in the disappearance of ventricular arrhythmia for 35 minutes.

Moss and MacDonald[5] obtained a Q-T prolongation with right stellate ganglion block and a shortening with left stellate ganglion block. Dear* observed no change in the Q-T interval after either left stellate ganglion or right stellate ganglion block. Furthermore, several authors found a prolongation of the Q-T interval both left and right stellate ganglion block.†[13] It was also reported that left stellate ganglion block in the cat was shown to produce significant

prolongation of the functional refractory period exclusively in the lateral and posterior left ventricle.[14] Randall and Rohse[15] showed that the left stellate ganglion mediates mainly inotropic effects while the right stellate ganglion mediates mainly chronotropic effects.

Stellate ganglion block is not a simple maneuver. Usually performed through a blind procedure, there can be no certainty about the exact spread of the anesthetic. Moreover, performance of this procedure under local anesthesia is likely to frighten the patient, resulting in increased sympathetic activity. An attempted left stellate ganglion block can even lead to a prolongation of the Q-T interval as a result of increased discharge through the ganglion, or from mechanical stimulation by the needle.

TABLE

25	0.51
30	0.53

The appearance of Horner's syndrome is sometimes believed to be the mark of an effective stellate ganglion block and, therefore, of a block of cardiac nerves: On the contrary, it only indicates blockade of the fibers which traverse the upper part of the stellate ganglion, and may or may not be accompanied by effective blockade of fibers innervating the heart. In our present case, the effects of a left stellate ganglion block were reproducible but it was a short effect (about 10 minutes), with incomplete blockade of cardiac fibers.

Despite such difficulties, knowledge of the effectiveness of stellate ganglion block as an emergency measure in interrupting the threat of a long Q-T syndrome may prove life-saving in patients with Romano-Ward symptoms.

The Development of an Acute Tolerance to Ketamine

JAMES F. CUMMING, MD, PhD*

A rapidly developing tolerance to the hypnotic effect of ketamine in rats and mice has been investigated. On the basis of plasma and brain concentrations of ketamine at the time the animals wakened, it seemed likely that a central nervous system tolerance to the drug explained the shortened sleeping times noted.

THE rapid development of tolerance to central nervous system (CNS) depression by a number of drugs has been reported. Drugs with which this effect has been associated include, among others, ethyl alcohol,[1] pentobarbital,[2] thiopental,[3,4] glutethimide,[5] and diazepam.[6] Two of the effects noted were a shortened sleeping time following repetition of the same dose of the drug, and an increase in the blood level required to produce an observed effect. Mirsky's group,[1] in 1941, described this latter type of acute tolerance to ethanol in the rabbit and in man, and Brodie and colleagues,[3] a decade later, showed that in the human, thiopental plasma levels on waking were higher after a large dose of the drug than after a smaller one. An acutely developing tolerance to the effect of thiopental on the rate of cerebral O_2 consumption has been described.[7]

For the past several years, a new short-acting IV anesthetic agent, ketamine, has been in clinical use. Animal experiments showed that, in monkeys, repeated injections to a total of 6 did not result in a change in sleeping time.[8] Extensive clinical experience seemed to indicate that repeated injections of the drug required little change in dosage and were not followed by any change in observed anesthetic time.

While we were investigating this drug for possible enzyme inductive effects, a sharp decrease in the sleeping time of rats consequent to the 2nd injection of the drug was observed. The abrupt onset suggested a rapidly developed tolerance. We have investigated this possibility.

MATERIALS AND METHODS

Animal Experiments.—Male rats weighing between 190 and 250 gm, obtained from a local supplier,† were housed in air-conditioned quarters and fed *ad libitum* on standard laboratory feed. Groups of rats were given IP injections of ketamine (90 mg/kg), and their sleeping times measured from loss to regaining of the righting reflex. One group received only the initial injection, and from these brain and plasma samples were obtained at the time of recovery of the righting reflex. The samples were analyzed for ketamine concentration. Other groups were allowed to recover and then further injections of ketamine (90 mg/kg IP) were given at 5, 6, 24, 48, and 72 hours following the 1st injection. Brain and plasma samples were obtained at the time of recovery of the righting reflex at each time interval. All the animals used in a sequence of experiments came from the same shipment lot.

Another set of experiments on male rats used a dose of 80 mg/kg IP of ketamine. These animals were tested only for sleeping time at 24-hour intervals to a total of 5 exposures.

Other sleeping time studies used male mice of 20 to 30 gm weight given ketamine (100 mg/kg IP). Sleeping time was recorded after the 1st, 2nd, 3rd, and 4th injections, administered at 24-hour intervals.

Chemical Analyses.—Ketamine concentrations in plasma were estimated as previously described.[9] Brain samples were assayed by making a 25 percent homogenate

(w/v) of brain in KCl 1.15 percent. To 6 ml of the homogenate was added 3 ml of 20 percent metaphosphoric acid. This was shaken on a vortex mixer, then centrifuged. Supernatant (5 ml) was placed in a reaction vessel containing 15 ml of chloroform and 20 μg of pheniramine maleate as an internal standard. NaOH (10 N) 0.5 ml was added to make the mixture strongly alkaline. From this point, treatment was as described earlier[9] for the assay of ketamine in plasma. Standard curves were constructed for each day's determinations from the results of known concentrations of ketamine in brain homogenate subjected to the same procedure. The peak height ratio of ketamine to internal standard related linearly to ketamine concentrations.

RESULTS

The results of repeated injections of ketamine into rats at 24-hour intervals for 4 successive doses are summarized in the table. Sleeping time decreased abruptly (26%) between the 1st and 2nd doses. A further but lesser decrease occurred between the 2nd and 3rd exposures. The decrease in sleeping time was accompanied by an increase in the brain and plasma ketamine levels at the time of wakening. Differences between initial values of each parameter and subsequent values at each exposure were significant, as indicated in the table. The brain/plasma ratio at wakening showed an initial decrease, but returned to its original value on the 4th exposure.

Figures 1 and 2 illustrate the changes in sleeping time and brain and plasma ketamine levels on waking between the 1st exposure and a repeated injection at 5 and at 6 hours. When a 2nd injection of ketamine was given 5 hours after the 1st, the animals slept a significantly longer time following

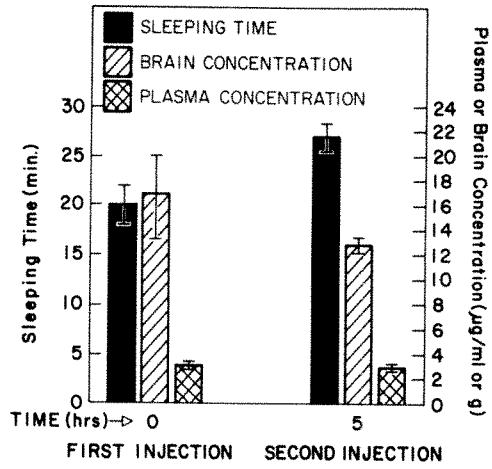

FIG 1. Sleeping time, waking brain and plasma concentration of ketamine in rats following the 1st and 2nd injections of ketamine (90 mg/kg IP) 5 hours apart.

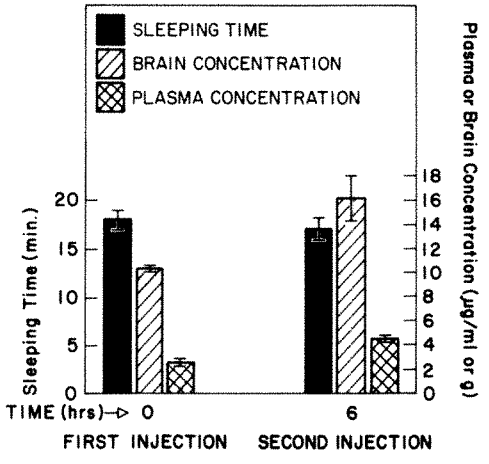

FIG 2. Sleeping time, waking brain and plasma concentration of ketamine in rats following the 1st and 2nd injections of ketamine (90 mg/kg IP) 6 hours apart.

the 2nd injection ($p<0.025$). The waking brain and plasma levels after the 2nd exposure were not different than after the 1st ($p<0.2$, $p<0.3$). When the 2nd injection was given 6 hours after the 1st, sleeping time was now decreased slightly. The difference between overall means was not significant, but between values where a paired *t*-test was possible, the difference was highly significant ($p<0.025$). Waking brain and plasma levels were significantly higher than after the 1st injection ($p<0.01$).

Figure 3 illustrates the effect of consecutive injections of ketamine, 80 mg/kg IP, on the sleeping time of rats. The decline in sleeping time noted, particularly between the 1st and 2nd injections, is similar to that noted when a dose of 90 mg/kg IP was given.

Mice respond to repeated injections of ketamine in a manner paralleling the response of rats (fig 4). Sleeping time decreases sharply between the 1st and 2nd doses and also between the 2nd and 3rd doses. The sleeping time after the 4th dose, however, is not significantly different than that after the 2nd dose.

DISCUSSION

The development of an acute tolerance to ketamine, evident in the present work, and to other CNS depressants reported elsewhere by others,[1-7] could be explained in various ways: by an increase in ability to biotransform the agent; by an alteration in the blood-brain barrier to the drug; or by an increase in resistance of CNS cells to the effect of the drug. An alteration in ability to biotransform the drug seems unlikely, since the onset of induction of drug-metabolizing enzymes is a relatively slow process compared with the rapid onset of the acute tolerance witnessed here. Early work done at the Parke-Davis Company* also showed that repeated parenteral doses of ketamine HCl administered to rats did not increase the *N*-demethylating capacity of the hepatic microsomal enzymes. Further, if a more rapid metabolism were the cause, there is little reason to expect a change in waking plasma and brain concentrations of the drug. A change in the blood-brain barrier is possible, but does not seem likely in view of the very rapid onset of anesthesia in all species given the drug IV.

The table does show some variation in the brain/plasma ratio between control and previously exposed animals. The deviations do not explain the higher waking brain concentrations of ketamine in the latter animals, and the ratio returns to that of the control animals at a time when the animals are still sleeping a shorter time and waking with higher brain concentrations. A change in blood-brain barrier would not be expected to alter the waking brain concentrations of the drug. By contrast, if the neurons of the CNS became rapidly resistant to the effect of the drug, a higher plasma and brain level on waking would be expected. This explanation would seem to fit best the data presented here.

Rapidly developing accommodation to the CNS effects of many sedatives and hypnotics has been reported. In Mirsky's investigation of the effect of ethanol in the rabbit and in man,[1] the effect of the drug in both

*Unpublished data.

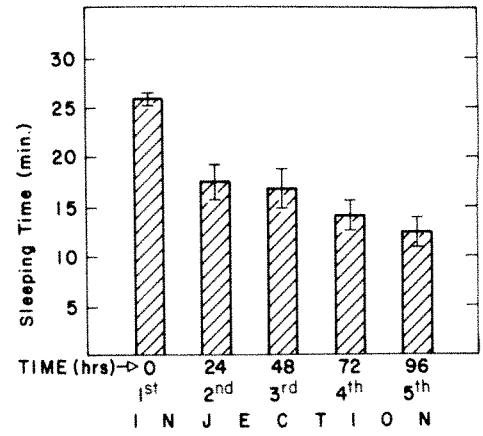

FIG 3. Sleeping time of rats following 5 successive doses of ketamine (80 mg/kg IP) at 24-hour intervals.

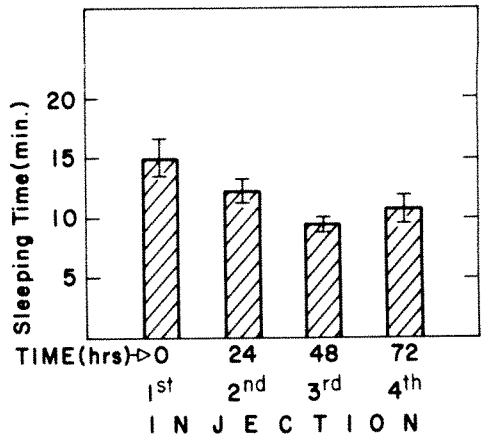

FIG 4. Sleeping time of mice following 4 successive doses of ketamine (100 mg/kg IP) at 24-hour intervals.

species (coma in the rabbit, drunkenness in man) disappeared while blood levels of ethanol were considerably above those noted at the onset of the effect. In both species, repeated administration of the drug showed that higher levels were required to produce the same effect at each subsequent exposure. In the rabbit, the repetition could be carried to several exposures, each resulting in a further rise of blood ethanol at which symptoms disappeared.

The work presented in this paper demonstrates a similar response. As shown in the table and in figures 3 and 4, subsequent exposures to ketamine in both rats and mice resulted in progressively shorter sleeping times to at least 3 administrations. A similar response to repeated injections of thiopental was noted in the male rat by Singh.[10] These observations all indicate that the limit of tolerance is not reached after 1 or even 2 moderate doses of the drugs used. Larger doses appear to elicit a greater response. This conclusion was also indicated in earlier work by Brodie[3] and by Dundee's group.[4]

Barnett and Fiore[6] showed the development of a tolerance to diazepam in cats by testing the linguomandibular reflex. Their experiments indicated the tolerance was due to a metabolite of diazepam, which presumably had a good affinity for the same CNS receptors as diazepam, but had a much weaker agonist effect and therefore acted as a partial antagonist to diazepam.

In the experiments here, a similar explanation might pertain. The biotransformation products of ketamine are presumed to be pharmacologically inactive, and they are also excreted in both urine and feces. The original investigative work by the Parke-Davis Company* showed that about 74 percent of an IP dose in the rat appeared in the urine and feces by 24 hours (as measured by radioactivity). It therefore seems unlikely that competition for receptor sites by an inactive metabolite would explain the shortened sleeping time observed in this work, following subsequent doses of ketamine at 24-hour intervals. Such an explanation might be postulated for the tolerance which developed by 6 hours.

The time required to demonstrate a tolerance in this work was 6 hours. Animals reinjected at 5 hours slept longer than after their 1st exposure (fig 2). It is possible that there was a residual effect from the 1st dose still present by 5 hours which could account for the increased sleeping time. The data presented here do not suggest any definite mechanism. At 6 hours after an initial dose, a 2nd dose of ketamine resulted in a shortened sleeping time, apparently by a mechanism of CNS tolerance to the drug, since the animals were waking with higher brain and plasma levels of ketamine (fig 3). Singh[10] reported that a minimum of 4 hours was required for female rats to develop tolerance to thiopental, a time quite similar to that observed here.

This work demonstrates a rapidly developing tolerance to the CNS-depressant effect of ketamine. The degree of the tolerance is of modest dimension, but was demonstrated in rats at 2 different dosage levels and in a different species (mice). The tolerance to ketamine resembles the tolerance to a number of other CNS depressants and seems to represent an unidentified adaptation of CNS neurons which permits them to accommodate to the presence of a depressant drug.

Lorazepam Premedication: Lack of Recall and Relief of Anxiety

ROBERT J. FRAGEN, MD*
NANCY CALDWELL, CRNA†
Chicago, Illinois‡

Premedication with lorazepam (4 mg), diazepam (10 mg), and a placebo was compared in a randomized, double-blind study of 95 adult surgical patients. Comparisons were made of recall of a memory card and events of the operative day, relief of anxiety, degree of somnolence, effects on blood pressure and heart rate, and incidence of side effects. Lorazepam produced a significant lack of recall (antegrade amnesia) compared to the other agents. Lorazepam produced a greater antianxiety effect than placebo and a greater degree of somnolence than diazepam or placebo. Since no adverse effects on blood pressure or heart rate occurred, lorazepam appears to show promise as a premedicant.

UPON arrival in the operating room, the patient should be calm and sedated, yet alert enough to be cooperative. Amnesia for the events of the operative day is also desirable. Premedicant drugs are commonly used to achieve these goals. They may in turn produce cardiorespiratory depression. With these points in mind, we compared lorazepam, a newer benzodiazepine, with diazepam and a placebo for preanesthetic medication. Premedication is usually given intramuscularly by a nurse on the hospital ward. Therefore, this route was chosen, although previous studies of oral[1] and IV[2] lorazepam premedication have been reported.

The widely used 1,4 benzodiazepines, chlordiazpoxide and diazepam, have the desirable premedicant properties of hypnosis, sedation, anxiolysis, antegrade amnesia, and a wide margin of safety.[3,4] Lorazepam, a newer member of this group of drugs, has the above properties but supposedly differs from diazepam in its longer duration of action and greater production of antegrade amnesia.[1] Diazepam (10 mg) IM has been shown to produce antegrade amnesia in 3 percent of patients.[4] Diazepam (0.24 mg/kg) IV was shown to produce a short period, 10 to 20 minutes, of lack of recall on all patients tested.[5] Lorazepam given IV for premedication produced a significant lack of recall at 3 mg, but 5 mg was associated with a high incidence of side effects.[2]

Evaluation of the efficacy of premedication is both subjective and objective. The patients' anxiety, apprehension, and state of consciousness and cooperation can be rated by both observer and patient. An important subjective measure is the patient's degree of recall of the event and his overall impression of the experience.[6] This concept was used in our study.

METHODS

After obtaining informed consent,§ 95 adult surgical patients, who verbalized anxiety about their forthcoming surgical experience, were admitted to the study. Medication was administered IM in a randomized

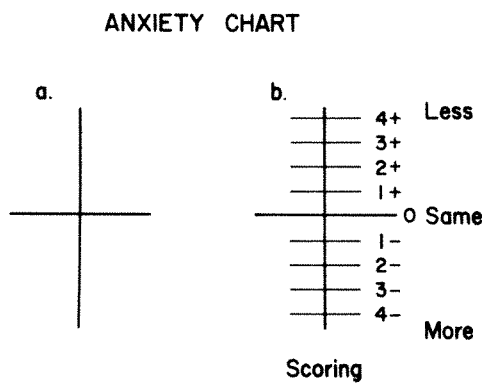

FIG 1. *a*. Chart containing no numbers, shown to patients to measure a change in degree of anxiety. *b*. Chart used to score change in anxiety level, based on point indicated by the patient in *a*. The baseline represents the same level of anxiety; above the baseline, less; below the baseline, more anxiety.

and controlled double-blind experimental design.

Patients were divided into 3 groups: group I received lorazepam (4 mg); group II received diazepam (10 mg); group III received a placebo consisting of benzyl alcohol, polyethylene glycol, and propylene glycol, the vehicle for lorazepam. The only other premedicant used was atropine sulfate (0.4 mg to 0.6 mg), as needed.

Recall was measured by a memory card, a large picture of a dollar bill, shown to the patient 120 minutes after injection. The day following the operation, patients were asked if they could recall this card. If they could not, they were shown a composite picture containing the dollar bill and seven other pictures. They were then asked if they had seen any of these pictures the previous day and whether they could remember certain events of the operative day. These events did not occur at the same interval after injection in all patients.

Relief of anxiety, using the chart shown at *a*, figure 1, was evaluated in the patient's room 60 minutes after injection. The midpoint of the vertical line represented the anxiety level prior to premedication. The patient was then asked to evaluate changes in anxiety by indicating a point on the vertical line. We recorded this point on a similar chart which contained cross-lines (*b*, fig 1) showing percentages of improvement or worsening. These values were then scored respectively as 1+, 2+, 3+, and 4+ or 1–, 2–, 3– and 4–.

The degree of somnolence was rated by one of the investigators (NC) as none, somnolent (drowsy but awake), and markedly somnolent (asleep but arousable). This was evaluated at 60 and 120 minutes postinjection.

A visit was made 24 hours postoperatively at which time patients were asked to evaluate the premedication as excellent, good, fair, or not acceptable; asked if the premedication made them sleepy or drowsy; examined for abnormalities at the injection site; and observed for any other adverse effect. Our impression of the premedication was then rated as satisfactory or unsatisfactory.

Blood pressure was measured by the Riva-Rocci method and heart rate was determined by counting the radial or temporal pulse. These were measured and recorded prior to injection, at 60 and 120 minutes postinjection, prior to induction of anesthesia, during anesthesia, in the recovery room, and at the time of the postoperative visit. Data were compared by chi-square analysis. Lorazepam patients were compared with patients in each of the other groups when analyzing recall data.

RESULTS

The groups were homogeneous for age, weight, height, and sex (table 1) and were

also homogeneous for race, ASA physical status, anesthetic medications, muscle relaxants, other intraoperative medications received, medications given in the recovery room, and types of surgical procedures.

Some patients who inadvertently received additional benzodiazepine in the operating room were dropped from the study except for the preoperative antianxiety evaluation. Two were dropped from the antianxiety study because they were brought to the operating room before 60 minutes had elapsed.

Approximately half the patients receiving lorazepam failed to recall most of the events of the day of operation (fig 2), while recall in groups II and III was extremely high.

Presentation of the memory card was the only event which occurred at the same interval after injection in all groups. Failing to recall the memory card (fig 3) were 22/29 in group I, 8/29 in group II, and 2/25 in group III. All patients in groups II and III who claimed not to recall the memory card did recognize it in the composite (fig 4). Of group I patients, 13/29, or 45 percent, failed both to recall the memory card and to recognize it in the composite.

Anxiety scores and the cumulative percent of patients at each score or higher were compared by patients and groups (table 2). A statistically significant difference was seen when lorazepam was compared with placebo ($\chi^2 = 5.003$, $p<0.05$). No difference

†Considered unsatisfactory because not calm when brought to OR.

was seen in comparing diazepam with either lorazepam or placebo.

No marked somnolence was seen in groups II and III at 60 and 120 minutes (table 3). Group I patients were sleepier than those in either of the other groups but were able to cooperate on command. When patients were asked the next day if the premedication made them sleepy or drowsy, 17/29 in group I said "yes," while this was true of only 7/29 patients in group II and 6/25 patients in group III.

Patient acceptance of lorazepam premedication was high, 26/29 rating it as excellent (15) or good (11) (table 4). We judged 27/29 patients in group I, 25/29 in group II, and 14/25 in group III to have satisfactory premedication. Patients were judged to have unsatisfactory premedication if they appeared nervous when entering the operating room. Thus, lorazepam and diazepam both produced objectively satisfactory sedation in a significantly higher ($p<0.01$) percentage of patients than did placebo, but did not differ between themselves.

Similar blood pressure and heart rate changes occurred in each group of patients and no change was great enough to require treatment. No adverse effects attributable to premedication were seen in any patient in the preoperative period or during the postoperative period the day of operation.

DISCUSSION

The most striking feature of lorazepam is lack of recall of events occurring between 1½ and 6 hours after injection. About 50 percent of the patients receiving lorazepam had amnesia for most events. The event having less recall than other concurrent events, for groups II and III, was showing the anesthesia mask. Leaving the recovery room was also poorly remembered, probably due to the combination of premedication, anesthetic agent residual, and postoperative medication effects. Recall was greatest when a long time elapsed between lorazepam injection and entrance to the operating room.

The dollar-bill picture has been shown to be a strong stimulus to memory,[2] yet 45 percent of the lorazepam patients had total amnesia for this memory card, as demonstrated by lack of recall and lack of recognition from the composite picture. This was not so for any patients in the other groups. Diazepam did not demonstrate any more amnesic effect than placebo. Inability to recall events of the operative day was a desirable property and none of the patients felt unfavorably about this when seen 24 hours later. Patient acceptance was greater for lorazepam.

Is lack of recall a desirable property of a drug? Not all patients may want amnesia, if they know they can undergo an operation without pain. Further, it may be considered disadvantageous to have retrograde or prolonged amnesia. This and previous

studies[1,6] have shown that lorazepam produced only antegrade and not prolonged amnesia.

While objective measurements are too involved to be used in this type of study, lorazepam (4 mg) was shown to be anxiolytic at least to the same degree as diazepam (10 mg) and superior to placebo. The number of patients claiming some relief of anxiety correlates well with the number rating the medication excellent or good in each group.

Since more patients claimed relief of anxiety than were somnolent at 60 minutes postinjection, relief of anxiety appears to be a different effect from somnolence in some patients. The greatest degree of somnolence was seen 60 minutes postinjection, in older patients and in those of small stature. Although somnolence was greater with lorazepam, more patients in each group thought they were somnolent than were observed to be.

Despite lorazepam's long duration of action, no patient had adverse circulatory or respiratory effects in the recovery room or during the first postoperative day. When premedication is ordered "on call," the patient may be brought to the operating room before the medication has time to act. Its effects may either complicate, or be masked by, anesthesia. Premedication with lorazepam well in advance of induction would obviate this problem and is feasible, due to its long duration of action.

ESOPHAGEAL OBTURATOR. The esophageal obturator airway (EOA) may offer a useful approach to ventilation management during cardiopulmonary resuscitation. To quantitate its usefulness arterial blood gases were measured in 18 apneic patients ventilated with an EOA in place. PaO_2 greater than 64 torr (F_IO_2 0.4-1.0) was achieved in 11 of 12 patients with supraventricular cardiac rhythms and greater than 77 torr in 3 of 6 patients still requiring external cardiac massage at the time of measurement. Arterial oxygenation did not improve significantly following tracheal intubation but there was a trend for $PaCO_2$ to decrease as compared with ventilation via the EOA. The adequate oxygenation achieved in most patients suggests that the EOA is a useful adjunct to cardiopulmonary resuscitation when tracheal intubation is not feasible. *(Schofferman J, Oill P, Lewis AJ: The esophageal obturator airway. Chest 69:67-71, 1976)*

Isoenzymes of Creatine Phosphokinase in Serum of Families with Malignant Hyperpyrexia

HERBERT Y. MELTZER, MD*
SHAKEELA Z. HASSAN, MD†
PAUL RUSSO‡
HYONG WON CHO, PhD§
Chicago, Illinois‖

The activity and isoenzymes of creatine phosphokinase (CPK) in the serum of 2 women vulnerable to malignant hyperpyrexia were studied. Serum CPK activity was markedly elevated but, in contrast to a previous report, only skeletal-muscle type CPK activity was present.

VULNERABILITY to malignant hyperpyrexia (MH) can be determined by estimation of serum creatine phosphokinase (CPK) activity.[1,2] However, because of the many possible causes of elevated serum CPK, including intramuscular injections, physical activity, trauma, and alcoholism, it is hazardous to rely too heavily on determinations of serum CPK activity in assessing vulnerability to MH. Examination of pathologic changes in skeletal-muscle fiber and of subterminal motor nerves may be of value, but such changes are nonspecific[4-7] and examination of subterminal motor nerves is not routinely feasible.

There are 3 major isoenzyme types of CPK: skeletal-muscle, cardiac-muscle, and brain type, each so named because of the organs in which they are most abundant.[8] The report of Zsigmond's group[9] of excessive levels of brain-type CPK in the serum of 21/23 individuals possibly vulnerable to MH and in skeletal muscle of 8/9 such individuals is therefore of considerable importance. In no other disease has brain-type CPK been reported to be so persistently present in serum.

Anido and associates[10] found large amounts of brain-type CPK in the serum of 3 patients during episodes of MH, when serum CPK activity was greatly increased. This is to be expected because of the massive brain and muscle damage. However, they did not study serum CPK isoenzymes in people vulnerable to MH. Small amounts may be transiently present after severe brain trauma.[11] Indeed, it has recently been reported,[12] and we have confirmed,[13] that brain-type CPK is unstable in serum both *in vitro* and *in vivo*, being rapidly converted

Paper received: 9/12/75
Accepted for publication: 3/1/76

to a species which migrates like skeletal-muscle type CPK during electrophoresis. Nealon and Henderson[14] reported that brain-type CPK is unstable at the temperatures used for incubation to detect enzyme activity following electrophoresis. We therefore studied the mechanism by which brain-type CPK was stabilized in serum of MH-vulnerable patients. We have found no published confirmations of Zsigmond's report[9] that brain-type CPK is present in the serum or muscle of such patients.

SUBJECTS AND METHODS

We located only 1 family with documented familial MH, 1 member of which has been previously described.[15] In brief, a male member in 3 generations of this family has expired with muscle rigidity and high fevers during or immediately after operation. *In vitro* study of a skeletal-muscle biopsy specimen from 1 member of the family revealed the development of excessive muscle tension in response to caffeine, with or without halothane, a phenomenon characteristic of MH.[15] We obtained serum samples from that member, age 44, her sister, age 41, her mother, age 69, and her daughter, age 19. The father and brother of these sisters died with MH, as did the son of one of them.

CPK activity was determined by Rosalki's method[16] with reagents from Calbiochem.* The upper limit of normal for white females is 50 mU/ml.[17]

The isoenzymes of serum CPK were studied by 2 methods: (1) Isoenzyme separation was initiated within 1 hour of removing a venous blood sample. The samples were kept at ice-bath temperature prior to use. Three μL of serum were electrophoresed on agarose gels (Pfizer pol-E-film) for 30 minutes and the isoenzymes identified by incubation with Rosalki reagents containing NAD† instead of NADP,‡ and examined for fluorescence.[18] (2) A 1-ml aliquot of serum was used for DEAE-Sephadex-A-50 column chromatographic separation of CPK isoenzymes by the method of Mercer.[19] Rat-brain and skeletal-muscle extracts were studied simultaneously, to assure the reliability of these methods.

RESULTS

Serum CPK activity in the 2 sisters was 351 and 437 mU/ml, respectively. Both levels are sufficiently elevated that concentration of the serum was not considered necessary for separation of the isoenzymes. The serum CPK activity of the daughter and mother was 31 and 29 mU/ml, respectively; they were not further studied.

TABLE

Recovery of Serum CPK Activity in Eluate of DEAE-Sephadex Columns

Sample	CPK activity (mU/ml) Total	Total CPK activity (mU) Fractions 1-2	3-8	9-10
Serum #1	351	306	10	0
Serum #2	437	365	28	0
Brain extract	845	10	50	756
Muscle extract	765	690	0	0

By both electrophoresis and column chromatography, only skeletal-muscle type CPK activity was identified in the serum of both subjects. Not even a faintly fluorescent band was noted in the gels in the region where brain-type CPK fluorescence was present in the brain extracts. Similarly, CPK activity was detectable only in fractions 1 and 2 of the DEAE-Sephadex columns, the region where skeletal-muscle type CPK is expected. Fractions 9 and 10, where brain-type CPK is present, were devoid of activity (table). Brain-type and skeletal-muscle type CPK were readily detected in the brain and muscle extracts.

DISCUSSION

Based on the family history and the study of skeletal muscle response to caffeine in one of these sisters, it seems highly probable that these 2 individuals would be considered typical cases of vulnerability to MH, yet only skeletal-muscle type CPK was present in the serum samples of the 2 sisters. Therefore, the absence of brain-type CPK in their serum cannot be attributed to misdiagnosis, by current criteria. It is conceivable, however, that there is heterogeneity in the group of people vulnerable to MH, such that brain-type CPK is found in the serum of only some people vulnerable to MH.

It is unlikely that a lack of sensitivity in our procedures for identification of brain-type CPK accounted for the difference between our results and those of Zsigmond.[9] We have found* that both the fluorescent

†Nicotinamide adenine dinucleotide.

‡Nicotinamide adenine dinucleotide phosphate.

*Cho HW: Unpublished results.

method and the DEAE-Sephadex chromatographic method are at least as sensitive for determination of CPK isoenzymes as the tetranitro-blue tetrazolium, phenazine-methosulfate, AMP method employed by Zsigmond. Nonspecific staining can occur with that technic because of the so-called "nothing dehydrogenease reaction,"[18] which can be avoided with the fluorescence method.

It is also unlikely that because of a delay in initiating electrophoresis or column chromatography, the brain-type CPK was transformed into a species resembling skeletal-muscle type CPK described by Frotscher[12] and by Cho.[13] It is not clear from Zsigmond's report whether the serum samples were handled after delay or perhaps frozen prior to use. In either case, brain-type CPK should have been lost rather than gained if transformations took place.

The serum and muscle isoenzymes of CPK of more people vulnerable to MH will have to be studied before the true incidence of brain-type CPK in this disorder is determined; in the meantime, it should not be considered necessary for the diagnosis of MH. Britt* also failed to observe brain-type serum CPK in the serum of an unspecified number of patients with MH. Should brain-type CPK be demonstrable in the serum of MH-vulnerable patients, it would be interesting to investigate the reasons for stability of this ordinarily unstable isoenzyme in their serum.[12,13]

ACKNOWLEDGMENT

The authors wish to thank Dr. Beverly A. Britt for help in locating the patients in this study.

Naloxone Antagonism After Narcotic-Supplemented Anesthesia

BENJAMIN J. KRIPKE, MD*
ALBERT J. FINCK, MD†
NARENDRA K. SHAH, MD‡
JOHN C. SNOW, MD§
Boston, Massachusetts‖

Narcotic-supplemented balanced anesthesia is increasing in popularity; however, the narcotic must frequently be antagonized postoperatively. Authorities differ in their recommendations as to dose and as to mode and duration of administration of the narcotic antagonist. In the present study of 58 patients undergoing narcotic-supplemented anesthesia, 60 percent of 42 fentanyl patients and 81 percent of 16 morphine patients required postsurgical naloxone for respiratory inadequacy. Naloxone dosage was initially 1.5 μg/kg IV, with repeat IV doses of 1.5 μg/kg, when needed, at 3-minute intervals, until a regular respiratory rate >15 breaths/min was attained. None of the fentanyl patients and only 25 percent (4/16) of the morphine patients required additional naloxone in the recovery room. For the latter, the dose of naloxone previously administered was given IM and proved satisfactory. Additional analgesia was needed by 12 percent (7/58) of the patients during the recovery-room stay. Judicious naloxone titration permitted respiratory adequacy to coexist with analgesia after narcotic-supplemented anesthesia.

THE use of balanced anesthesia, with large doses of opioids to supplement N_2O-O_2, hypnotics, and muscle relaxants, is increasing. Seven factors contribute to the popularity of this procedure: (1) minimal circulatory depression and morbidity with high-risk patients;[1] (2) a nonexplosive anesthetic approach with the expanding intraoperative use of cautery and electronic monitoring; (3) the use of epinephrine for local vasoconstriction; (4) elimination of the risk of renal and hepatic toxicity associated with halogenation and biotransformation of the volatile anesthetics, especially with multiple operations within a short time; (5) facilitation of management of controlled respiration; (6) availability of satisfactory methods for monitoring the degree of patient weakness and assessment of recovery from curare;[2] (7) rapid reversal of narcotic effect with the new antagonist, naloxone.

Various naloxone regimens have been proposed to counter the undesirable respiratory depression associated with large doses of narcotics.[3-5] Our investigation undertook to study the use of naloxone after *moderate* doses of a short-acting narcotic, fentanyl, and a long-acting narcotic, morphine.

MATERIALS AND METHODS

Subjects were 58 adults scheduled for elective nonthoracic surgery and for whom a balanced anesthesia technic was recommended. Informed consent was obtained after consultation.

All patients were premedicated with pentobarbital (75 to 100 mg IM) and atropine (0.5 mg IM), 1 to 1½ hours before operation. In addition, they received droperidol to a maximum of 12.5 mg (0.17 mg/kg), thiopental (3 to 4 mg/kg), N_2O-O_2 (3:2), succinylcholine (1 mg/kg) for intubation, and d-tubocurarine (0.3 to 0.5 mg/kg) or pancuronium (0.06 to 0.08 mg/kg) for muscle relaxation. In all patients, the motor response to ulnar-nerve stimulation was evaluated by Block-Aid® monitor. Relaxants were reversed with up to 15 μg/kg of atropine and 35 μg/kg of neostigmine IV, given ± 10 minutes before the end of the surgical procedure.

Forty-two patients received fentanyl (0.35 mg IV) within 20 minutes of induction and 0.05 mg every 20 minutes thereafter or earlier, if clinically warranted, and 16 received morphine (0.5 mg/kg) within 30 minutes of induction. Ventilation was controlled to maintain intraoperative $Paco_2$ between 32 to 36 torr.

At the conclusion of operation, muscle contraction to tetanic stimulation was noted, and N_2O was washed out with 100 percent O_2 for 5 minutes. Subsequently, the patient was tapped on the forehead and called by name. All opened their eyes and breathed on command. If the spontaneous respiratory rate exceeded 15/min, the patient was extubated; otherwise naloxone (1.5 μg/kg) was injected IV every 3 minutes until this rate was achieved.

All patients received humidified O_2 by nasal cannula at 5 to 8 L/min during the recovery-room stay. Pulse rate, indirect blood pressure by cuff, and respirations were recorded every 5 minutes. Nursing routine consisted of dressing observation, positional changes, and patient questioning for pain, every 15 minutes. If pain was present, an analgesic was administered. Hourly, arterial blood was drawn and analyzed for Pao_2, $Paco_2$, pH, and calculated HCO_3.*

All patients were observed for at least 3 hours and received an IM dose of naloxone equal to that which stimulated respiration originally, or 1.5 μg/kg IM if the patient had not received naloxone in the operating room, whenever any of the following conditions existed:

1. Unable to be aroused;
2. Signs of respiratory obstruction;
3. $Paco_2$ >47 torr;
4. Respirations <14/min.

*Model 113, Instrumentation Laboratories, Lexington, Massachusetts.

RESULTS

Patient sex, age, ASA risk, duration of anesthesia, blood loss, and operative site are given in table 1.

The median dose of fentanyl was 0.6 mg (range 0.35 to 1.5), with 0.4 to 1 mg in the 10th to 90th percentile. For morphine, the median dose, range, and 10th to 90th percentile were 36, 15 to 48, and 24 to 45 mg, respectively. These values indicate approximately a 60:1 fentanyl:morphine potency ratio for clinical anesthesia, resembling the 50 to 100-fold potency difference cited elsewhere.[6]

The need to administer naloxone was apparent with either agent (table 2). When fentanyl was used, the need to antagonize was ostensibly related to the time interval between the last dose and termination of

operation. Forty-five minutes after the last dose of fentanyl only 35 percent of patients required naloxone, but after 60 minutes after the last dose of fentanyl, none did. In contrast, the longer duration of action of morphine was evident, as 83 percent of patients required antagonism after more than 1 hour from the last dose.

To achieve the clinical goal of sustained respirations greater than 15/min (table 3), additional increments of 1.5 μg/kg were needed more frequently after morphine (11/13 patients) than after fentanyl (11/25 patients). Circulation was stable throughout the procedures and varied less than 10 percent in both groups.

Patients in both groups were oriented, comfortable, and responsive to command on entrance to the recovery room, and, when not stimulated, all appeared to be asleep but were easily aroused. Much of this effect was attributable to the use of droperidol.

*Patients required narcotic for analgesia.

In the recovery room, 4/16 morphine patients required additional antagonist but none of the 42 fentanyl patients did. The dose required to reverse recurrent narcotization was 1.5 μg/kg IM in 2 cases, and 3 μg/kg IM in the remaining 2.

It is noteworthy that the 2 morphine patients who were successfully treated with the lowest dose of naloxone in the operating room required additional antagonist during the 2nd postoperative hour. Their respirations dropped from 16 to 10 and 9/min, respectively, along with a rise in $Paco_2$ from 42 and 41 torr to 50 and 52 torr, respectively. The remaining 2 who required additional antagonist had similar respiratory changes, their respirations dropping from 16 to 12 and 10/min, respectively, along with a rise in $Paco_2$ from 40 and 43 torr to 47 and 50 torr, respectively. Either marked obtundation or signs of upper respiratory obstruction were associated with the respiratory change. Naloxone IM successfully reversed these signs without further recurrence.

Analgesia persisted well into the recovery period after narcotic-supplemented anesthesia (table 5). Only 5/42 fentanyl and 2/16 morphine patients complained of pain and required additional analgesia. Antagonism with naloxone by titration did not enhance the need for further analgesia.

Postoperative vomiting occurred in only 3/58 patients, 2/42 patients after fentanyl and 1/16 after morphine. Naloxone did not appear to be a causative factor in this regard, since of the 3 who vomited, 2 had received naloxone and 1 had not.

DISCUSSION

Naloxone is the most effective narcotic antagonist currently available. It can completely counteract not only massive narcotic overdose[7] but, in contrast to other antagonists, even therapeutic doses.[8] Further, it can counter overdose by pentazocine,[9] propoxyphene,[10] and the agonistic actions of other narcotic antagonists.[11]

The availability of naloxone has broadened the indications for narcotic-supplemented balanced anesthesia. The major concern with this approach was the prolonged or recurrent respiratory depression arising from either the muscle relaxant or narcotic. The widespead use of the Block-Aid monitor has markedly reduced the difficulties associated with muscle relaxants.[2] Thus, the management of the narcotic must be understood if problems are to be avoided.

Initially, a distinction must be made between a desired state, in which the pharmacologic properties of analgesia, sedation, euphoria, and mild respiratory depression occur, and the undesired state of narcotization. This is characterized, in part, by minimal responsiveness to stimuli, depressed pharyngeal and laryngeal reflexes, probable airway obstruction, and marked respiratory depression. In managing narcotics, an attempt is made to achieve the former and to avoid the latter. Thus, some respiratory depression is acceptable in order to preserve other clinically desirable agonistic effects.

The potential for prolonged narcotization after anesthesia is related to the narcotic used, its total dosage, and the elapsed time from the last injection. As an illustration, agonistic effects of 0.1 mg fentanyl are apparent for ½ to 1 hour[12] while those of 10 mg morphine average 4 hours.[13] These doses do not produce narcotization. In contrast, the anesthetic dose of fentanyl may easily exceed 0.006 mg/kg (0.42 mg/70 kg); for morphine, 0.5 to 1 mg/kg and more are often used. Anesthetic fentanyl doses produce significant narcotic depression for 4 hours,* while narcotic depression after morphine may range from 4 hours[3] at the lower dose up to 21 hours at the higher dose.[4]

Using fentanyl, we noted (table 2) that the time between the last dose and completion of the operative procedure is important in determining the need for naloxone. Within 45 minutes of the last dose, antagonism

*Harper MH, Hickey RF, Cromwell TH: The magnitude and duration of the effect of fentanyl and Innovar on the ventilatory response to carbon dioxide in man. Presented at the Pulmonary-Respiratory Pharmacology Conference, Davis, California, August 19, 1975

by naloxone is usually required. Beyond an hour, respiratory depression will probably come from other causes. We were unable to show a similar relationship with morphine, but our sample was small, and this requires further study.

The manufacturer of naloxone initially recommended a dose of 0.4 mg IV to counter narcotic depression.[14] Clinicians have varied from this, following a report in 1974 suggesting that naloxone titration permitted better control.[5] To counter fentanyl depression, Heisterkamp and Cohen[5] recommended naloxone increments of 0.1 mg IV every 2 minutes while Petty[15] suggested 1.5 μg naloxone/μg fentanyl IV. Our study used naloxone increments of 1.5 μg/kg IV every 3 minutes until regular respirations exceeded 15/min.

Our regimen and Heisterkamp's may require repeated IV injections of naloxone within the operating room. In addition, Heisterkamp recommends that an additional dose of naloxone equal to half the successful IV dose be given IM 30 minutes later. Our patients did not need a repeat dose after fentanyl (table 4). Differing protocols probably account for the varying regimens. The dose of fentanyl (1.5 ± 0.3 mg) employed by Heisterkamp and Cohen was much higher than Petty's or ours. The prolongation of narcotic action due to the larger dose probably accounts for the supplementary IM recovery room dose of antagonist.

Petty used 0.3 mg of fentanyl for a D & C. Although this dose is less than ours, the duration of this procedure is short. Thus insufficient time for significant excretion of fentanyl required a higher dose of antagonist. We used 0.6 mg of fentanyl to meet clinical requirements, the need for antagonism being related to the time interval from the last dose.

Using morphine, agonistic actions of anesthetic doses may outlast the antagonism of naloxone, inasmuch as the half-life of the former is 207 minutes[4] and that of the latter is but 19 minutes.[16] Clinical suggestions concerning appropriate naloxone dosage have also varied.[3-5,15,17] We used increments of 1.5 μg/kg IV every 3 minutes until regular respirations exceeded 15/min at the completion of operation, and noted a satisfactory postsurgical course in 75 percent of patients (12/16); the remainder required an incremental dose of 1.5 μg/kg naloxone IM in the recovery room. Again, differences in protocol probably account for the varying experiences of others. However, our recommendations stem from the variations in duration of surgery, morphine being injected within 30 minutes of induction.

Narcotics inhibit the respiratory system, raising $Paco_2$, depressing minute ventilation, and depressing responsiveness to CO_2 challenge. However, depression of the respiratory rate is not a consistent finding at usual clinical doses. Eckenhoff[18] reported that 6/21 patients had a decrease in respiratory rate; the remainder either had no change or an increase in rate at a time when the respiratory system was depressed. In contrast, Foldes[19] indicated a consistent decrease in respiratory rate after narcotic supplementation of thiopental-N_2O anesthesia, and narcotic antagonists restored control values.

Heisterkamp and Cohen[5] reported that depression of respiratory rate correlated significantly with depressed minute ventilation and elevated $Paco_2$, yet concluded that rate was a poor criterion for evaluating respiratory adequacy in the individual patient. The postsurgical patient is subject to numerous factors which influence respiratory performance. Stimulation from the wound (not necessarily perceived as pain), awareness, and the antagonistic action of naloxone increase ventilation, while lingering anesthetic, muscle relaxant and narcotic action, binders, immobility, and position decrease ventilation.

Our data indicate that antagonism of the narcotic to the point at which respirations are regular and exceed 15/min in the operating room and 14/min in the recovery room will yield satisfactory ventilation (table 4).

In agreement with other reports,[5,15] we believe that adequate analgesia for the immediate postoperative period can be preserved by judicious titration with naloxone. Only 5/38 patients who received naloxone required additional analgesia in the recovery room (table 5). This confirms the effectiveness of titration, wherein respiratory adequacy can coexist with analgesia.

Vomiting has been reported after naloxone antagonism. Johnstone[4] cited its appearance in 5/6 volunteers, and Longnecker[3] reported 50 episodes after 79 injections of naloxone, used to reverse relatively large morphine doses. Vomiting is a well-known side effect of narcotics and its incidence is accentuated in ambulatory patients. Hasbrouck[20] did not note emesis after naloxone and suggested that incomplete

reversal of the agonist by naloxone may be the cause of vomiting.

We observed 2 episodes of emesis in 38 patients given naloxone, but 1/20 patients not receiving naloxone also vomited. Therefore, it appeared that naloxone did not increase the incidence of emesis. However, droperidol, a potent antiemetic, was included in the anesthetic management and this may have contributed to the lessened incidence.[21]

Our study suggests that titration of naloxone affords safety and comfort in the early postsurgical period after narcotic-supplemented anesthesia.

Enflurane as a Primary Anesthetic Agent for Patients with Chronic Obstructive Pulmonary Disease

RENE RODRIGUEZ, MD*
MARTIN I. GOLD, MD†
Miami, Florida‡

For years, halothane has been the anesthetic agent of choice for patients with chronic obstructive pulmonary disease (COPD) and reversible airway disease (asthma). Enflurane was compared with halothane in 100 patients with COPD substantiated by spirometry and history. Intraoperative and postoperative complications in each relatively homogeneous 50-patient group were assessed. Spirometry, blood gases, chest x-rays, incidence of complications involving secretions, coughing, wheezing, and cardiovascular problems were similar in both groups. Enflurane appears to be equivalent to halothane as an anesthetic in such patients.

HALOTHANE has long been found useful for the anesthetic management of patients with chronic obstructive pulmonary disease (COPD) and reversible airway disease (asthma).[1] Enflurane also has been reported clinically successful in patients with COPD.[2] The purpose of this investigation was to compare these 2 agents as the primary agent for such patients.

METHOD

After informed consent, patients with a "chart diagnosis" of COPD for both elective and daytime emergency operations were spirometrically screened. The vital capacity (VC) and 1-second forced expiratory volume (FEV_1) were measured at the bedside§ 3 times in all patients. Patients with an $FEV_1 < 70\%$ of VC, were admitted to the study.[3] Arterial blood gases were measured before operation ($F_{IO_2} = 0.21$). Odd-aged patients received halothane and even-aged patients received enflurane.

Patients were premedicated with 2.5 mg/kg of pentobarbital and/or 0.10 mg/kg of morphine sulfate plus 0.5 mg of atropine. In the operating theater, a blood-pressure cuff and ECG leads were applied and IV infusion started, followed by thiopental induction and the primary anesthetic, enflurane or halothane, plus a 50 percent mixture of N_2O-O_2 ($F_{IO_2} = 0.5$). All patients were intubated with the aid of succinylcholine and most were ventilated with a mechanical ventilator; pancuronium was used as the primary relaxant.

Tidal volumes and F_{IO_2} were measured with a Wright respirometer and a Beckman O_2 analyzer, respectively. One investigator (RR) performed the spirometry, withdrew arterial blood for gas analysis, and monitored each patient; he and the anesthetist assigned to this patient made independent judgments concerning the anesthesia, noting all complications and other useful data.

After operation, each patient was extubated and transferred to the postoperative

recovery room (PAR), inhaling O_2 through a nasal cannula ($FIO_2 = 0.3$). After leaving the PAR, he went to the surgical intensive care unit or ward, where he was under observation until hospital release. Statistical analysis was by computer.*

RESULTS

Figures 1 and 2 and tables 1 and 2 show preoperative data and types of operation. Duration of anesthesia (mean 3 hours) and mean dosage of thiopental and pancuronium were similar in both groups, as were tidal volumes and respiratory rates, which averaged 800 ml and 12/min, respectively. Blood gases (fig 3), analyzed preoperatively, intraoperatively, and postoperatively, showed no significant differences between groups.

Intraoperative complications (fig 4) included troublesome wheezing, coughing of more than 2 minutes duration, difficulty in managing secretions, and cardiovascular problems; no significant differences (chi^2 test) were seen between the 2 groups. Hypotension was defined as a persistent (more than 1 min) decrease of 33 percent in systolic blood pressure. Pulse rates <60 or >120 were defined as bradycardia or tachycardia, respectively. Arrhythmias were considered significant if >1 minute in duration. They were primarily atrial in origin, with some premature ventricular contractions.

Nine patients wheezed before receiving enflurane; wheezing disappeared intraoperatively in 5. No patient in the halothane group wheezed preoperatively. No clinical evidence of severe bronchospasm occurred in

any patient. One patient developed severe hypotension; operation was postponed until after treatment for hypovolemia, when he received enflurane without sequelae.

After leaving the PAR, of those who received halothane, 12 (24%) developed pneumonia, 6 ((12%) atelectasis, and 5 (10%) pleural effusion. Of those who received enflurane, 8 (16%) developed pneumonia, 7 (14%) atelectasis, and 7 (14%) pleural effusion.

DISCUSSION

This investigation involved patients with COPD defined by spirometry and history, not merely a "chart diagnosis." While demographic data reflect relative homogeneity between the 2 groups, a few more patients with upper abdominal surgery and less with extremity and superficial operations received enflurane, and the mean ASA physical rating was slightly lower in the halothane patients. Therefore, more "worse-risk" patients and some for more complicated surgery were maintained on enflurane. However, this skewing does not affect the validity of the comparison.

Enflurane and halothane intraoperative blood gases were basically similar, as was the clinical incidence of wheezing, troublesome coughing, and secretions, all potentially dangerous in this type of patient. Hypotension was frequent but, again, the incidence was similar in both groups. Both of these liberally halogenated anesthetic agents carry this stigma, especially in poor-risk patients.[4-7] Bradycardia, tachycardia, and persistent arrhythmias occurred rarely and with similar incidence in both groups. Halothane was associated with more arrhythmias than enflurane ($p<0.05$), while enflurane was associated with more frequent hypotension ($p<0.05$).

No patient was considered to have been hypoxemic, although a few isolated Pao_2s were lower than one would have expected from the associated FIO_2 and estimated PAO_2. COPD is associated with an increased incidence of respiratory complications, decreased Pao_2, and hypotension. Decreased cardiac output plus a higher $PA\text{-}ao_2$ difference was not unexpected.[8-11]

In the PAR, blood gases in both groups were similar. Each patient had been extubated and was receiving an FIO_2 estimated to have been 0.25 to 0.3 (40% O_2 was delivered to the nasal cannula; as this was diluted by a variable amount of air, FIO_2 could only be estimated). Postoperative wheezing and late postoperative respiratory complications in both groups were virtually identical (average of 3 postoperative chest

x-rays). Twelve (24%) halothane and 8 (16%) enflurane patients developed pneumonia ($p<0.05$); however, the site and duration of operation are interdependent variables related to incidence of respiratory complications and were not analyzed because of low sample numbers.

Patients with COPD must be considered far more of a risk than normal patients, and complications may arise either during or after anesthesia for reasons that are not clear.[8-12] There is decreased ciliary activity, especially in smokers;[13] there is also an increase in secretions. Such patients rely on the cough mechanism to bring up secretions and foreign material. During anesthesia, the cough reflex is significantly diminished, as is patient response to CO_2.[8] Patients with COPD have an exaggerated depression of CO_2 response unrelated to the operative procedure or anesthesia. Therefore it is not surprising that these patients have an increased incidence of intraoperative and postoperative respiratory complications.[8-12] Halothane, a beta-adrenergic stimulating agent,[14] has been clinically successful in such patients, probably because it is also a mild bronchodilator, is not as irritating as other inhalation agents, and is not associated with a significant amount of secretions.[15,16] A second anesthetic agent for patients with COPD with similar characteristics would be a welcome addition in the anesthesiologist's quest to avoid morbidity in these patients.

The interdependent influences of many variables reflect the limitations of such a 2-drug investigation as reported here. Nevertheless, the objective and clinical evidence presented in these 100 patients, within the limitations of the protocol, leads us to suggest that enflurane be ranked equally with halothane for anesthesia in patients with COPD.

Unexpected Hepatic Dysfunction Found by Multiple Laboratory Screening

WILLIAM H. SCHEMEL, MD*

During a 1-year period, 7620 elective surgical admissions were given multiple laboratory screening (SMA-18) determinations. Of these, 11 healthy patients, aged 10 to 54, with a pretest classification of ASA 1 (no systemic disease) were found to have clearly abnormal elevations of the SGOT, SGPT, and LDH levels. The proposed elective surgical procedures and anesthesia were canceled. All 11 patients proved to have overt liver pathology by further testing, and 3 later became clinically jaundiced. No cases of unexplained postsurgical jaundice occurred in any of the other 7609 operated cases during the 1-year study. The incidence of clearly elevated enzyme levels in voluntary hospital surgical admissions is approximately 1/700 and the incidence of clinical jaundice is approximately 1/2540. There appears to be a seasonal variation, with the preponderance of elevated enzyme levels in the winter and spring months.

THE toxicity of halogenated anesthetics remains a frustrating and controversial subject, primarily due to lack of necessary information. Carney and Van Dyke[1] reported the incidence of hepatitis following halothane anesthesia to be approximately 1/2500, and mortality from post-halothane hepatitis is reportedly somewhere between 1/9000 and 1/40,000.[2] The need has existed for a prospective study to determine the incidence of undiagnosed hepatitis in the general population, which might become clinically evident after surgical anesthesia. The purpose of the present study was to determine the incidence of hepatic dysfunction in patients admitted for elective surgery, with relation to 1 year's experience with preoperative SMA-18 multiple laboratory screening.

METHOD

Our institution is a 550-bed voluntary general hospital with mostly private patients. During the period July 1, 1974, to June 30, 1975, a total of 7620 patients admitted for elective surgery were studied. Blood for SMA-18 determination was drawn the afternoon of admission on the day before operation, with the report in the chart preoperatively. The SMA-18 determines SGOT, SGPT, LDH, alkaline phosphatase, total bilirubin, creatinine, uric acid, cholesterol, inorganic phosphorus, K^+, Na^+, Ca^{++}, Cl^-, albumin, total protein, glucose, BUN, and CO_2.[3]

While all these have proved of value in the diagnosis, treatment, and anesthetic management of individual cases, the enzyme determinations (SGOT, SGPT, and LDH) have been of critical importance, especially concerning the determination of hepatic dysfunction.

The range of normal values (± 2 SDM) accepted in this laboratory are:

SGOT	7 to 40 mU/ml
SGPT	7 to 40 mU/ml
LDH	100 to 225 mU/ml

The normal range is based on the statistical concept of the normal distribution of the Gaussian curve. It has been shown that 66 percent of the population fall within 1 SD and 95 percent within 2 SDs.[4] Many

Paper received: 11/10/75
Accepted for publication: 2/17/76

factors, as well as disease processes, can produce slight, transient elevations of these enzymes; these are of no real consequence.[5] As a "rule of thumb," the values may be considered clearly abnormal only when they are more than twice the upper limit of normal.

DISCUSSION

As all 11 patients had clearly abnormal enzyme levels, the proposed operations were canceled. The tests were repeated and in all cases were again clearly abnormal. At this point, the patients were again interviewed (the routine history having been taken and physical examination made on admission) and questioned regarding symptoms related to hepatic function. None of the patients had any of the usual symptoms related to hepatic disease. Some were indignant at having their proposed surgical procedures canceled. All were referred to their primary physician for further diagnosis and treatment and all were diagnosed as having definite liver disease on the basis of further laboratory testing or pathology reports of liver biopsies. Three developed clinical jaundice. During the period when enzymes were elevated, most patients experienced no symptoms; a few had some minor complaints, such as tiredness and loss of appetite. The course of the disease in the 3 patients with jaundice was benign, with apparent complete recovery.

The incidence of clearly elevated enzymes in this group was approximately 1/700 and the incidence of clinical jaundice was 1/2540. During the first 6 months of the study, only 1 patient was found with clearly abnormal enzyme elevations; the other 10 were found between January and June.

The results of this 1-year's experience revealed a number of significant findings and raised some questions. The 11 patients reported here, all ASA status I, would have undergone elective surgical procedures had they not been found to have elevated enzyme levels preoperatively. At least 3 of them would have developed jaundice in the postoperative period. Would the diagnoses of viral hepatitis, subsiding viral hepatitis, and infectious mononucleosis have been different had they received halogenated anesthetics? Would the normal course of hepatic disease have been altered by anesthesia and surgery? At this point, it is interesting to note that there have been no reported cases of unexplained postoperative jaundice in this hospital since the advent of multiple laboratory screening.

When the enzyme levels are clearly abnormal, it is best to postpone surgery until the reason for the elevation has been determined. When the enzyme levels are slightly elevated, it is difficult to determine the proper course of action. In these instances, it has been our policy either to use regional technics or, if inhalation anesthesia is required, to avoid the use of halogenated compounds.

TABLE
"Healthy" Surgical Admissions with Elevated SGOT, SGPT and LDH Tests
(All Patients ASA Status I)

Patient	Age	Sex	Operation proposed	Post-test diagnosis	Became jaundiced
1	10	M	Scalp wen	Infectious mononucleosis	No
2	47	F	Hysterectomy	Viral hepatitis*	Yes
3	24	F	Laparoscopy	Viral hepatitis*	No
4	54	F	D & C	Cirrhosis	No
5	23	F	Laparoscopy	Infectious mononucleosis	Yes
6	21	M	Inguinal hernia	Acute alcohol hepatitis*	No
7	23	M	Menisectomy	Chronic hepatitis	No
8	35	M	Skin graft	Early cirrhosis	No
9	16	F	Breast biopsy	Viral hepatitis	Yes
10	26	M	Laminectomy	Alcoholic hepatitis	No
11	25	M	Dental extractions	Hepatic dysfunction (industrial toxin?)*	No

*Liver biopsy.

Several other patients with known systemic disease (ASA II or greater) also had their elective surgical procedures postponed or canceled by their primary physician as a result of these tests, but they are not included in this report.

The incidence of postoperative hepatitis reported by Carney (1/2525) is nearly identical with the incidence of clinical jaundice in our preoperative studies (1/2540). A similar report from another institution in this community[6] revealed almost identical results, 1/2180 jaundiced and 1/727 elevated enzymes. Their seasonal distribution also was similar to ours.

CONCLUSIONS

From these data, we conclude that it is possible that many cases which have been diagnosed as halothane hepatitis could well have been infectious hepatitis becoming clinically evident after surgical procedures. From the incidence of undetected hepatic dysfunction in ASA I patients admitted for elective surgery, obviously many thousands of such patients have been anesthetized over the years by a variety of technics and have remained asymptomatic.

It is our recommendation that multiple laboratory screening, including SGOT, SGPT, and LDH, be done routinely on admission, to identify those patients in the general population who might need further evaluation, therapy, and observation before elective surgery.

HYPERTENSION. Postoperative hypertension may occur in nearly one-third of patients following aorta-coronary bypass graft operations. In addition to increasing the risk of hemorrhage the hypertension may increase myocardial oxygen requirements. Seven of 12 patients investigated by the authors became hypertensive (blood pressure >140/90) after myocardial revascularization. Systemic vascular resistance was greater in hypertensive as compared with normotensive patients while heart rates and cardiac outputs were similar. Thoracic epidural anesthesia administered to the hypertensive patients reduced systolic blood pressure to an average of 105 torr and improved the diastolic pressure-time index/systolic pressure-time index ratio (an indirect measurement of subendocardial oxygenation). In addition to the pharmacologic sympathectomy epidural anesthesia has the added advantage of analgesia. *(Hoar PF, Hickey RF, Ullyot DJ: Systemic hypertension following myocardial revascularization. A method of treatment using epidural anesthesia. J Thorac Cardiovas Surg 71:859-864, 1976)*

Postpartum Hypertension and Convulsion After Oxytocic Drugs

EZZAT ABOULEISH, MB, BCh, MD*

An 18-year-old primipara developed acute hypertension leading to cerebral edema and convulsions following the IV injection of a bolus of 10 units of oxytocin with 0.2 mg methylergonovine maleate. Oxytocin in a dose of more than 2 units should not be administered IV in a single injection, as severe hypotension may result. If oxytocin is required, it can be injected either IM, or by IV pump or drip. The use of ergot in obstetrics should be limited to the treatment of life-threatening postpartum hemorrhage and be given only by the IM route. Ergot should not be administered to patients with cardiac, renal, or hypertensive disease, or in association with a vasoconstrictor.

DESPITE the documented potential danger of administering oxytocin and/or methylergonovine maleate intravenously in a bolus,[1-9] this procedure is still used by some physicians. The present report is intended to remind the anesthesiologist of the hazards of this therapy.

CASE REPORT

An 18-year-old gravida 1, para 0, was admitted to the hospital at 0100 hrs on her expected date of confinement. Her antepartum course was uneventful, total weight gain was 10.9 kg, and average blood pressure was 110/70. On admission, she was apprehensive, with a blood pressure of 140/100, reflexes were brisk, and the cervix was 7 cm dilated with vertex presentation. Hemoglobin was 13.2 gm/100 ml, there was no edema, and urine was negative for albumin and dextrose. After IM injection of 50 mg of phenothiazine and 50 mg of meperidine, the blood pressure decreasd to 110/70 and reflexes became normal. Labor progressed satisfactorily, and, in about 2 hours, the patient was ready for delivery.

At 0305 hrs, subarachnoid block to T-10 was achieved without difficulty, using 50 mg of lidocaine through a 26-gauge spinal needle. Blood pressure was stable at 110/65, and no vasopressor was administered. At 0316, a female baby weighing 3520 gm was delivered (Apgar 9-10). At 0318, the placenta spontaneously separated and was delivered. Immediately afterward, 10 units of oxytocin and 0.2 mg of methylergonovine maleate were injected in a single IV dose, and 10 units of oxytocin in 5 percent dextrose in water (D/W) were administered in a continuous IV drip.

At 0335, the blood pressure increased to 140/100. In the recovery room, at 0345, blood pressure reached 200/130 and the patient complained of severe headache. There was no edema and reflexes were normal. The IV injection of 5 mg of diazepam and the IM injection of 15 mg of morphine failed to lower the blood pressure or relieve the headache, and the patient became nauseated and began vomiting. Bladder catheterization revealed 1100 ml of clear urine, followed by a urine output of 100 ml/hr. There was no proteinuria. At 0430, an IM injection of 120 mg of phenobarbital was followed by sedation and decrease in blood pressure, which was maintained around 160/100.

At 0855, the patient became incoherent, with body tremors, followed by generalized rigidity and a grand mal seizure. Phenobarbital (100 mg) was injected IV, O_2 was administered, and the seizure stopped without recurrence. Examination of the eye fundi showed constricted blood vessels without hemorrhage or exudates, and neurologic examination showed no signs of localization. Lumbar puncture with a 20-gauge spinal

*Associate Professor of Clinical Anesthesiology, University of Pittsburgh School of Medicine; Director of Obstetric Anesthesia, Magee-Womens Hospital, Pittsburgh, Pennsylvania 15213.

Paper received: 6/30/75
Accepted for publication: 3/1/76

needle showed clear CSF with grossly elevated pressure. Actual measurement of the pressure was not possible because of the patient's lack of cooperation. The urine output, after temporary reduction to 20 ml/hr for 2 hours, rapidly increased to preseizure level (100 ml/hr). Albuminuria and hematuria were present only during the oliguric period.

Blood examination showed WBC 10,000, hemoglobin 12.7 gm/100, platelets 150,000, fibrinogen 341 mg/100 ml, prothrombin time 12 sec, partial thromboplastin time 34 sec, plasma thrombin time 26 sec, urine/serum osmolality 602/282 mOsm/kg water, Na^+ 137 mEq/L, K^+ 4.7 mEq/L, Cl^- 105 mEq/L, BUN 13 mg/100 ml, and creatinine 0.5 mg/100 ml.

Fluid intake in the first 24 hours was 1 L of 5 percent D/W plus 1.5 L of 5 percent dextrose with 0.2 percent NaCl. The patient was maintained on injection of phenobarbital, 60 mg IM every 8 hours and diphenylhydantoin, 100 mg IM every 12 hours. Her body temperature remained normal and her consciousness rapidly improved 24 hours after delivery. Thereafter, blood pressure remained around 110/70, her stay in the hospital was uneventful, and on the 8th postpartum day she and her baby were discharged in good condition.

DISCUSSION

Oxytocic drugs have a significant effect on the cardiovascular system. Oxytocin causes vasodilation of both alpha- and beta-adrenoreceptive blood vessels.[8] The action occurs in less than 30 seconds and is maintained for 3 to 5 minutes.[7] The vasodilating effect of oxytocin causes transient hypotension, the degree and duration of which are proportionate to the dose of the drug and the rate of injection. The average drop in blood pressure after oxytocin injection (0.1 unit/kg) in the form of an IV bolus is 45 percent.[9] Hypotension due to oxytocin is minimized by the lithotomy position.[8] However, such hypotension becomes especially dangerous in a hypovolemic patient in whom vasoconstriction is an important factor in maintaining the blood pressure.

Five to 10 seconds after the onset of hypotension, tachycardia occurs, with an average increase in heart rate of 20 beats/min.[9] The tachycardia, which is reflex in origin and secondary to the hypotension, is associated with S-T segment depression and T wave inversion, denoting myocardial ischemia. This is due to coronary insufficiency as a result of hypotension, combined with increased O_2 demand secondary to the tachycardia.[2,8,10] There is also mild myocardial depression, manifested by antiarrhythmic properties of oxytocin.[11] Such mild myocardial depression becomes significant in a patient with cardiac disease.

Therefore, if oxytocin is required, it can be injected either IM, or by IV pump or drip; it should not be administered by IV bolus in a dose exceeding 2 units.

Ergot preparations, in contrast to oxytocin, are known to cause vasoconstriction.[12] The vasoconstrictive action of ergonovine is less than that of other ergot alkaloids, and methylation further reduces its vasoconstrictive effects. A pressor effect has been seen in about 48 percent of patients following ergonovine administration and in 22 percent after methylergonovine.[4] The incidence of severe hypertension (systolic elevation of >25 torr and diastolic of >20 torr) was reported in 2 percent of cases following IV injection of methylergonovine and in 4.6 percent with concomitant administration of vasopressor.

Hypertension also can follow the IM injection of ergot alkaloids.[3] Vasoconstriction, through a direct stimulation of blood vessels both at the arterial and venous sides,[13] leads to increased peripheral resistance and rise of both arterial blood pressure and central venous pressure. Ergot also has a depressant effect on the vasomotor center, preventing compensatory vasodilation secondary to afferent impulses from the baroreceptors. The increased venous return to the heart following relief of the inferior vena caval compression after delivery and the diminution of the vascular bed following tetanic contraction of the uterus potentiate the postpartum rise of blood pressure. The vasoconstrictive effect of ergot becomes manifest in 3 minutes and lasts for several hours.[8]

Blood pressure elevation following ergot preparations is particularly pronounced in toxemias of pregnancy, hypertension, presence of hypoxia, administration of vasopressors,[3] or marked apprehension.[5] In our case report, toxemia was excluded, the high blood pressure and hyper-reflexia encountered on admission probably being due to apprehension, since blood pressure and reflexes became normal following phenothiazine and meperidine administration.

Since the incidence of a dangerous rise of blood pressure after administration of ergot alkaloids is rare and hypertension would otherwise be attributed to postpartum toxemia, some obstetricians continue to give ergot IV. However, this is particularly dangerous in patients with cardiovascular disease, hypertension, respiratory disease, renal disease, or chronic anemia. Sudden hypertension produced by ergot causes a strain on the heart and may be associated with coronary vasoconstriction, leading to myocardial ischemia, acute heart failure, and acute pulmonary edema. It may also lead to cerebral edema, as in the case reported, or even to cerebral hemorrhage.[3] Retinal detachment following IV injection of 0.2 mg methylergonovine and 5 units oxytocin also has been described;[6] the mechanism was thought to be spasm of the choroidal vessels, producing an increase in choroidal hydrostatic pressure and transudation of fluid into the subretinal space.

If ergot is administered during general anesthesia under such potent drugs as halothane, or during regional analgesia, its vasoconstrictive action may be counteracted by the vasodilative effect of these technics. Thus, the hypertensive effect of ergot may be masked and the lungs and brain may be temporarily protected from edema or hemorrhage until the vasodilation wears off.

To treat the hypertensive episode produced by ergot, slow IV injection of 12.5 to 15 mg of chlorpromazine is recommended. Hydralazine infusion has also been effective, since it causes generalized vasodilation, particularly of the renal vessels.[14]

Although pharmaceutic literature[15] suggested that methylergonovine maleate might be slowly injected IV over a period of no less than 60 seconds while monitoring the blood pressure this is not safe enough in view of the delay (3 min) in evidence of the hypertensive response.[8] Therefore, if ergot is to be used, it should be administered by IM route for a life-threatening uterine atony resistant to oxytocin.

Since the vasoconstrictive effect of ergot is opposite to the vasodilative action of oxytocin, this may lead to the erroneous assumption that, by simultaneous IV administration of both drugs, the effect of one will nullify that of the other. However, onset and duration of action of the 2 drugs are so different that the patient is exposed to the harmful effects of both.

ACKNOWLEDGMENT

My appreciation extends to Dr. Eberhard Mueller-Heubach for his advice and to Miss Lois Sprague and Miss Kathy Kutzavitch for secretarial help.

A Simple Technic to Minimize Tracheal Aspiration

ROY F. CUCCHIARA, MD*

THE safe induction of general anesthesia for emergency surgery in a patient with a full stomach can be challenging to even the most experienced clinician. The presence of ileus, bowel obstruction, or gastric-outlet obstruction may place the gastric contents under greater than normal pressure. Regurgitation under such circumstances may be so voluminous as to overwhelm the awake debilitated patient and cause him to aspirate a significant quantity of gastric contents. The volume of such gastric contents may exceed the capacity of available suction apparatus.

Anesthesiologists have proposed various devices,[1] positions,[2] and technics, such as cricoid pressure,[3] the "crash induction,"[4] the awake intubation,[5] and use of a clear anesthesia mask, to help prevent catastrophic regurgitation. This report adds a simple, but apparently not widely known, adjunct. The case is representative of five in which the technic has been employed effectively.

CASE REPORT

This patient was a slender 68-year-old woman with signs and symptoms of acute small-bowel obstruction, believed to be secondary to peritoneal adhesions from a previous hemicolectomy. A trial of medical management with a Miller-Abbott tube had been unsuccessful. With a nasogastric tube in place, her respiratory rate was 32/min and shallow. Except for a markedly distended abdomen, physical examination was unremarkable. Laboratory and electrolyte values were within normal limits and she was not significantly dehydrated.

A rapid induction was planned. The nasogastric tube was suctioned, irrigated, and intermittently suctioned as it was withdrawn, with no return of gastric contents. After administration of 3 mg of d-tubocurarine, the patient was preoxygenated for 3 minutes. With cricoid pressure applied, she was then given 2 mg/kg of sodium thiopental, followed immediately by 2 mg/kg of succinylcholine. The mask was removed and the laryngoscope inserted for intubation. With no visible signs of movement, the patient promptly regurgitated sufficient quantities of gastric material to overwhelm the capacity of the suction apparatus. Gastric material ran out of her mouth and completely obscured the view into the pharynx.

The endotracheal tube was immediately inserted into the esophagus with the realization that no view of the larynx could be obtained, and the cuff was inflated. Gastric contents continued to pour out of the endotracheal tube, but the oropharynx could be quickly suctioned dry. A second endotracheal tube was rapidly inserted into an easily visualized larynx. The tube in the trachea was suctioned and O_2 was administered by positive pressure while checking the tube position. Gastric contents continued to drain from the esophageal tube for a full minute after the tracheal airway was secured. The esophageal tube was removed, a nasogastric tube was placed, and the remaining gastric contents were suctioned from the nasogastric tube.

The laparotomy was performed uneventfully under halothane-O_2 anesthesia with pancuronium for neuromuscular blockade. Blood gases drawn during the operating procedure showed a Pao_2 of 376 torr. Postoperatively, the patient was admitted to an intensive care unit with the endotracheal tube in place. Chest x-ray revealed a small right upper lobe infiltrate. On the 1st postoperative day, the infiltrate had begun to

Paper received: 3/22/76
Accepted for publication: 4/16/76

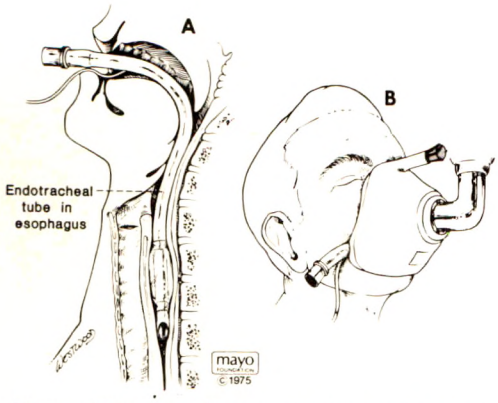

FIGURE. When gastric regurgitation occurs, an orotracheal tube (A) can be inserted blindly into the esophagus and the cuff inflated to provide an exit pathway for gastric contents. The mouth can be suctioned dry and mask ventilation (B) resumed, while the air entry pathway is thus separated from the exit pathway of gastric contents.

resolve, blood-gas tensions were acceptable, and the patient was extubated. The remainder of her recovery to discharge was uneventful.

DISCUSSION

It is often taught that, if vomiting occurs during the induction of general anesthesia, the first treatment should be tracheal intubation with a cuffed endotracheal tube. Many clinicians have witnessed a struggling colleague's attempt to intubate the trachea in a gush of regurgitant gastric contents with the suction at full power in the mouth. The real emphasis should be on protection of the airway from regurgitant material. From this viewpoint, the lungs can best be protected by separation of the exit pathway of regurgitant material from the entrance pathway of O_2.

The most common method of accomplishing this separation is by placing a cuffed tube into the trachea, but placement of a cuffed tube into the esophagus can also be effective. During regurgitation, intubation of the esophagus *or* trachea and inflation of the cuff can be lifesaving. A blindly placed tube may fortuitously enter the larynx. If, however, it enters the esophagus, effective separation of air entry and regurgitant outflow pathways can still be obtained, if the cuff is inflated and the tube left in place. The pharynx can be suctioned clear and positive-pressure ventilation can be immediately begun, if necessary, by excluding the esophageal tube from the mask area (figure). Another tube can be placed into the trachea as soon as feasible.

Thus, when the anesthesiologist encounters a patient regurgitating on induction, intubation of the trachea should be attempted immediately. If this is not possible, the esophagus should be intubated, and the cuff inflated. Then it is possible to quickly pursue whatever technical course is necessary to establish a stable separation of esophageal reflux and air entry, so that ventilation and oxygenation can be resumed.

Two possible complications of esophageal intubation with a cuffed tube should be considered: (1) the tube may perforate the esophagus and pass into the mediastinum, and (2) overinflation of the cuff may compress the trachea. Neither of these events is likely, however, and the small potential risk seems acceptable when weighed against the risk of uncontrolled regurgitation.

The Anesthetic Potency of Lidocaine in the Rat

COSMO A. DiFAZIO, PhD, MD*
JAMES R. NIEDERLEHNER, MD†
ROBERT G. BURNEY, MD‡
Charlottesville, Virginia§

The anesthetic effect of lidocaine was evaluated in rats by determining the change in anesthetic requirement of cyclopropane MAC that was produced by blood concentrations of lidocaine in the clinically useful range. A linear reduction in anesthetic requirement was produced with concentrations up to 1 μg/ml. Further increases in lidocaine up to 5.5 μg/ml resulted in no further decrease in cyclopropane requirement. Lidocaine was found to contribute a maximum MAC fraction of 0.4.

RECENT concern with the problems associated with the administration of volatile anesthetics[1] and of atmospheric contamination[2] has placed greater emphasis on the development of alternative anesthetic technics. Intravenously administered lidocaine has been used with varying enthusiasm since the drug was introduced, either for analgesia or as part of a general anesthetic procedure.[3-5] However, no adequate measurements of the effective contribution of lidocaine to a general anesthetic procedure have been reported. The purpose of this study was to determine the anesthetic potency of lidocaine in rats by observing the reduction in the mean anesthetic concentration (MAC) of cyclopropane achieved by the addition of clinically useful levels of lidocaine.

METHOD

MAC was determined by the tail-clamp technic[6,7] in 25 cyclopropane-anesthetized rats weighing 239 ± 18 gm each. The external jugular vein was surgically exposed and cannulated and a slow (0.01 ml/min) constant infusion of lactated Ringer's solution was started. MAC was again determined after completion of the surgical procedure, and the control MAC was established as being the average of the values obtained before and after operation. The animal's rectal temperature was determined by a Yellow Springs temperature probe and maintained by a warming mattress.

A lidocaine bolus of 250 or 750 μg was followed by a constant infusion of 50, 75, 150, or 250 μg/min for up to 1 hour. MAC was again determined, beginning after the animal had received the lidocaine constant infusion for at least 15 minutes. Heart blood was assayed for blood lidocaine concentration by gas chromatography[8] immediately after MAC determination.

RESULTS

Control cyclopropane MAC (13.8%) was found (table 1) to be comparable to the previously reported MAC for cyclopropane,[9] and a linear reduction in MAC was observed with lidocaine concentrations up to

1 μg/ml (fig 1). Linear regression of the values below 1.1 μg/ml (1st part of curve in fig 1) produced the equation Y = 40.2X + 1.5 (lidocaine MAC equivalents = 40.2 lidocaine concentration + 1.5). The correlation coefficient was 0.93. A ceiling effect was noted at blood levels above 1 μg/ml. Further increases in lidocaine up to 5.5 μg/ml resulted in no further change in cyclopropane requirements. A mean reduction of 42 percent in cyclopropane MAC was observed with lidocaine concentrations of 1.1 to 5.5 μg/ml.

Gas chromatography allowed measurement of the lidocaine metabolites MEXG (monoethylglycinexylidide) and GX (glycinexylidide), concentrations of which were seen consistently to be less than 0.1 μg/ml and were noncontributory to the anesthetic effect.

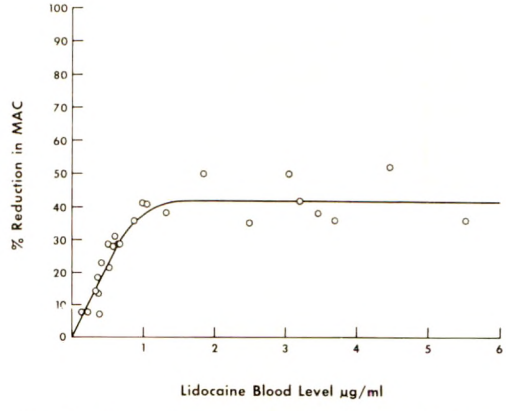

FIG 1. The percent reduction in anesthetic requirement (cyclopropane MAC) that results from increased lidocaine blood levels is shown. A ceiling effect is present above 1 μg/ml in blood lidocaine concentrations.

DISCUSSION

Concomitant use of IV lidocaine with other agents to produce general anesthesia has been reported by several authors. deClive Lowe[3] reported administering 750 mg of lidocaine in the first hour of varying procedures along with sodium thiopental

and N_2O. Steinhaus and Howland[4] and Phillips and coworkers[5] also reported on the administration of lidocaine, thiopental, and N_2O for general anesthesia, observing that lidocaine had an anesthetic effect which resulted in a 13 percent mean reduction in thiopental requirement. Blood levels of lidocaine were not determined.

In a variety of circumstances, lidocaine blood levels equal to or greater than those used in our experiment have been observed in man. Levels of 2 to 5 μg/ml have been sought for arrhythmia control.[10] Mean peak blood levels as high as 6.4 μg/ml have been reported with regional anesthesia.[11] These levels are considered safe for man. Convulsant levels are reported to be 8 to 10 μg/ml in unpremedicated man and 15 μg/ml in the rat.[12]

The rat has been previously established as a model for anesthetic requirements, and correlations between MAC and the oil/gas partition coefficient comparable to those found in man[16] and the dog have been observed (fig 2). A marked difference, however, exists between rat and man in the metabolic pathway of lidocaine. In the rat, large amounts of 3-hydroxy lidocaine and 3-hydroxy MEGX are produced (table 2). The anesthetic contribution of these metabolites which predominate in the rat are unknown. While the absolute anesthetic requirement and the percent reduction produced by lidocaine should show species variation, this experiment provides an approximation of what may be expected in man.

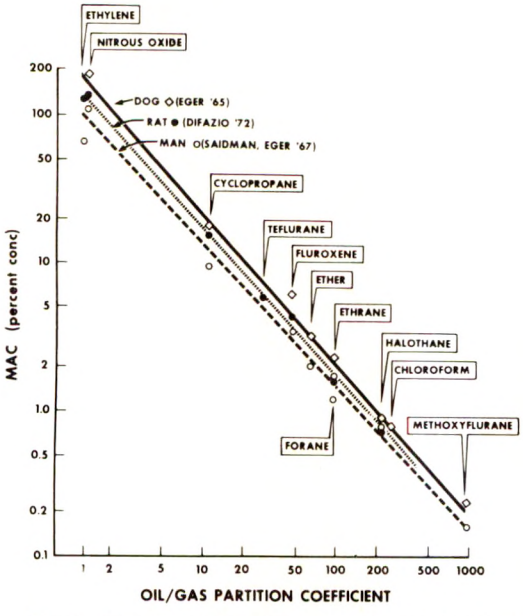

FIG 2. The correlation of anesthetic requirement (MAC) and the oil-gas partition coefficient is shown for man, rat and dog. Anesthetic requirements are highest for the dog, least for man and the rat is intermediate.

TABLE 2
Species Variation in Urinary Excretion of Lidocaine and Metabolites[17]

Compound	Percent of dose in urine	
	Rat	Man
Lidocaine	0.2	2.8
MEGX	0.7	3.7
GX	2.1	2.3
3-hydroxy-lidocaine	31.2	1.1
3-hydroxy-monoethylglycine-xylidide	36.9	0.3
2,6-xylidine	1.5	1.0
4-hydroxy, 2,6-xylidine	12.4	72.6

The combination of volatile and almost all other anesthetics has been shown to produce a purely additive effect,[9,13,14] such an effect resulting when the sum of the MAC fractions of the 1st and 2nd agents is equal to 1 MAC, although the result of combination of a MAC fraction of a fixed drug with a MAC fraction of a volatile anesthetic has not been established.

An additive effect appears present over a considerable dosage range (linear reduction in MAC) when morphine and meperidine are used as fixed drugs.[15] The MAC for these fixed agents, however, could not be established without encountering respiratory toxicity. In the present study, a MAC for lidocaine could not be established because a ceiling effect resulted. A mean maximum MAC fraction of lidocaine was established to be 0.4 MAC (maximum lidocaine MAC = 0.4).

The production of 0.4 MAC by low levels of lidocaine suggests that the addition of any anesthetic capable of contributing 0.6 MAC should result in the production of general anesthesia. In previous reports in man, however, both lidocaine and thiopental were required to supplement 70 percent N_2O (0.65 MAC). It would appear, therefore, that the anesthetic effect of lidocaine in man is considerably less than in the rat. Further studies in man are underway.

LIDOCAINE METABOLISM. Congestive heart failure, as may follow acute myocardial infarction (AMI), may be associated with a decreased volume of drug distribution and slowed hepatic and renal elimination. As a result drug concentrations may be higher in patients with cardiac failure and the risk of drug toxicity increased. Plasma lidocaine concentrations during and after constant rate infusion (1.4 mg/min) were measured in 12 patients with AMI and 6 normal patients. Lidocaine concentrations were significantly higher in patients with cardiac failure than in normals. The mean values at the conclusion of infusion were 4.1 and 2.8 μg/ml respectively. The rate of decrease after drug infusion was always slower in patients with heart disease. The terminal plasma half-life was prolonged almost threefold (1.5 hours in normals). Impaired lidocaine metabolism probably reflects reduced hepatic blood flow associated with a low cardiac output. *(Prescott LF, Adjepon-Yamoah KK, Talbot RG: Impaired lignocaine metabolism in patients with myocardial infarction and cardiac failure. Peridural analgesia was combined with the respiratory-stimulant effect of doxapram for intermittent hyperinflation of the lungs to reverse early postoperative (PO) hypoxemia following inhalation anesthesia for upper abdominal operations. Twenty unpremedicated men undergoing upper abdominal operations were studied for 5 hours in the recovery room. Ten of these patients received doxapram plus peridural analgesia; the other 10, doxapram plus morphine analgesia. Rectal temperature, Pa_{O_2}, Pa_{CO_2}, respiratory rate, exhaled minute ventilation ($\dot{V}_E$), tidal volume (V_T), and blood pressure and pulse were measured. The mean increase from control for $\dot{V}_E$ was 9.6 L/min and for V_T, 356 ml/breath during doxapram therapy for the morphine group. Corresponding values for the peridural group were 14.4 L/min for $\dot{V}_E$ and 660 ml/breath for V_T. Mean Pa_{O_2} for the morphine group decreased significantly from the corresponding preoperative value ($p<0.005$). Lack of significant change between preoperative and PO values for Pa_{O_2} for the peridural group would indicate that under the conditions of this study, early PO hypoxemia can be reversed by the combination of peridural analgesia with doxapram therapy.

HYPOXEMIA often follows inhalation anesthesia for upper abdominal or thoracic operations. It may be reversed by combining peridural analgesia with doxapram-induced hyperinflation of the lungs. In the present study, hypoxemia refers to a decrease greater than 15 percent in Pa_{O_2} within the first 5 postoperative (PO) hours, when both preoperative (control) and PO blood samples were obtained while the patient was breathing room air ($F_{IO_2} = 0.21$). Hypoxemia may persist for up to 5 days.[1-4] Voluntary stir-up regimes, IPPB with O_2, and CO_2 rebreathing have failed to reverse or shorten such hypoxemia.[2,5]

The condition can be circumvented in the recovery room by the use of supplemental inhaled O_2 via disposable face mask or nasal prongs.[4] The Pa_{O_2} value under these conditions will usually equal or exceed preoperative Pa_{O_2} values on room air, if the PO arterial blood is obtained while the patient is breathing supplemental O_2.[4] However, supplemental inhaled O_2 does not, by itself, correct the causes of early PO hypoxemia. When the O_2 is removed, the Pa_{O_2} on room air usually falls to pretreatment levels.[6]

The level of the hypoxemia may be most

critical during the first 5 to 6 hours after anesthesia.[4] If recovery-room patients are transferred to their ward beds within 1 to 2 hours after anesthesia without supplemental O_2, they may become hypoxemic.

Pain on sighing or deep breathing may reduce pulmonary compliance and functional residual capacity associated with the hypoxemia.[7,8] Narcotic analgesia plus the respiratory stimulant effect of doxapram has been used for reversal;[9] however, this combination is not always successful, and pain due to incomplete narcotic analgesia may restrict the respiratory response to doxapram. Segmental peridural analgesia provides excellent pain relief but does not, by itself, correct the hypoxemia.[3,5]

METHODS

Twenty unpremedicated men undergoing upper abdominal operations were studied for 5 hours in the recovery room. They were divided into 2 groups, each consisting of 10 patients who randomly received either (1) peridural or (2) morphine analgesia with doxapram hyperinflation. Informed consent was obtained from all subjects. Patients were accepted for study if they were not hypoxemic, had normal chest x-rays, no uncontrolled systemic disease, and no history of vascular hypertension, seizures, or cerebrovascular accidents.

Preoperatively, a Teflon catheter was inserted into a radial artery for blood sampling. All patients received general anesthesia with halothane (0.5 to 1.5%) and N_2O-O_2 (60:40). Pancuronium was used for muscle relaxation. Ventilation was maintained with a bird® Mark IV anesthesia ventilator. Following endotracheal intubation, patients in the peridural group had a catheter inserted at T10-11 but without injection of local anesthetic solution. Patients in the morphine group were not so catheterized.

Postoperative peridural analgesia was obtained in the operating room by injecting 6 to 8 ml of 0.5 percent bupivacaine, which produced segmental analgesia localized to the area of surgical incision. Analgesia was maintained by intermittent peridural reinjection and was not supplemented by other forms of pain relief. Dermatome levels of analgesia were evaluated by pinprick.

In the morphine group, morphine was administered in IM doses of 10 to 15 mg, depending on patient size and age, at intervals calculated to keep the patient comfortable but not obtunded (3 to 5 hr).

No attempt was made to evaluate directly the magnitude of pain experienced by any individual patient or any group of patients. The following variables were measured both preoperatively and postoperatively: rectal temperature, Pa_{O_2}, Pa_{CO_2}, respiratory rate, exhaled minute ventilation ($\dot{V}_E$), tidal volume (V_T), blood pressure (BP), and pulse.

Doxapram intermittent hyperinflation was started in the recovery room 1 hour postoperatively and followed baseline resting values. The IV doxapram injection was then repeated hourly for 4 hours. Doxapram dosage was individualized (0.5 to 2 mg/kg) to obtain a V_T increase of 2 to 3 times resting values. All patients received 0.5 mg/kg for the first or test dose. All doxapram infusions were diluted with 1 N saline solution to a final volume of 8 ml, which was injected into the IV tubing over a 60-second period. Further IV dosage was determined by the response to the test dose.

Supplemental O_2 was provided for 5 minutes before, during, and 10 minutes after doxapram hyperinflation, to prevent O_2 debt due to increased physical activity. The O_2 was supplied via anesthesia mask, Hans Rudolph nonrebreathing valve, and a Puritan humidifier, set to deliver 40 percent O_2. $\dot{V}_E$ was monitored during doxapram hyperinflation by attaching a Wright respirometer to the exhalation port of the Hans Rudolph valve. Respiratory rate was counted by visual observation of chest movement, and V_T was calculated by dividing $\dot{V}_E$ by respiratory rate for 1 minute. Pulse and BP were obtained 5 minutes after the doxapram injection, as this is reportedly the time of peak cardiovascular changes due to doxapram.[9]

Arterial blood-gas and pH samples were obtained before anesthesia induction in the operating room and 30 minutes postoperatively in the recovery room, and again 50 minutes after doxapram and O_2 therapy, hourly for 5 hours. In all cases, samples were obtained with the patient continuously breathing room air (F_{IO_2} = 0.21) for at least 30 minutes.

Rectal temperature was obtained before drawing blood samples. Arterial blood-gas analysis was completed with an Instrumentation Laboratories 113 blood gas analyzer, with appropriate corrections for body temperature. Preoperative and 30-minute PO measurements were used as control values.

Single values for 1 to 4-hour PO data

TABLE 1
Patient Data and Significant Measurements at 30 Minutes to 5 Hours PO (Means ± SD)

	Age, yr	Weight, kg	Height, cm	Maximum doxapram injection, mg	Rectal temperature 30 min PO, C	Rectal temperature 5 hours PO, C	△ temperature 30 min to 5 hr PO, C

(n =10)	±13.9	±9.7	±7	±14.9	±0.66	±0.32	±0.43
II. Peridural group	44.3	71.8	176	75.0	36	37.8	1.8*
(n =10)	±11.3	±15.4	±10	±15.8	±0.55	±0.6	±0.82

*Significant change, $p<0.001$, for designated time periods within a single group.

were obtained by finding the mean for results for PO hours 1, 2, 3, and 4. Also, single values for 2 to 5-hour data (Pao_2, $Paco_2$, rectal temperature) represent the mean for PO hours 2, 3, 4, and 5. Significance was determined by Student's *t*-test for paired data.

RESULTS

No significant difference was noted between mean values for the morphine and peridural groups for age, weight, height, doxapram dosage, or body temperature (table 1). However, a significant ($p<0.001$) change in mean values for rectal temperature was noted within both groups. All patients revealed a relative hypothermia in 30-minute PO rectal temperature compared with their 2 to 5-hour values.

No significant difference was found in BP and pulse mean values between the 2 groups (table 2). However, a significant change ($p<0.005$) was noted within the morphine group for both these values after doxapram injection.

No significant difference in respiratory rate, $\dot{V}_E$, or V_T between groups was found (table 3). However, doxapram did produce a significant rise in respiratory rate in the morphine group ($p<0.01$) and a similar increase in $\dot{V}_E$ and V_T for both groups ($p<0.001$). The mean increase from control for the morphine group was 9.6 ± 4.9 L/min for $\dot{V}_E$ and 356 ± 213 ml/breath for V_T. For the peridural group, the mean increase was 14.4 ± 4.7 L/min for $\dot{V}_E$ and 660 ± 276 ml/breath for V_T.

A significant decrease in mean Pao_2 was noted between preoperative and postoperative values in the morphine group (77.3 versus 66 torr; $p<0.005$) (table 4). This drop in Pao_2 is characteristic of the hypoxemia under study. A significant difference was also noted (1.1 versus −7.1 torr; $p<0.01$) between the peridural and morphine groups. The lack of change between mean preoperative and postoperative values for Pao_2 for the peridural group (77 versus 78 torr) would indicate that, under the conditions of this study, the hypoxemia was reversed by the combination of peridural analgesia with doxapram. Figure graphically represents these changes.

The doxapram as used in this study produced a respiratory response within 40 to

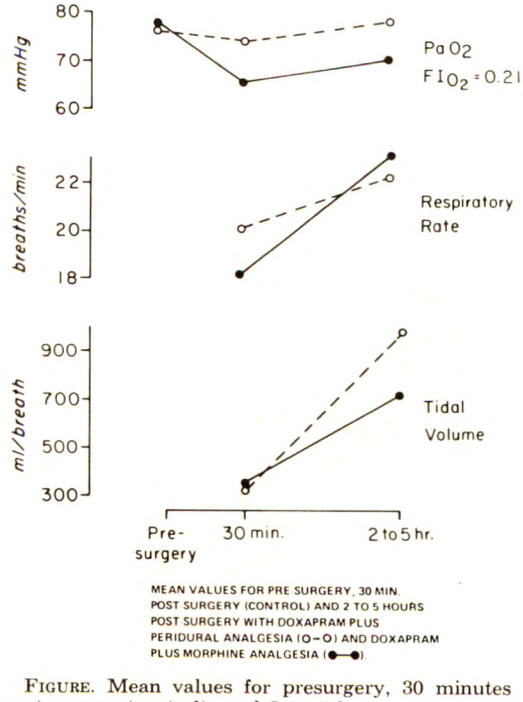

FIGURE. Mean values for presurgery, 30 minutes postsurgery (control), and 2 to 5 hours postsurgery with doxapram plus peridural analgesia (0-0) and doxapram plus morphine analgesia (0--0).

*Significant changes, $p<0.005$, for designated time periods within a single group.

60 seconds from beginning of injection, developed a maximum response at ± 1 minute after injection, and the effect disappeared 2 to 3 minutes after the onset of respiratory stimulation. A mean doxapram dose of ± 1 mg/kg body weight (table 1) was required to obtain an increase in V_T of 2 or 3 times the resting value (table 3). In the morphine group, 4/10 patients and in the peridural group 1/10 patients did not achieve the desired V_T increase. The dosage of doxapram was often decreased in the morphine group patients to reduce the pain associated with increased respiratory effort. No major adverse reaction due to doxapram was noted in either group.

DISCUSSION

Aldrete[4] reported the incidence of PO hypoxemia to be about 75 percent. The risk of serious hypoxemia is increased by advanced age, obesity, multiple system disease, trauma, advanced chronic lung disease, upper abdominal or thoracic operations, and/or prolonged shivering in the recovery room.[4] Tissue hypoxia resulting from hypoxemia can result in serious complications, such as metabolic acidosis, cardiac arrhythmias, vascular hypotension, and respiratory insufficiency.[4]

Schmidt and colleagues[10] found 9 cm of continuous positive airway pressure (CPAP) for 24 hours by nasal intubation and spontaneous ventilation useful in preventing hypoxemia in high-risk patients. Arterial blood-gas tensions were improved, and none of the CPAP patients developed PO respiratory insufficiency. This method, however, involves the risk of complications inherent in nasal intubation, CPAP, and increased levels of narcotic analgesia.

The Pain Factor.—Breathing with a V_T of 700 to 1000 ml/breath at a rate of 20 to 25/min within 1 or 2 hours after upper abdominal incision may induce considerable reflex pain. Conventional morphine analgesia does not completely abolish the pain associated with such rapid deep breathing. Segmental peridural analgesia abolishes the somatic and some, but not all, of the visceral pain.

Some of the patients in our peridural analgesia group complained of vague deep abdominal discomfort and/or shoulder pain when deep breathing. This discomfort may have represented an incomplete block of deep visceral or phrenic nerve reflexes. The

degree to which pain restricted deep breathing in our study is best estimated by the $\dot{V}_E$ response to doxapram under standardized conditions ($\dot{V}_E$ = 16 L/min for the morphine group versus 20.9 L/min for the peridural group) of factors other than analgesia which might influence hypoxemia (sex, age, weight, height, preoperative Pao_2, intraoperative anesthesia, abdominal incision, hypothermia, and IV doxapram dosage).

The hypoxemia noted in our morphine group (16% drop in Pao_2 between preoperative and 30 minutes postoperatively) is close to the changes in Pao_2 under similar conditions reported by Winnie,[9] Aldrete,[4] and Spence.[3] This early decrease in arterial blood oxygenation was also found with peridural analgesia without doxapram for patients with upper abdominal incisions.[3,5]

We noted that a 1 mg/kg injection of doxapram administered to the morphine group patient resulted in a V_T less than that achieved with the same dose in a patient given a peridural block (table 3). The morphine group patients also complained of pain more often than the peridural-block patients. We assumed that the reduced V_T resulted from increased abdominal pain. However, Mitchell and Herbert[11] showed in cats that respiratory stimulation by doxapram in the recommended therapeutic dosage range (0.5 to 2 mg/kg) is through stimulation of the carotid chemoreceptors. Ventilation response to respiratory stimulation can be reduced by a morphine-associated shift in the CO_2 response curve.[12] Therefore, the carotid chemoreceptor response to doxapram stimulation may also be reduced by morphine. Morphine analgesia alone, or combined with pain, may account for the reduction in V_T noted with doxapram in our morphine group.

*Significant change, $p<0.005$, for designated time periods within a single group.

†Significant difference, $p<0.01$, between values for groups.

Peridural analgesia in our study usually extended from T-6 down to T-12. This block with 0.5 percent bupivacaine produced satisfactory analgesia with minimal intercostal muscle paralysis. Rib movement during doxapram hyperinflation appeared normal clinically and $\dot{V}_E$ under these conditions compares closely with reported responses to doxapram in adult males without an operation or analgesia (peridural $\dot{V}_E = 20.9$ L/min, no anesthesia $\dot{V}_E$ = 14.7 L/min.)[13]

Winnie and associates[9] studied the effect of doxapram lung hyperinflation on hypoxemia in patients who had upper abdominal incisions and morphine analgesia. They gave doxapram as an IV bolus of 1 mg/kg at PO times 0, 1, and 4 hours and then every 4 hours for a total of 8 injections (24 hours). The respiratory response to doxapram they reported (change in respiratory rate = 5.5/min, $\triangle V_T$ = 314 ml, $\triangle \dot{V}_E$ = 14.3 L) is close to our morphine group values (table 3). Patients given doxapram demonstrated a return of Pao_2 values to preoperative levels 20 hours postoperatively. It must be noted, however, that their doxapram infusions were at 4-hour intervals rather than our 1-hour intervals.

Aldrete[4] studied over a one-hour period the effect of 1 mg/kg bolus of doxapram IV on patients with PO hypoxemia given morphine, reporting no improvement in PO arterial oxygenation for their doxapram group.

In our study, the sympathetic nervous system blockade accompanying peridural analgesia may account for the reduced cardiovascular response to doxapram noted in the peridural-block patients (table 2). The definite increase in blood pressure and pulse associated with doxapram therapy in the morphine group (△ BP = 24/13, △ pulse = 21) was almost completely abolished by the sympathetic blockade in the peridural group (△ BP = 3/1, △ pulse = 10).

Local Anesthetic Agents—Pharmacologic Basis for Use in Obstetrics: A Review

LARRY SALTS, MD*
MARYANN OTT, MS†
PHILIP D. WALSON, MD‡
Tucson, Arizona§

Because of minimal effects on mother and fetus, regional anesthetic technics are widely employed for labor and delivery. However, the literature describes at least 35 fetal and neonatal deaths and a frightening incidence of fetal distress associated with paracervical block for 1st-stage labor. Continuous lumbar epidural anesthesia for 1st-stage labor has also been associated with fetal distress, but this is minimal and no deaths have been reported. Bupivacaine, a relatively new, long-lasting local anesthetic, is extremely toxic when administered paracervically, but no deaths have been reported with its use for epidural anesthesia. While choice of method and agent must be individualized, continuous lumbar epidural block with bupivacaine appears as effective as and less often dangerous to the fetus than paracervical block.

PAIN during childbirth may be controlled by hypnosis, general anesthesia, systemic narcotic administration, and numerous local anesthetic procedures. Local anesthetics reversibly terminate nerve conduction; therefore, pain impulses originating in specific body regions may be abolished selectively while the patient retains consciousness. There is a popular belief that obstetric block with local anesthetics is safer for the fetus than use of potent general anesthetics. However, local anesthetics are rapidly absorbed into the maternal circulation and subsequently presented to the placenta.

Since Bromage and Robson[1] first reported placental transmission of a local anesthetic agent in 1961, many studies have established that these agents can cause severe fetal toxicity and that fetal or neonatal death can result.

This review focuses on the types of block and the local anesthetic agents most commonly used for the relief of 1st-stage labor pain. Before the drug-block combination with the best risk:benefit ratio can be selected, the pharmacokinetic aspects of the drugs that determine fetal toxicity must be understood, as must the relationships between technics, drugs, and their neuroanatomic rationale and potential risks. Basic also is an understanding of the separate neuroanatomic pain pathways of the different stages of labor.

I. LOCAL ANESTHETIC AGENTS

Characteristics.—In general, local anesthetics consist of 3 parts: (1) a lipophilic aromatic group, (2) a tertiary or secondary amine group, and (3) an ester or amide linkage. The class of local anesthetic agent

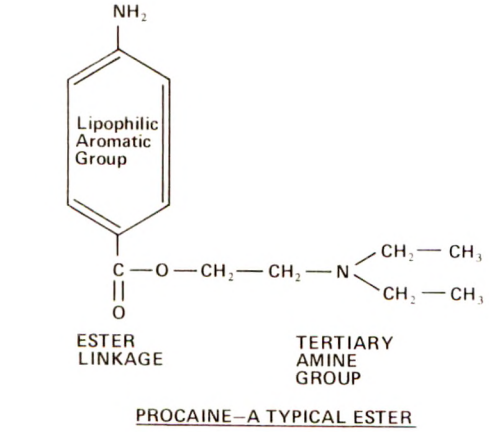
TABLE 1
General Characteristics of the Major Local Anesthetic Drugs

Local anesthetic	Concentration, percent	pKa	Duration of action, hr	Maximum dosage, mg	Adult toxic blood level, μg/ml	Placental transfer
Amide						
Lidocaine	1.0-1.5	7.9	1¼-3	500	5	Yes
Mepivacaine	1.0-1.5	7.6	1½-2½	500	6	Yes
Bupivacaine	0.24-0.50	8.1	3¼-7	200-500	4	Yes
Ester						
Procaine	1.0-2.0	8.9	¾-1½	1000	ND*	Yes
2-chloroprocaine	2.0	8.9	¾-1	1000	ND	Probably
Tetracaine	0.15-0.25	8.5	3½-6	200	ND	Probably

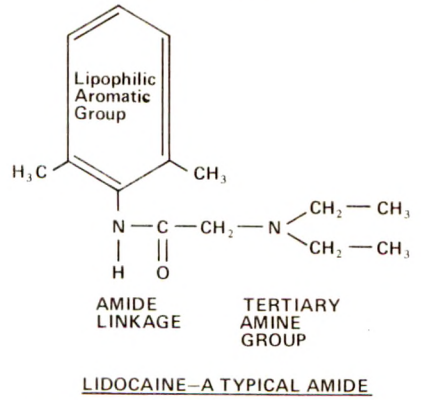
*ND = no data.

is determined by the linkage. Table 1 illustrates the general characteristics of the better known agents of the two classes.

Values for duration of action in table 1 apply to peripheral nerve blocks in general.



PROCAINE–A TYPICAL ESTER



LIDOCAINE–A TYPICAL AMIDE

FIG 1. Chemical characteristics of the two classes of local anesthetics.

Longer values are obtained when epinephrine is added to the anesthetic solution.[2] Studies of the duration of paracervical blocks show a different pattern. Freeman's group[3] found that paracervical blocks lasted about 1½ hours with all the agents employed in their study (procaine, tetracaine, cyclaine, nupercaine, and lidocaine) as long as the solution contained epinephrine. While cyclaine is an ester and nupercaine is an amide, both are very toxic. Paracervical block with 1 percent mepivacaine was found to give a mean duration of action of 1¼ hours in 1 series.[4] Other observers reported that 0.25 percent bupivacaine paracervical block lasted a mean of slightly less than 1½ hours, but 2⅔ hours with epinephrine.[5] Gudgeon[6] reported that paracervical block with 0.25 percent bupivacaine lasted a mean of 3 hours.

Despite these studies, one of the amides is usually chosen because this class is generally believed to provide a longer duration of action than the esters. Amides are preferred because labor usually lasts between 3 to 6 hours after the first paracervical block.[4] Paradoxically, however, paracervical block with epinephrine containing ester-linked local anesthetics can last as long as paracervical block with most of the amide-type agents.[3]

Metabolism.—An advantage of the esters is that systemic absorption does not result in high fetal levels because these agents are rapidly hydrolyzed by maternal plasma cholinesterases.[7] The amides must be metabolized in the liver; thus higher concentrations of amides are available to enter the fetal circulation. Therefore, amides may well be more toxic to the fetus and/or the mother than an equipotent dose of an ester.

Although these concepts about the metabolism of local anesthetics are true in general, details of the metabolism of the amide-linked local anesthetic agents in human fetuses and neonates have become available only recently. Studies by the Weiss group[8] and by Yaffe and coworkers[9] indicate that the human neonate is deficient in some drug-metabolizing enzymes, such as those required for hydroxylated metabolites of mepivacaine. Meffin and colleagues[10] reported that the ratios of N-demethylated, 3-hydroxy and 4-hydroxy metabolites to unchanged mepivacaine are lower in the neonate than in the adult. However, decreased neonatal metabolism may be protective in that the demethylated or de-ethylated amide metabolites appear to be more toxic than the parent compound.

Excretion. — Meffin showed that both adults and neonates excrete anilide local anesthetics almost entirely via the kidneys, but the adult excretes less than 5 percent of a dose as unchanged mepivacaine, and the neonatal kidney can clear the unchanged drug.[10]

Ostheimer's group[11] have shown that the neonate is able to N-de-ethylate bupivacaine to 2,6 pipecoloxylidide (PPX). Although the mothers excreted both bupivacaine and PPX in the urine, neonates rarely eliminated unchanged bupivacaine but all infants excreted PPX, beginning at about 12 hours and ending by 48 hours.

Placental Transfer. — Local anesthetics used for obstetric anesthesia are transferred across the human placenta to the fetus (Shnider and Way[12]). Placental transfer of these agents occurs by simple diffusion. The major drug factors contributing to this transfer are lipid solubility, ionization constant, size or molecular weight, protein binding, acid-base status of the patient, and electrochemical gradient.[7,13,14]

Maternal Toxicity.—Regardless of metabolic pathways, all local anesthetics are associated with some toxicity. Most of the available data on human toxicity have come from reports of the clinical use of these agents for delivery.

Foldes and associates,[15] studying the toxicity of lidocaine and 3 ester-linked local anesthetics in 12 adult male volunteers, described "generalized twitchings, convulsions, severe breathing difficulties, loss of consciousness, or total disorientation." The esters studied by this group were procaine, 2-chloroprocaine, and tetracaine. Generalized convulsions developed in 1 volunteer given tetracaine at 0.125 mg/kg/min IV. Three of 10 patients tolerated the procaine infusion (1 mg/kg/min) for 25 minutes. None of the 10 volunteers given a lidocaine infusion (0.5 mg/kg/min) tolerated this drug for more than 18 minutes. Because of pseudocholinesterase activity, plasma levels of procaine and 2-chloroprocaine were too low to be determined at the end of the experiments. Therefore, while the esters appeared less toxic than the amide, lidocaine, in these adult volunteers, the ester-linked agents obviously also have some toxic effects.

Lidocaine, mepivacaine, and bupivacaine were studied by Jorfeldt and colleagues[16] in dogs and man. Lidocaine and mepivacaine induced the same subjective symptoms as those observed by Foldes in volunteers. Bupivacaine produced no objective signs of toxicity other than slight eyelid numbness. Again, lidocaine convulsions were induced in 1 volunteer at a plasma concentration of 5 μg/ml. Jorfeldt's data suggest that generalized convulsions may be elicited when plasma concentrations reach 6 μg/ml of mepivacaine and 4 μg/ml of bupivacaine.

Despite the fact that these adult toxicity studies were conducted with intravenously infused local anesthetics, the data are pertinent because all drugs are systemically absorbed, regardless of the site of injection or the intended site of action. After absorption into the maternal blood stream, local anesthetics are subject to the pharmacokinetic factors which normally affect drug action and are subsequently presented to the placenta.

Fetal Toxicity.—Signs of fetal toxicity develop at plasma concentrations of the local anesthetics well below those plasma levels which are tolerated by adults. Fetal and neonatal toxicity is manifested by tachycardia, bradycardia, acidosis, apnea, convulsions, and death. Heyman[17] has correlated tachycardia with in-utero convulsions in experimental animals. Since the toxic reactions of the fetal myocardium and central nervous system appear to be a result of direct local anesthetic action,[17] O_2 and atropine will not reverse these effects.[18]

Shnider and Way[12] reported that within 3 to 5 minutes of detection of lidocaine in the maternal arterial circulation, the drug was transferred across the placenta to the fetus. Umbilical venous concentration of lidocaine was 53 percent of that simultaneously found in the maternal artery. At a low

physiologic concentration (2 μg/ml), practically all the lidocaine is plasma-protein bound. At higher concentrations, 30 percent is unbound. This concentration-dependent binding of lidocaine explains the large transplacental concentration gradient at high plasma concentrations of the drug.[19]

Morishima's group[20] reported the ratio of the mepivacaine concentration in the umbilical vein to the maternal antecubital vein concentration as 0.71/1 at 60 minutes after epidural anesthesia. Martin and coworkers[21] reported a ratio of 0.54 at 60 minutes after paracervical block.

The placental transfer of bupivacaine follows closely the pattern reported for lidocaine.[22] The ratio of umbilical to maternal plasma concentration at delivery varies from 0.14 to 0.86. There does not appear to be an obvious explanation for the wide patient-to-patient variation in placental transfer of either bupivacaine or lidocaine, but bupivacaine values for placental transfer are lower than those for mepivacaine or lidocaine.

Probably the most commonly observed toxic effects of local anesthetics on the fetus are bradycardia and acidosis. The cause of fetal bradycardia is subject to some controversy. Teramo and Widholm[23] suggested that the local anesthetics depress the fetal myocardium and CNS directly. On the other hand, Jung's group[24] contended that the changes are due to a disturbance in placental and umbilical blood flow. Most of the investigators seem to agree that the bradycardia represents the pharmacologic effect of the local anesthetic on the fetus, and it is possible that both mechanisms are responsible.

Infants with lidocaine levels greater than 3 μg/ml show a pattern of depression similar to that seen with mepivacaine.[12] Shnider also notes that the toxic threshold (depressed ventilation and abolished cutaneous reflexes) in the neonate is half that of the adult. The additive effects of birth asphyxia, drug depression, and a lower blood/brain barrier to the drug in the infant is a possible explanation. An inverse relationship between arterial P_{CO_2} and the threshold for lidocaine toxicity in experimental animals has also been demonstrated.[25]

II. REGIONAL BLOCK IN OBSTETRICS

Pain Pathways.—The pain of the 1st stage of labor originates from both the corpus and cervix of the uterus. The major sensory component is the sympathetic nervous system. The sympathetic fibers from the corpus uteri originate in the posterior cervical ganglia and the pelvic plexus and ganglia before eventually entering the spinal cord with the posterior roots of T-11 and T-12. Higher cord levels may be encountered in a few patients who receive alternate afferent pathways along the ovarian vessels.[26]

With the beginning of the 2nd stage of labor at full cervical dilation, the descent of the fetus causes the painful impulses to shift from the uterus to the distending vagina, perineum, and vulva. Since the mons pubis and the anterior portions of the labia majora are stimulated minimally during routine deliveries, 2nd-stage labor pain can be controlled satisfactorily by blocking the pudendal nerves or the first 3 sacral cord segments.

Types of Block.—Of the numerous regional technics used for 1st-stage labor pains, paracervical block is specific, in that it blocks only the pelvic (inferior hypogastric) ganglia and plexus. Continuous lumbar epidural anesthesia not only can block spinal cord segments T-11 and T-12 for 1st-stage labor pains, but the injection of more local anesthetic solution can extend the block to include the sacral segments for 2nd-stage labor pains. Therefore, lumbar epidural block is the preferred technic of many obstetric anesthesiologists.[26,27] Because of intense pain, it is common practice to initiate an analgesic technic during the 1st stage of labor. Because this stage may last up to 8 hours, analgesia must often be continued for many hours, with increased risk of fetal toxicity.

Paracervical block and continuous lumbar epidural block are the most commonly employed technics for 1st-stage labor pain.[26-30]

III. CLINICAL USE OF REGIONAL BLOCK

Paracervical Block. — Paracervical block with any agent is of potential danger to the fetus (table 2). The signs of fetal toxicity occur at a significant rate after block. Many studies have described the risk of fetal toxicity with this technic.

Paracervical Lidocaine. — Nyirjesy and colleagues[29] reported an incidence of 22 percent (15/68 cases) of fetal bradycardia after paracervical block with lidocaine. One fetal death occurred with a toxemic primagravida. Three minutes after the block, the

TABLE 2

*ND = no data.

fetal heart tones disappeared. A stillbirth occurred 12 minutes after the application of the paracervical anesthetic.

Shnider and Gildea[31] describe bradycardia after paracervical blocks with prilocaine, lidocaine, or mepivacaine. In the fetuses with no signs of distress before anesthesia, there was an 18.1, 19.3, and 8.4 percent incidence of bradycardia after paracervical block with lidocaine, mepivacaine, and prilocaine, respectively. When there had been fetal distress prior to the paracervical block, bradycardia developed in 60 percent of the lidocaine, 44.7 percent of the mepivacaine, and 35.9 percent of the prilocaine blocks.

Paracervical Mepivacaine.—Freeman[3] reported a 26.1 percent incidence (24/92 cases) of fetal bradycardia following paracervical block with 200 mg of mepivacaine. Six of the 24 fetuses that developed bradycardia experienced the distress longer than 10 minutes and developed metabolic acidosis. The mean pH fell from 7.3 to 7.18 before returning slowly toward, but not reaching, baseline by 45 minutes. No deaths occurred in this series.

In a study[32] of the effects of mepivacaine paracervical blocks on 12 fetuses, 6 had bradycardia and a decrease of pH. Bradycardia did not develop in the fetuses whose mothers received a total of 200 mg of mepivacaine, but 1 fetus developed a pH decrease of 0.07 units. Five of the mothers received a 400 mg mepivacaine paracervical block, and the sixth received 300 mg. The fetal plasma concentration reached 8.3 μg/ml in the mother who received only 300 mg. The mean plasma concentration of the 6 fetuses with bradycardia was 3.07 (range 0.5 to 8.3) μg/ml. Those without distress had a lower mean plasma concentration (1.52 μg/ml), but the plasma concentration range (0.4 to 2.5 μg/ml) overlapped the values reported in the toxic group.

Rosefsky and Petersiel[18] reported 2 fetal deaths after paracervical blocks with 300 mg and 240 mg of mepivacaine. Six minutes after the 300 mg block, fetal heart rate decreased from 136 to 80. Eighty minutes later, fetal heart tones were lost. Ten minutes after the 240 mg block, fetal bradycardia of 80 bpm developed. At birth, the infant was flaccid; at 3 hours, the neonate developed opisthotonus; at 20 hours, seizures were present; and, at 45 hours, the infant died. Mepivacaine levels in the urine were 6.2 μg/ml at 36 hours and 0.75 μg/ml at death.

A recent report[33] describes 3 infants who manifested severe toxicity after maternal paracervical blocks with mepivacaine, 2 surviving with permanent neurologic damage following protracted convulsions and hypotonia. The third died after 7 days of life.

We reviewed the records of 23 parturients given mepivacaine block at our institution. The anesthetic technics included paracervical blocks, pudendal blocks, local infiltration, and 1 lumbar epidural block. There were detectable mepivacaine levels in the umbilical vein samples from 9 patients (39.1%). The cord mepivacaine levels were less than 1 μg/ml in 7 cases (30.4%). Five cases (21.7%) had mepivacaine levels ranging from 1 to 1.7 μg/ml. Three cases (13.4%) had toxic umbilical cord mepivacaine concentrations ranging from 2.5 to 9 μg/ml. The infant with a mepivacaine level of 2.5 μg/ml had been delivered under a paracervical followed 35 minutes later by a pudendal nerve block. The infant with 5 μg/ml of mepivacaine in the cord blood had been delivered with 2 paracervical blocks. The mother of the infant with an umbilical vein mepivacaine concentration of 9 μg/ml had received only a pudendal nerve block. The one recorded episode of bradycardia occurred after a paracervical block had been administered, but the cord mepivacaine level was only 1 μg/ml at birth. All 23 infants survived.

Paracervical Bupivacaine.—Baskett and Carson[5] observed bradycardia in only 3/95 cases after paracervical block. Two cases followed 50 mg of bupivacaine (the third occurred with 200 mg of lidocaine). Fetal heart tones were checked only at 15-minute intervals, which may explain the low incidence of bradycardia in this series.

Teramo[34] reported that 13/38 bupivacaine paracervical block cases developed fetal bradycardia of a moderate degree (100 to 118 bpm) and that 8 cases developed severe bradycardia (<100 bpm). The mean pH of the fetuses 2 minutes before the block was 7.351. After the block, the mean pH fell progressively 0.049 units at 15 minutes. By 40 minutes the pH value had returned toward the initial value but was still down 0.028 units. Also, there was a direct correlation between severity of bradycardia and the intensity of acidosis.

Paracervical block with bupivacaine has been associated with significant mortality. Whitehouse[35] reported on 25 cases of paracervical block with 0.5 percent bupivacaine

containing epinephrine 1:200,000. In 3 cases, 30 to 45 minutes after the paracervical blocks with 10 ml of the bupivacaine-epinephrine solution, significant bradycardia occurred. In 1 of these cases, fetal heart tones were lost, and a stillbirth was delivered 8 hours later. Other authors[36] reported that "several cases of extreme foetal bradycardia were seen following the injection of 2 x 10 ml of 0.5% bupivacaine into the paracervical space. . . ." One of these cases terminated in an intrauterine death within 20 minutes of the paracervical block.

In a retrospective study[37] of 32,652 cases of paracervical block from 107 German maternity units, bupivacaine was found to have been used in 19,907 cases. In 7887 cases, mepivacaine alone or in combination with bupivacaine was used. Fetal deaths occurred in 30 paracervical blocks with 20 ml of 0.5 percent bupivacaine, and 1 death was seen after 20 ml of 0.25 percent bupivacaine. One mortality followed in the 7887 cases of local anesthetic mixture, but other factors may have been responsible.

Epidural Lidocaine. — No deaths have been reported in any of the epidural lumbar series studied (table 3). Shnider[12] reported fetal toxicity from lidocaine, whether injected by the epidural, paracervical, pudendal, or caudal route. In a series of 57 patients, 3 groups were established. One group of 7 patients received single-dose caudal or lumbar epidural anesthesia. A second group of 27 patients had continuous caudal or lumbar epidural anesthesia. The other 23 patients had multiple-dose paracervical and pudendal blocks. The average lidocaine doses in these groups were 3 to 4.8 mg/kg, 8.19 mg/kg, and 5.6 mg/kg, respectively. Although the fetal toxicity was not given for each type of anesthesia, it was established that only 1 infant had a low Apgar score when the umbilical vein lidocaine concentration was <2.5 μg/ml. On the other hand, 4/8 infants had low 1-minute Apgar scores when the lidocaine concentration was >2.5 μg/ml. Two of these depressed infants had lidocaine levels of >3 μg/ml. No deaths were reported in this series.

Neonatal depression after maternal lumbar epidural anesthesia with lidocaine and mepivacaine has been described.[38] Of 32 infants in this series, 3, whose mothers had endured labor of 6, 9, and 9 hours, had 5-minute Apgar scores of 5 or less, requiring extensive resuscitation. The epidural anesthetics had required 625 mg of lidocaine, 975 mg of mepivacaine, and 950 mg

TALBE 3
Continuous Lumbar Epidural Block

Author	Cases	Drug	Dose/length of labor	Maternal, μg/ml	Fetus, μg/ml	Apgar	Bradycardia

No deaths reported in these series.

of mepivacaine, respectively. Although the plasma concentration of mepivacaine in the mothers or depressed infants was not reported separately, the average maternal concentration from all mepivacaine epidural cases was 2.2 μg/ml, and the mean concentration of mepivacaine from all infants was 1.6 μg/ml. The dose range of administered lidocaine was 135 to 930 mg. The plasma concentrations were almost identical to those of the mepivacaine group. The maternal mean lidocaine concentration was 2.2 μg/ml and the neonatal plasma concentration was 1.55 μg/ml. Despite the low neonatal plasma concentrations, epidural anesthesia with either lidocaine or mepivacaine produced fetal toxicity.

Epidural Mepivacaine.—In a study of fetal depression caused by mepivacaine lumbar or caudal epidural anesthesia in 56 mothers,[20] 5 infants of 19 patients who received lumbar epidural anesthetics were depressed at birth, with Apgar scores of 6 or less (compared to 7/37 after caudal). These 5 infants were delivered after continuous anesthesia where mepivacaine dosage ranged from 4.4 to 9.4 mg/kg. The mepivacaine levels in the maternal blood ranged from 2.37 to 7.47 μg/ml. Fetal umbilical vein levels measured 1.65 to 3.81 μg/ml. The Apgar scores of these infants were 1, 2, 3, 6, and 6. The mother of the Apgar-1 infant had experienced mepivacaine toxicity with apprehension, nausea, and vomiting; her mepivacaine-blood concentration was 7.47 μg/ml, and the umbilical vein concentration was 3.81 μg/ml. There were no fetal or maternal complications in 1 of the 2 infants with an Apgar score of 6. The low Apgar scores of the other 3 infants resulted from either fetal or maternal complications not related to the anesthetic agent.

Although local anesthetics are not thought to show a substantial depression in concentrations below the toxic levels discussed above, neurologic and behavioral tests do show consistent changes in the babies born after epidural block. Standardized neonatal neurologic tests[39] have shown that babies born after epidural block have decreased muscular strength and tone during the first 8 hours of life. It has been suggested[40] that long-term investigations are needed to explore implications of these findings, for neonatal adjustment and maternal-neonatal relationships.

Although no direct comparisons can be made from the literature, the reported incidence of fetal toxicity after lidocaine or mepivacaine epidural anesthesia does not appear to offer any significant advantage over the toxicity associated with paracervical blocks with these agents. However, neonatal deaths appear to be uncommon after epidural anesthesia with either. The literature concerning bupivacaine appears to differ significantly.

Epidural Bupivacaine.—Continuous epidural anesthesia with bupivacaine has not been reported to be associated with maternal, fetal, or neonatal toxicity. In a description of 12 cases of bupivacaine epidurals,[22] the longest labor was 8¼ hours. Maternal plasma levels ranged from 0.22 to 0.61 μg/ml and umbilical venous plasma levels ranged from 0.25 to 0.94 μg/ml at birth. No maternal or fetal toxicity was observed, which is consistent with Jorfeldt's projected toxic bupivacaine levels (4 μg/ml for adults and 2 to 2.5 μg/ml for infants).[16]

In a study of maternal plasma concentrations after continuous lumbar epidural anesthesia in 18 parturients,[41] the maximal maternal plasma concentrations with 0.5 percent bupivacaine averaged 0.744 (range 0.45 to 1.33) μg/ml. The maximal mean level with 0.5 percent bupivacaine containing epinephrine 1:200,000 was 0.555 (range 0.388 to 0.908) μg/ml. Umbilical-vein concentrations were 0.037 to 0.343 (mean 0.161) μg/ml for 0.5 percent bupivacaine and 0.092 to 0.337 (mean 0.18) μg/ml for 0.5 percent bupivacaine with epinephrine 1:200,000, epinephrine lowering the maximal maternal plasma concentration but slightly increasing neonatal blood concentration. No toxicity was observed in this study, neither the maternal nor the fetal plasma bupivacaine levels approaching the projected toxic levels.

Thomas' 12 cases[22] and Reynolds' 18 cases[41] represent small series. Crawford,[42] however, reported on 1000 cases, in which all complications were attributed either to the procedure (inadvertent subarachnoid taps, etc) or to the block but none to bupivacaine toxicity. Although he did not specifically comment upon fetal or neonatal depression, apparently no neonatal deaths occurred in this series.

CONCLUSIONS

The longer duration of action and lower effective total dose of bupivacaine appear to make this agent the amide of choice for continuous lumbar epidural anesthesia. Paracervical block is a hazardous technic; if

it must be used, careful attention must be paid to total dose of the drug, avoidance of intravascular injection, and evidence of fetal distress prior to block. Placental insufficiency and prematurity are absolute contraindications to paracervical block, according to Shnider.[43]

Although bupivacaine does not appear to offer any advantage over the other amide agents for paracervical block, the ester class of local anesthetics appear to offer definite advantages in terms of blood levels achieved and toxic manifestations. Local block with the ester anesthetics is reportedly effective for at least 1¼ hours; therefore, these anesthetics would appear to be the agents of choice within 1 hour of delivery for any block. The relative safety and efficacy of the ester versus amide anesthetics should be carefully considered whenever a choice between paracervical, pudendal and local block is to be made. In addition, the relative efficacy and toxicity of bupivacaine for continuous epidural blocks should continue to be studied.

Obstetric Anesthesia Training Centers in the U.S.A.—1975

JAMES S. HICKS, MD*
GERSHON LEVINSON, MD†
SOL M. SHNIDER, MD‡
San Francisco, California§

The current status of obstetric anesthesia training in the United States is reviewed. The 39 anesthesia residency training programs having full time chiefs of obstetric anesthesia were surveyed regarding clinical practice, physical facilities, teaching and research. This paper reports the results and compares them to recommendations of JCAH, ACOG and ASA, concerning standards of patient care and resident teaching.

THE training of personnel to provide obstetric anesthesia and the provision of this care to patients are continuing problems. Of the 171 approved anesthesia residency training programs in the United States, 39 have full-time chiefs of obstetric anesthesia. Presumably the teaching, research, clinical practice, and physical facilities for labor, delivery, and neonatal care at these centers would be of highest quality and may serve as models for all hospitals providing maternity care. The present study evaluates their compliance with recommendations of the Joint Commission on Accreditation of Hospitals (JCAH),[1] American College of Obstetrics and Gynecology (ACOG),[2,3] and American Society of Anesthesiologists (ASA),[4,5] and how they have dealt with weaknesses previously identified by ACOG[6] and by Shnider.[7]

METHOD

In 1974 and 1975, with the assistance of the Society of Obstetric Anesthesia and Perinatology, 39 chiefs of obstetric anesthesia responded to questionnaires designed to determine:

1. The professional category of the personnel administering obstetric anesthesia;
2. The amount of faculty supervision;
3. The type of anesthesia used for vaginal delivery and cesarean section;
4. The physical facilities in the labor and delivery room and neonatal intensive care unit (ICU);
5. The methods, amount, and scope of teaching obstetric anesthesia to anesthesia, obstetric, and pediatric residents and nurse anesthetists (RNA);
6. The extent of research currently conducted in obstetric anesthesia and source of funding for research.

RESULTS*

Geographic distribution of the programs surveyed represents 22 states and the District of Columbia. Twelve centers are in the East, 9 Southeast, 5 Midwest, 2 Southwest, and 11 Far West. All have both obstetric and anesthesiologic training programs and 3

Paper received: 1/9/76
Accepted for publication: 2/24/76

are military hospitals. The total births per year among the hospitals is 121,210 (3% of the national births) with a mean of 3190 (range 650 to 10,800). Of the 1376 anesthesia residents in the USA, 711 train in these hospitals. An average of 2 residents are assigned to obstetric anesthesia at any one time.

Since perinatology encompasses aspects of anesthesia, obstetrics, and pediatrics, we queried directors as to the organization of their departments. Five of the 39 (13%) employ a chairman of perinatal medicine overseeing parts of all 3 disciplines; 32 (82%) have conventionally organized departments, and 2 (5%) report other unspecified structures.

Clinical Practice.—Anesthesiologists give 56 percent of anesthetics; obstetricians, 32 percent; and RNAs, 10 percent. Three-quarters of patients delivering vaginally receive regional anesthesia, primarily pudendal nerve blocks, lumbar epidurals, and low spinals ("saddle-block") (table 1). Only 6 percent of such patients receive caudal anesthesia (1-shot or continuous). General anesthesia is used in only 6 percent, and an endotracheal tube is placed in 2/3 of these cases. Lamaze or other psychoprophylactic technics are elected by 10 percent of the patients, with analgesic supplementation required in 60 percent of these.

*ACOG Survey 1970.[6]

The cesarean section rate is 10.6 (range 7 to 20) percent. Conduction anesthesia is most frequently used, with epidurals more popular than spinals (table 2). General anesthesia is used in 43 percent of cases.

In at least 69 percent of the hospitals, patients with epidural blocks started during labor always are monitored by a physician, while in the other hospitals, RNs or RNAs monitor them. A physician or RN provides continuous patient care in 59 percent, but in 20 percent, the patient is monitored for less than 30 minutes after block (table 3).

Despite severe fetal complications described after paracervical block (PCB),[8] 80 percent of respondents use PCB occasionally to control pain during the 1st stage of labor. Fetal heart rate (FHR) changes always are monitored following the block. In half the hospitals, FHR is continuously monitored electronically, and in half by

auscultation at varying intervals for 5 to 20 minutes after block.

In half the hospitals, obstetricians administer major conduction anesthesia, accounting for 19 percent of the total blocks. In 10 percent, RNAs administer regional anesthesia, but only a small fraction (2%) of the total number of blocks performed.

Antepartum education of mothers and fathers to reduce anxiety and establish rapport with the staff is an important aspect of contemporary obstetrics. Although most expectant mothers and often fathers tour the obstetric suite during the antepartum period, in 3/4 of the hospitals, the anesthesia department plays no role in these activities (table 4). Lamaze instruction is available to the patients in 82 percent. In 55 percent, preanesthetic evaluation of the parturient is immediate on arrival at the hospital; in 45 percent, evaluation is just before anesthesia administration.

Physical Facilities.—Each hospital has an average of 6 labor rooms, giving a ratio of 0.7 labor rooms/delivery/day. Only 1 respondent reports use of a combined labor/delivery room, but another 7 (17%) plan to incorporate this feature in future construction or remodeling plans.

In almost all hospitals, the labor suite possesses emergency resuscitation equipment, and in over half, O_2, suction equipment, and a resuscitator bag are kept in each labor room. In 85 percent, cesarean sections can be performed in each delivery room. While ECG monitors are available in 3/4 of the delivery suites, less than 1/5 have automatic blood pressure monitors.

The immediate availability of blood products is of particular concern to the obstetric anesthesiologist. Fifteen percent report that low-titer Rh-negative type O whole blood or packed cells are always available in the delivery room and in 95 percent, a blood bank is an average of 6 minutes away.

Three-quarters of the hospitals can continuously record FHR and intrauterine pressure in each labor room. All can monitor these variables in selected patients. The overall patient-monitoring rate is 42 percent. Fetal scalp blood sampling is available in 31/39 centers (79%). Facilities for blood-gas analysis exist in 56 percent of the obstetric suites.

Seventy-nine percent of hospitals have an independent obstetric recovery room, while 10 percent use the surgical recovery room. However, only 13/31 centers with obstetric recovery rooms employ specially trained recovery-room nurses.

Adjacent to the delivery rooms, 23 percent have an area designed for intensive neonatal resuscitation. Each hospital has a distinct intensive care nursery (ICN), 36 percent of which are located near the obstetric suite. Twenty-one percent have a full-time neonatal anesthesiologist and 82 percent have at least 1 full-time pediatric neonatologist. The neonate:nurse staffing ratios in these well-equipped units vary from 1:1 to 4:1 (table 5).

TABLE 5
Neonate to Nurse Ratio in ICN

Teaching.—In addition to the chief, 70 percent of the hospitals use an additional 1 or 2 faculty members to teach obstetric anesthesia. Faculty anesthesiologists are present at all times in 31 percent of the hospitals and in 85 percent, the faculty take both obstetric and surgical-anesthesia call nights and weekends.

In 18 (46%) programs, over half the anesthetics administered for vaginal delivery are directly supervised by faculty anesthesiologists. In 34 (88%) programs, more than half the anesthetics for cesarean sections are directly supervised by the faculty. In 18/39 centers, every anesthetic for cesarean section is supervised by a faculty anesthesiologist.

Teaching sessions, composed of formal lectures and informal rounds, vary widely (table 6). Two-thirds of the hospitals conduct at least weekly case-review conferences; 3/4 hold at least monthly perinatal morbidity-mortality conferences, and 1/2 conduct at least monthly infant-resuscitation seminars.

Obstetric residents rotate through the obstetric anesthesia service in 51 percent, and these residents also rotate through the surgical anesthesia service in 31 percent. Rarely are pediatric residents assigned to anesthesia: they rotate through the obstetric anesthesia service in 8 percent and also through the surgical anesthesia service in 3 percent. Anesthesia residents rotate to the neonatal nursery in 21 percent and to obstetrics in 5 percent.

Thirteen centers train RNAs in obstetric anesthesia. The majority teach administration of general anesthesia and the monitoring of regional blocks. Five teach spinal and epidural anesthesia.

Research. — Three-quarters of the programs include research of some type: 29 pursue clinical studies while 14 also perform animal research. The most common source of funding research is the drug industry (44%). Thirty-two percent of the programs receive NIH support, while 24 percent receive money from their schools of medicine.

Only 10 centers currently have a clinical or research trainee (total, 21 trainees) in obstetric anesthesia, although 37 openings are currently available. Two-thirds of the chiefs believe that research experience should be required of all residents planning careers in obstetric anesthesia.

DISCUSSION

The 39 hospitals surveyed represent a small fraction of the 5000 obstetric services in the United States.[6] However, they are responsible for the major proportion of residency training in obstetric anesthesia, and presumably the practice in these centers eventually will be reflected throughout American obstetrics.

While the mean delivery rate at these hospitals is 3190/year, 13 have fewer than 2000 and 23 have fewer than 3000 deliveries/year. A minimum of 2000 to 3000 deliveries/year probably is necessary to support round-the-clock coverage and teaching in obstetric anesthesia as well as ancillary services such as neonatal intensive care.[7,9] Smaller units likely are subsidized by the hospital or anesthesia departments to provide training in obstetric anesthesia and optimal care for parturient and neonate. This situation obviously is not ideal, and hopefully efforts will be made to merge these units with others in the community to create larger maternity and child-health centers.

The JCAH requires that "the same competence of anesthesia personnel shall be available for obstetrical . . . procedures as is available for elective procedures."[1] Two surveys of all American maternity units[6,10] published in 1970 and 1962, respectively, showed that anesthesiologists administer a minor percentage of total anesthetics for vaginal delivery (table 7), RNAs and obstetricians administering most of the anesthetics. This has been attributed to problems of manpower, economics, and motivation.[11] In the centers, where these factors are not as significant, anesthesiologists do provide most anesthesia (table 7).

While it appears that obstetricians are

†ACOG survey.[6]

administering an inordinately large percentage of the anesthetics for vaginal delivery, the majority of these are pudendal nerve blocks, minor regional procedures not performed by anesthesia personnel (table 1). If all parturients, nationwide, were to receive the same anesthesia coverage as those in the centers, anesthesiologists would administer anesthesia to 2/3 of the 3 million annual deliveries. Such optimal obstetric anesthesia is not feasible without a major consolidation of maternity units and unless more anesthesiologists join in obstetric units.

For the foreseeable future, obstetricians and RNAs must provide the major share of obstetric anesthesia. In 1/3 of the hospitals nationwide, obstetricians do most of the anesthesia for vaginal delivery. The Council on Resident Education in Obstetrics and Gynecology (CREOG), an intersociety organization founded to improve all aspects of residency training in obstetrics and gynecology, believes that all obstetricians should possess skill in using common anesthetic and analgesic technics, including local infiltration, spinal, epidural, and general anesthesia.[12]

Accordingly, ACOG has recommended[13] that all obstetric residents receive organized instruction for 2 or 3 months in anesthesia technics and management of anesthetic complications. Shnider's 1965 survey[14] showed that 49 percent of obstetric residents received no formal instruction in obstetric anesthesia from an anesthesiologist. Our present survey indicates little progress. Again, only about half the residents in obstetrics receive training in a department of anesthesia. Increased efforts in this area are essential.

We believe that although a 2-to-3 month period of anesthesia training is a desirable aspect of an obstetrical residency, this length of time is insufficient to accomplish the CREOG aims. We endorse the 1974 ACOG standards:[3]

"Whenever possible, obstetric anesthesia should be supervised by a qualified anesthesiologist, and administered by an anesthesiologist or a certified registered nurse anesthetist. It is further recommended that the safest methods for the obstetrician himself to use, when the above personnel are not available, are infiltration anesthesias such as local block, paracervical block, or pudendal block."

In 25 percent of American maternity hospitals, RNAs administer most anesthetics for vaginal delivery.[6] They primarily administer inhalation anesthesia and analgesia and monitor but never administer a major regional anesthetic.[10] Regional anesthesia is preferred for vaginal delivery in the 39 units we surveyed. At present, only 5 centers, 3 of which are in military hospitals, train RNAs to administer major conduction anesthesia. Should not more RNAs be trained to do regional blocks under supervision? The obstetric anesthesia centers would be logical sites for such training.

The anesthesia used in the centers differs from that used in most other American maternity units. This reflects both the availability of fully trained obstetric anesthesiologists and also their belief as to the best anesthetic technics. For example, ACOG (table 8) found that the majority of vaginal deliveries were conducted under inhalation anesthesia in 36 percent of maternity units,

TABLE 8
Percent of Hospitals Classified by Type of Anesthesia Most Often Used for Vaginal Delivery

Type of anesthesia	All maternity* units, percent	Obstetrical anesthesia centers, percent
Inhalation	36	0
Local and pudendal	16	33†
Spinal and epidural	14	57‡
Other	12	5

‡57% = 31% saddle; 21% epidural; 5% caudal.

but in no center is inhalation anesthesia the most popular technic; only 6 percent of vaginal deliveries were conducted under general anesthesia (table 1), and we believe obstetric indications necessitated this use. It is noteworthy that 2/3 of these patients had endotracheal intubation to protect them from aspiration pneumonitis.

The majority of vaginal deliveries are conducted under spinal or epidural anesthesia in only 14 percent of American hospitals but in 57 percent of the centers (table 8). Most patients in the centers receive major regional anesthesia (table 1), the most popular technic being continuous lumbar epidural anesthesia. Caudal epidural blocks, long popular in obstetrics and considered by many authorities one of the best methods of obstetric anesthesia,[15] are used only in 6 percent of deliveries.

Patients who receive continuous epidurals must be carefully monitored by trained personnel. The ACOG technical bulletin[2] recommends measurement of blood pressure at least every 2 minutes for the first 10 minutes and then at least every 5 minutes for the next 20 minutes after anesthetic injection. This is a minimum standard, considering the constant supervision a surgical patient receives following an epidural block in the operating room, but even this recommendation is not followed in 20 percent of the centers (table 3).

Despite widespread publicity and the availability of Lamaze instruction (82% of centers), only 10 percent of parturients use this technic, and the majority of these require some form of supplementary analgesia. This suggests that psychoprophylaxis should not be depended upon to replace conventional obstetric anesthesia.

Ideally, an anesthesiologist should see each parturient either individually or in a group setting as part of antepartum orientation and education, to establish rapport with the patient and describe the risks and benefits of the various types of anesthesia available. Yet in only 5 percent of centers are mothers interviewed during the antepartum period. Failing such an antepartum opportunity, an intrapartum, unhurried preanesthetic evaluation and discussion of anesthesia should be performed immediately on the parturient's arrival in the delivery suite. Unfortunately, in half the hospitals an anesthesiologist does not see the patient until *immediately* prior to administration of anesthesia.

Within the centers, the popularity of epidural anesthesia for cesarean section is striking. Whereas the ACOG study of all maternity units showed that epidural anesthesia was used in only 3 percent of cesarean sections, in the centers it is used in 32 percent. Both groups use conduction anesthesia with similar frequency for cesarean section, but spinal is less popular within the centers (table 2). We speculate that although the onset of anesthesia is more rapid with spinal, department chiefs prefer the slower onset and more controllable anesthetic levels and cardiovascular alterations with epidural blocks.

Perinatology.—Progress toward a multitrained specialist in perinatology is slow. Only 13 percent of the centers have a combined perinatology service, 8 percent of the hospitals have pediatric residents rotate in obstetric anesthesia, and 21 percent have anesthesia residents rotate to the neonatal nursery. Whether perinatology as a distinct specialty represents a discipline of the future is not clear. Physicians still attach great significance to the concept of the "fully trained" specialist. Whether there can exist a "perinatologist" who is obstetrician but not gynecologist, obstetric but not surgical anesthesiologist, and neonatologist but not general pediatrician is speculative. At present, the majority of the centers have combined interdisciplinary conferences and seminars. Surprisingly, a quarter of the centers have no conferences on infant resuscitation.

Equipment and ICUs.—JCAH requires, and ASA and ACOG recommend, that equipment for the obstetric patient equal that available for surgical patients.[1-3] Most centers comply with these recommendations. Virtually every delivery room has an anesthesia machine, wall suction, piped O_2, and infant resuscitator. In 85 percent of the hospitals, cesareans can be performed in *each* delivery room. In contrast, a quarter of the nationwide hospitals surveyed by ACOG required *more than 40 minutes* to prepare for an emergency cesarean.

While each center has a well-equipped neonatal ICU, only 23 percent have an area immediately adjacent to the delivery room for major resuscitation of the premature or severely asphyxiated newborn. Such an area is indispensible in minimizing the delay between delivery and the institution of definitive resuscitation.

ICU staffing in the centers is generally good, with 82 percent having at least 1 full-time neonatologist. However, the neonate:

nurse ratio is not ideal; in only 42 percent is a very ill neonate attended by a nurse at all times, and in only 72 percent is the ratio of 1 nurse to 2 neonates observed.

CONCLUSIONS

Between 250 and 400 major referral centers for obstetric and neonatal problems ("Level III" facilities) will be necessary to provide optimal maternal and neonatal care in the USA.[16] A group of concerned organizations represented in the Committee on Perinatal Health has produced the following recommendations for such centers:

"Anesthesia services *must* be directed by an anesthesiologist with special training in maternal-fetal and neonatal anesthesia. . . ."

Obstetric anesthesia centers must assume responsibility for this special training in addition to their routine training of obstetricians and anesthesiologists.

Currently, 75 percent of these centers do not have a clinical or research trainee in obstetrical anesthesia either because of lack of funds or qualified or interested candidates. If the modest goals of the Committee on Perinatal Health are to be attained, significant increases in financial support, training facilities and personnel must be forthcoming.

MEDICAL STATISTICS

Statistical Pearls III. The Most Likely Interpretation

PATRICK D. HARRIS, PhD*

PROBABILITY is probably the most important word in modern biomedical research. Yet, it would be difficult for most of us to answer the question, "What is probability?" In a sense, probability is like a pregnant woman in that it is a currently existing condition which defines an *expected* future event. Probability is a prediction of the *future*, but our *measure* of probability comes from past observations. The more information we have about past events, the better is our prediction of a future possibility.

Recently, a colleague, D. L. Wiegman, brought me some interesting data which involved one interpretation of probability. Essentially, he had used a well-defined protocol to hemorrhage rats for 1 hour. He had records of body weight (grams) at the time of hemorrhage and death (d) or survival (s) for the 24-hour period which followed reinfusion of the hemorrhaged volume. These data were: 166/s, 196/d, 146/d, 191/s, 204/s, 153/d, 208/d, 206/s, 220/d, 119/d, 185/s, 175/s, 151/d, 140/s, 140/d, 139/d, 179/s, 158/d, 161/s, 143/s, 155/d, 144/d, 145/s, 180/s, 196/s, 172/s, 172/s, 112/d, 159/s, 120/d, 115/d, 116/s, 127/d, 155/d, 117/s, 110/d, 114/s, 150/s. The average weight was 156 gm, with a range from 110 to 220 gm and survival was 52.6 percent (20sX100/38). At this point, one might predict that any future rat would have a 52.6 percent probability of being alive 24 hours after hemorrhage with the protocol. Is this a good prediction regardless of the weight of this future rat?

An investigator might attempt to answer this question by construction of a histogram[1] for the existing data. One such attempt would give a histogram with "percent survival in each weight class" on the

*Investigator, Dalton Research Center; Associate Professor of Physiology, University of Missouri School of Medicine, Columbia, Missouri 65201.

ordinate and with "body weight in grams" on the abscissa. The abscissa would be divided into 8 class intervals with a starting point of 100 gm and with an interval size of 15 gm. This histogram would be difficult to interpret, however, because 6 of the intervals would contain 5 or less observations (animals).

For the individual weight/survival data above, we posed the question, "Is the probability for survival independent of body weight (ie, the same for weights between 110 and 220 gm)?" We will approach the answer to this question by use of a *cumulative distribution* curve (fig 1). For our data, the abscissa is expressed as "body weight in grams" with "steps" which are *as small as* possible. Ideally, we should have *one* observation for each abscissa step from the smallest weight to the largest weight, so we have selected a 3-gm step size (approximately [200-110]/38). The first step is selected by the formula: the "largest weight" (220 gm) minus the product of the "step size" (3) and the "number of observations less one" (38 − 1). Thus, our starting point is 220 − (3 × 37) or 109 gm. For each "step" on the abscissa, an ordinate value is calculated as the cumulative survival for *all* observations with body weight *less than* or *equal to* (≤) the "step weight."

For example, the 1st step is 109 gm. Since our data do not contain any animals with weight ≤ 109 gm, we move to the next step (109 + 3 = 112 gm). Our data contain 2 animals (112/d and 110/d) with weights ≤112 gm. Since neither of these animals survived, the cumulative survival (ordinate value) is 0 percent. The next step (112 + 3 ≙ 115) contains 4 animals (112/d, 115/d, 110/d, 114/s) with weights ≤115 gm. The cumulative survival is 25 percent. The cumulative survival is calculated for each of the remaining steps in a similar fashion and is plotted on the ordinate in figure 1. The last step (217 + 3 = 220) includes all animals, and thus has the ordinate value which is the survival (52.6 percent) for all observations.

How does one interpret this cumulative distribution curve to investigate the possibility of a relationship between survival and body weight? Perhaps an insight for this interpretation can be gained from examination of theoretic data. I have generated a sequence of 38 theoretic observations of survival and death by using a table of random numbers to assign 1 observation to each 3-gm step over the range 109 to 220 gm.

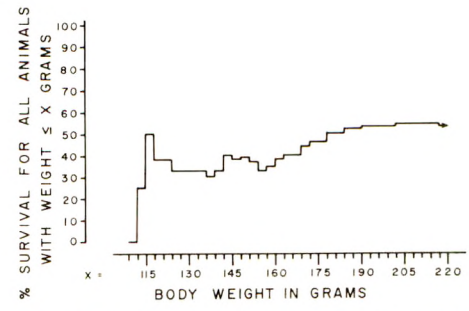

FIG 1. Cumulative distribution curve for survival of 38 rats during the 24-hour period following hemorrhage. (Data from D. L. Wiegman)

Each observation has a 50 percent chance of being a death or a survival and there is no relationship between survival probability and "weight."

A cumulative distribution curve for this theoretic data is shown (fig 2); this curve demonstrates the characteristic of "convergence," in that the percent survival for the first 10 to 16 steps is above *or* below the "real" probability of 50 percent; however, the "error" between the calculated value and the "real" value becomes smaller as more steps are added.

This property of convergence is better demonstrated in another manner. A cumulative distribution curve is arbitrarily constructed for the lower *one-half* (19) of the total number of theoretic observations. This curve appears in the left half of figure 3 for steps from 109 to 163 gm. Another cumulative distribution curve is constructed for the upper one-half (19) of the total number of observations by *starting with the highest* weight and stepping downward (right half of fig 3). In this curve, the ordinate value for each step is the cumulative survival for

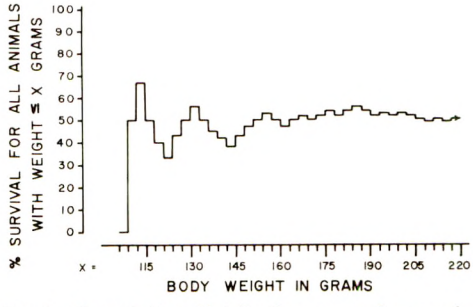

FIG 2. Cumulative distribution curve for survival of 38 "theoretic" animals for which the probability of survival is 50 percent and is independent of body weight. The sequence of survival and death observations was obtained from a random number table.[2]

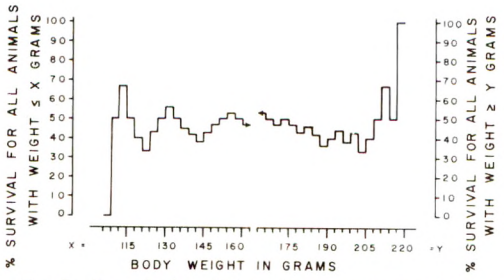

FIG 3. Cumulative distribution curves for survival of 19 "theoretic" animals with weights ≤163 gm (left panel) and 19 "theoretic" animals with weights ≥163 gm (right panel). The sequence of theoretic survival and death observations is the same as used for the cumulative distribution curve in fig 2.

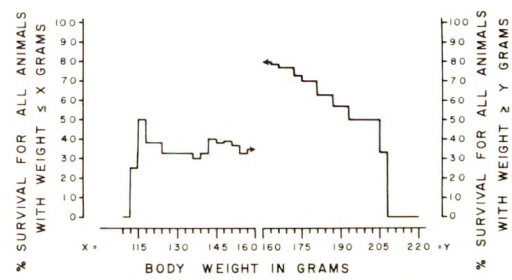

FIG 4. Cumulative distribution curves for survival of 23 rats with weights ≤160 gm (left panel) and for 15 rats with weights ≥160 gm (right panel) during the 24-hour period following hemorrhage. These were obtained from the same raw data as used for the cumulative distribution curve in fig 1.

all observations (theoretic animals) with weight *greater than* or *equal* to (≥) the abscissa value. (For example, the first step is 220 − 3 = 217 and the ordinate is percent survival for all "animals" with weight ≥217 gm.) Figure 3 demonstrates convergence because the survival (47.3%) in the last step (160-163 gm) for the lower cumulative curve (left panel) approaches the survival (52.6% in the last step (166-163 gm) for the upper cumulative curve (right panel). These survivals (47.3% and 52.6%) also approach (ie, converge toward) the "real value" of 50 percent.

Comparison of our animal data (fig 1) to our theoretic data (fig 2) suggests the absence of convergence in the animal data (fig 1). The cumulative distribution in figure 1 appears to converge toward 35 percent until step 163 is reached. Following this step, the cumulative curve appears to converge toward the survival of 52.6 percent for the "last step" (217-220). This suspicion of *divergence* (lack of convergence) is better investigated by arbitrarily dividing the data at the point which precedes the suspected change (step 160).

Figure 4 shows the cumulative distribution curve for 23 animals with weight ≤160 gm (left panel) and that for 15 animals with weight ≥160 gm (right panel). In contrast to "convergence" for our theoretic data in figure 3, our animal data in figure 4 appear to *diverge* (35% survival for the 157-160 step in the left curve and 80% survival for the 163-160 step in the right curve). This suggests that body weight in the 110 to 220 gm range influences survival of hemorrhage. In other words, we would *not predict* that a future rat would have a 52.6 percent probability of being alive 24 hours after hemorrhage, with my colleague's protocol.

As a conclusion to this discussion on probability and cumulative distribution curves, several points need emphasis:

(a) The end (last) step in a cumulative distribution gives a "best estimate" of probability; yet, it does not necessarily give the exact probability (or chance) that an event will happen.

(b) The "lower" and "upper" cumulative distributions can *indicate* convergence if the end step probabilities are as close to each other as in figure 3, or divergence if they are as far from each other as in figure 4. (How close is "close?" This is most appropriately answered by *statistical* tests, which have not been discussed here.)

(c) Cumulative distribution curves usually work very well for 18 or more observations, whereas histograms usually require 40 or more observations to give useful interpretations.

(d) Cumulative distribution curves *do not prove* or statistically test anything; yet, they can lead to a hypothesis which could otherwise be overlooked and which can subsequently be tested statistically.

Cerebrospinal Fluid Pressure During O_2 Encephalography and N_2O Inhalation

WILLIAM L. PAUL, MD*
EDWIN S. MUNSON, MD†
JACK E. MANISCALCO, MD‡
Gainesville, Florida§

Cerebrospinal fluid (CSF) pressure was studied in 8 patients and 5 dogs during pneumoencephalography (PEG) or ventriculography in which either O_2 or N_2O was used as the contrast gas prior to and during N_2O inhalation. In 7 patients, the use of O_2 as the contrast gas increased CSF pressure 8.7 torr (range 4 to 12 torr) following N_2O inhalation. In 1 patient, when N_2O was used as the contrast gas, CSF pressure did not change after N_2O inhalation. These findings were confirmed in anesthetized animals ventilated at a constant $Paco_2$. The authors conclude that if N_2O inhalation is required during PEG, maximum patient safety can be achieved if the contrast gas is also N_2O.

THE inhalation of N_2O during pneumoencephalography (PEG) has been shown by Saidman and Eger[1] to markedly increase cerebrospinal fluid (CSF) pressure. Increase in pressure during PEG is related to the differential solubility of N_2O and N_2 in blood, which results in a greater transfer of N_2O from blood to gas than of N_2 from gas to blood. Since N_2O inhalation is commonly used during and after this procedure, some clinicians use O_2 as the contrast gas medium to avoid this hazard.

Although O_2 is more soluble than N_2O in blood, the differential solubility between O_2 and N_2O is sufficiently great that the inhalation of N_2O during O_2 PEG theoretically would increase CSF pressure. Therefore, we measured CSF pressure in patients during PEG, in which O_2 was used as the contrast gas before N_2O inhalation. Anesthetized dogs ventilated at constant levels of $Paco_2$ were similarly studied.

METHODS

Clinical Studies.—Eight patients ranging in age from 10 to 53 years and scheduled for PEG or ventriculography were studied.* Each patient was premedicated with sedative doses of barbiturate and narcotic drugs. Additional sedation was obtained by administering Innovar® IV as necessary. Arterial blood pressure was measured by standard auscultatory methods, and heart and respiratory rates were recorded continuously. Each

Paper received: 3/22/76
Accepted for publication: 5/12/76

patient was in the sitting position when studied, and a spinal or ventricular catheter was attached to a pressure transducer. Lumbar subarachnoid or CSF pressure was continuously recorded on a Grass polygraph. Contrast gas in 7 patients was O_2 and in 1 patient was N_2O. All inhaled gases were given at an inflow rate of 10 L/min by face mask attached to a Bain circuit.

Following administration of the O_2 contrast and stabilization of CSF pressure, we recorded control pressures after patient inhalation of 100 percent O_2 for 5 minutes. Patients then inhaled 50 percent N_2O until no further rise in CSF pressure was noted, then N_2O was discontinued and O_2 inspired until CSF pressures returned to control levels. This sequence was repeated 1 to 6 times in each patient, with all patients in the sitting position. The patient given N_2O for contrast also inhaled N_2O 5 times in concentrations ranging from 30 to 70 percent.

Animal Studies.—Additional experiments were performed on 5 male mongrel dogs ranging in weight from 16 to 18 kg. Each animal was anesthetized with pentobarbital (25 mg/kg) and immobilized with pancuronium. Following endotracheal intubation, animals were placed supine and ventilated with O_2, using a volume-limited ventilator. End-tidal CO_2 concentration was continuously monitored with a Godart capnograph to maintain $Paco_2$ values constant within a range of 35 to 45 torr. Blood pressure was recorded by a pressure transducer from a catheter placed in the femoral artery.

With the animal's head in flexion, an 18-gauge spinal needle was placed percutaneously into the cisterna magna and was attached to a pressure transducer to continuously measure CSF pressure. Dogs were ventilated with 100 percent O_2 to obtain control pressures, after which N_2O (50 or 70%) was inspired for 10 minutes. Fluid-gas interchange was achieved by removing 5 to 10 ml of CSF in 1 to 2 ml increments in exchange for equivalent volumes of either N_2O or O_2. When the cisternal administration was complete and CSF pressure had stabilized, N_2O was inhaled in 50 or 70 percent concentrations until no further rise in CSF pressure occurred. When more than 1 gas was studied during the same experiment, N_2O was inhaled before the next contrast gas was administered. If no pressure rise occurred, we assumed that the previous contrast gas had been absorbed.

TABLE 1

Mean ± SD (and Ranges) CSF Pressures During O_2 Encephalography in 8 Patients Following Inhalation of 50% N_2O

Patient number	Age (years)	Contrast volume (ml)	Number of exposures to N_2O	Increase in CSF pressure (torr)

RESULTS

Clinical Studies.—CSF pressure increased 8.7 torr (range 4 to 12 torr) in 6 patients whose initial CSF pressures were normal (table 1). This increase occurred within 3 minutes (range 2 to 3.5 min). The CSF pressure in 1 patient with known hydrocephalus (initial CSF pressure 20 torr) increased 22 torr. The volume of O_2 injected as a contrast gas ranged from 10 to 70 ml. No correlation between the volume of injected gas and the CSF pressure increase was observed.

No change in CSF pressure was seen in the patient who received N_2O inhalation prior to injection of intrathecal N_2O. No changes in arterial blood pressure or respiratory rate occurred during N_2O inhalation. Both O_2 and N_2O contrast produced satisfactory x-rays.

Animal Studies.—In each animal there was a small increase in CSF pressure (1 to 2 torr) prior to cisternal gas injection, and in arterial blood pressure (10 to 20 torr) during N_2O inhalation (table 2). These pressure changes did not return to control levels when N_2O inhalation was discontinued. Following O_2 encephalography, an increase in CSF pressure of 9.7 torr (range 3 to 21 torr) was observed when N_2O was inhaled in 50 or 70 percent concentration. In 3 animals which also received N_2O injections while breathing N_2O in 50 or 70

percent concentration, no changes in CSF pressure were noted.

DISCUSSION

The inhalation of N_2O during air encephalography, first shown to increase CSF pressure by Saidman and Eger,[1] is a phenomenon related to the 34-fold difference in blood/gas partition coefficients between N_2O (0.46) and N_2 (0.013). Therefore, at the same partial pressure, for every molecule of N_2 that moves from the gas space into the blood, 34 molecules of N_2O move from the blood into the gas cavity. When this differential gas exchange occurs in a noncompliant space, such as the cerebroventricular system, an increase in pressure results.[2]

The differential solubility between N_2O and O_2 also is sufficiently great to produce a gas bubble amplification effect. We calculate that the functional partition coefficient for O_2 is approximately 0.08, the difference between the O_2 content that blood *can* hold (about 20 volumes percent) and the amount present in cerebral venous blood (about 12 volumes percent). These assumptions are supported by the work of Philippart,[3] who observed that the O_2 content of ventricular gas during air encephalography with N_2O anesthesia does not fall below 12 volumes percent. In each patient, the use of O_2 as the contrast gas increased CSF pressure following N_2O inhalation. The same response, although to a lesser degree, was observed in dogs ventilated at constant $Paco_2$ levels.

Gordon and Greitz[4] showed that PEG during N_2O anesthesia in normal patients increased CSF pressure. However, this increase always remained within the normal range. They suggested that N_2O contrast would be safer in patients in whom increased intracranial pressure existed. Recent studies by Elwyn and his colleagues[5] support this recommendation.

Our findings show that the use of O_2 contrast during N_2O anesthesia in patients also elevates CSF pressure. While these changes are moderate and probably clinically insignificant in normal patients, caution must be exercised with patients who have abnormal ventricular systems. Such patients frequently have decreased ventricular compliance, so that small changes in intracranial volume greatly increase CSF pressure. Therefore, N_2O diffusion into the O_2 "space" could produce increased ventricular volume and pressure. Our patient with hydrocephalus showed just such a significant increase in CSF pressure.

We conclude that if N_2O inhalation is used during PEG, the use of O_2 as the contrast gas may be associated with some increase in CSF pressure, but increase of CSF pressure from the contrast gas during N_2O inhalation can be prevented if the contrast gas is also N_2O.

Guest Discussion

RICHARD A. ELWYN, MD
Department of Anesthesiology
University of Utah
Primary Children's Medical Center
Salt Lake City, Utah

Thank you for the opportunity to discuss Dr. Paul's paper. We have been interested in the technic of encephalography since

1965, when Eger and Saidman first suggested the hazards of combining N_2O anesthesia and air contrast medium because of increased CSF pressures.[1] In those instances where N_2O was used in the anesthetic, they suggested that N_2O also be used as the contrast gas. This would decrease operative complications and postoperative morbidity.

Dr. Paul has shown that O_2 can be satisfactorily used as a contrast medium in encephalography, but that the CSF pressure will increase to moderate levels when N_2O is inhaled.

Why then, since 1965 when it was first suggested, has N_2O not been used as the contrast medium for encephalography? The only quoted negative opinion is the 1969 paper by Collan and Iivanainen,[2] which attributed a cardiac arrest to the technic and was explained by the rapid elimination of ventricular N_2O with a fall in CSF. An analysis of that paper reveals other possible causes of the cardiovascular collapse.

When Collan and Iivanainen published their paper, they reported 300 successful cases, where the anesthetic gases were injected as the ventricular contrast medium. At Primary Children's Medical Center, we had completed over 240 pneumoencephalograms in children, using 100 percent N_2O as the ventricular contrast medium and using halothane-N_2O-O_2 anesthesia. We continued to use our technic and have now studied a total of 475 encephalograms.[3] There were no instances of subdural hematoma or cardiovascular collapse following the procedure nor were there any other neurologic complications.

The rationale for general anesthesia in pneumoencephalography is a more comfortable and a quiet patient and thus better and quicker radiologic results. If general anesthesia is chosen, then the optimum advantages of the technic of N_2O anesthesia and N_2O contrast medium can be obtained. All things being equal, we can conduct a safer anesthetic course by eliminating rises in CSF pressure and in minimizing the risk of venous embolism. Postoperatively, the rapid elimination of the ventricular contrast N_2O results in less emesis, less headache, a more comfortable patient, and a more rapid hospital discharge, when compared to air as the contrast medium.

As early as 1951, Davidoff[4] recognized that the aim of treatment in decreasing morbidity from gas encephalography should be the rapid elimination of the contrast medium. Most of the ventricular N_2O will be gone within 15 minutes. Ventricular air may remain for a week or more and be responsible for emesis and headache.

Fatalities occur during and following pneumoencephalography because of the underlying disease, brain herniation, and air embolism. Fatal venous gas embolism has occurred with helium, air, and O_2. It is difficult to understand that the report of 1 cardiovascular collapse in the literature forms the basis for condemnation of a useful technic. If smaller amounts of CSF are removed, the fluid will be replaced rapidly. CSF forms at a rate of 0.4 ml/min and is independent of CSF pressure up to 200 mm H_2O pressure. In our study, we routinely injected 2 to 4 times the amount of N_2O compared to CSF removed. CSF pressures taken within minutes of the N_2O injections were normal. This may help explain our lack of neurologic complications.

Dr. Paul has again shown that CSF pressures increase when N_2O anesthesia is used with contrast gas media other than N_2O. The patient with an abnormal ventricular system may react unfavorably to the increased CSF pressure. For the comfort and safety of patients, N_2O contrast medium and N_2O anesthesia should be considered.

Uptake and Excretion of 1-Bromo-1,2,2-Trifluorocyclobutane (42M-9) in Man: Comparative Study on Pharmacokinetics and Metabolism of Inhalation Anesthetics

DUNCAN A. HOLADAY, MD*
VERA FISEROVA-BERGEROVA, PhD†
Miami, Florida‡

1-bromo-1,2,2-trifluorocyclobutane (42M-9) has physical properties similar to those of methoxyflurane and has been suggested for use as an anesthetic agent. Its MAC value, predicted from its lipid solubility, is 0.26 percent. No clinically significant changes were observed in cardiovascular or respiratory function or in clinical laboratory tests. Ventricular dysrhythmias were not seen in this study at analgesic concentrations in contrast to those reported at anesthetic concentrations by others. Pulmonary uptake was high and wash-out was slow. The total amount exhaled comprised 60 percent of the dose. Fluorine, equivalent to 11 percent of total uptake, was rapidly excreted in urine as nonvolatile fluorinated metabolites. An additional 9 percent of 42M-9 was degraded to fluoride and excreted in urine. Since an amount of fluoride equivalent to that excreted in the urine tends to be deposited in the skeleton, approximately 29 percent of uptake may possibly be accounted for as metabolites. Based on fluorine recovery, the fate of 11 percent of 42M-9 uptake remains unknown. The kinetics of uptake, metabolism and excretion of 42M-9 did not differ significantly over a fivefold change of inspired concentration. A comparison of the pulmonary clearance of unaltered 42M-9 and the fraction of uptake converted to urinary metabolites or unrecovered with those of other volatile halogenated anesthetics and their physical properties supports the conclusion that 42M-9 is relatively resistant to biotransformation.

REPORTS of hepatotoxicity and nephrotoxicity following the administration of commonly used halogenated anesthetic agents have stimulated the search for safe alternative volatile anesthetics. The toxicity of halogenated anesthetics is related to metabolism;[1-5] therefore, the search for an ideal agent has turned to compounds which would be metabolized little or not at all.

Compound 42M-9 (1-bromo-1,2,2-trifluorocyclobutane)* has been tested in animals and found to be a stable, potent anesthetic agent.[6] The following study was undertaken to establish the susceptibility of 42M-9 to biotransformation in man and to get information about the pharmacokinetics of its uptake and excretion. The effect of inhaled concentration on extent of metabolism was also investigated.

METHOD AND PROCEDURE

Administration of 42M-9.—The subjects were 8 healthy informed male volunteers averaging 22 (± 2.76)† years of age, of normal build [mean body weight 82 (± 12) kg and body height 181 (± 5.4) cm.] None of

Accepted for publication: 3/23/76

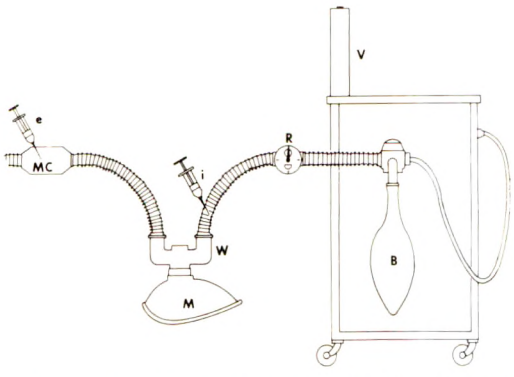

FIG 1. Equipment used for administration of 42M-9 to volunteer. V: vaporizer; B: rebreathing bag; R: Wright respirometer; M: mask; W: 2-way valve; MC: mixing chamber; i: sampling of inhaled air; e: sampling of exhaled air.

the subjects had a history of preexisting disease or drug treatment. 42M-9 was vaporized in a Verni-Trol®* vaporizer and administered in O_2 for 1 hour by mask in a closed, nonrebreathing system (fig 1). Pulse rate and blood pressure were measured at 5-minute intervals. The ECG was monitored continuously and pulmonary ventilation was measured with a Wright respirometer at 5-minute intervals.

The average concentration of inhaled 42M-9 was 0.047 (± 0.006) percent for 5 volunteers in group I and 0.24 (± 0.026) percent for 3 volunteers in group II.

After 1 hour of exposure, each volunteer returned to breathing room air through the nonrebreathing circuit for an additional 45 minutes, during which monitoring was continued. Thereafter, the volunteer resumed normal activities. Strenuous exercise was discouraged for the rest of the week.

Gas Sampling.—During exposure, inhaled and mixed exhaled air samples were collected in gastight glass syringes† at 5 to 10-minute intervals and immediately analyzed for 42M-9 (fig 1). After exposure, samples of mixed exhaled air were collected each 15 minutes during the first 2 hours, then at intervals of approximately 1 hour for 8 hours, then 4 times a day for 2 days, and finally 3 times a day for the rest of the week. The volunteer inhaled through his nose and exhaled through a nylon mouthpiece into an all-glass apparatus (fig 2).

*Ohio Medical Products, Division of Air Reduction Company, Inc.

†Precision Scientific Instruments, Inc.

After washing the apparatus with exhaled air for 3 minutes, 3 to 5 samples were taken during the next 2 minutes in a gas syringe and were analyzed for 42M-9. At the same time, the pulmonary ventilation was measured over a 5-minute period with a Wright respirometer.

Blood Sampling.—Blood was collected for hematologic, hepatic, and renal function profiles (table 1) and for fluoride determination before the experiment and at 24 and 72 hours after exposure. Samples for fluoride determination were heparinized and refrigerated until analyzed. During exposure, arterial blood was drawn from a radial artery anaerobically into a glass syringe for determination of 42M-9 after approximately 30 and 55 minutes of exposure. These samples were analyzed on the day of collection.

Urine Sampling.—All urine was collected as 12-hour samples in polyethylene bottles for 2 days before the experiment and 5 days after exposure. Urine volume, pH, density, concentration of inorganic fluoride, total fluoride, and nonvolatile fluorine were measured. On the 1st day, random samples of freshly voided urine were analyzed for 42M-9.

Analytical Procedures.—42M-9 in air was determined by injection of 0.2 to 1 ml of

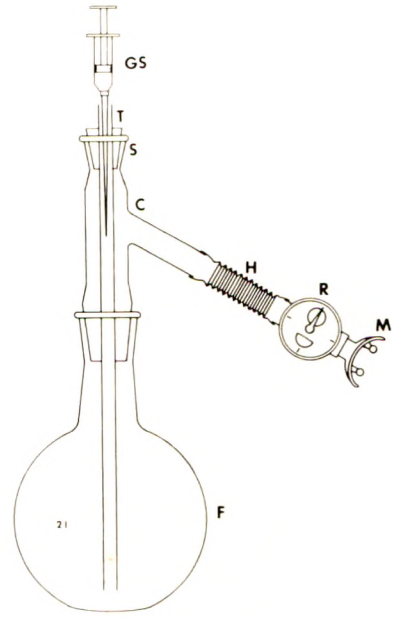

FIG 2. Apparatus for sampling exhaled air. M: mouthpiece; R: Wright respirometer; H: nylon hose; C: glass tube connector; F: glass flask (2-L capacity); S: cork stopper with hole; T: glass tube (ID 6 mm): GS: glass syringe for sampling.

a gas sample into a 2-meter (3 mm ID) glass column packed with 10 percent diisodecylphthalate on Chromosorb P, 60/30 mesh heated to 100° C. A Hewlett-Packard gas chromatograph 7610A equipped with electronic digital integrator 3373B and flame ionization detector was employed for analysis of gas samples. When the concentration of 42M-9 dropped below 0.1 μg/L a Microtek 2500 R equipped with a tritium electron capture detector was employed. Column temperature was 80° C. Standards were prepared by injection of an exactly measured volume of liquid 42M-9 into evacuated glass flasks of known volume. After equilibration to atmospheric pressure an electromagnetic stirrer was used to keep the gas mixture in the jar homogeneous. The magnetic bar was wrapped in aluminum foil in propeller shape to achieve efficient mixing.

42M-9 Concentrations in Blood and in Urine.—After 1 ml of blood was extracted with 1 ml of hexane in a 5-ml glass-stoppered centrifuge tube and shaken gently for 5 minutes, 0.2 to 0.5 μl of extract was injected into a gas chromatograph column connected to an electron capture detector operated as above. Five ml of urine was extracted with 2 ml of hexane in a 10-ml glass-stoppered tube, and the rest of the procedure was the same as for blood. The samples were centrifuged before injection if the phases did not separate spontaneously. Standard curves were constructed by adding 0.2, 0.4, or 0.6 μl of 42M-9, appropriately diluted with hexane to samples of blood and urine obtained before exposure. These samples were analyzed by the same procedure and glassware as for the experimental samples, in order to achieve the same distribution of anesthetic among sample, hexane, and air.

Fluoride in urine[7] *and blood*[8] were determined by direct measurement with a specific fluoride-ion activity electrode. *Nonvolatile fluorine* was measured as fluoride after evaporation of 1 ml of urine at pH 9 on combustion paper in a stream of hot air and combustion in a Schoniger combustion flask.[7]

*Resuming normal activity.

† $\frac{100\ (C_{in} - C_{ex})}{C_{in}}$ at 60th minute of exposure.

‡The half times are derived from the slopes of three exponential functions of the desaturation curve designated as VRG (vessel rich group), MG (muscle group) and FG (fat group).

Total fluorine was determined after combustion of 1 ml of urine sample in an H_2O_2 flame.[8,9] Acidified urine was introduced directly into the flame and the combustion products were trapped in 1N NaOH solution and measured as fluoride ion at pH 6.5.

RESULTS

Hematologic and clinical chemistry measurements are summarized in table 1. The results of all analyses are in the range of normal levels with the exception of 1 volunteer (I/3), who had slightly increased bilirubin (1.2 to 1.4 mg %) and cholesterol (252 to 267 mg %) in preexposure as well as postexposure samples. There were no significant differences between pre- and postexposure values by *t*-test for paired values except for an increase of alkaline phosphatase 24 hours after exposure and an increase of white blood cells on postexposure day 3.

Cardiovascular and Pulmonary Ventilation Data.—Blood pressure remained within normal limits during exposure. No abnormal ECG patterns were observed. Sinus bradycardia (pulse rate <56) occurred during exposure of 3 subjects in group I, representing pulse reductions of 0, 1, and 4 bpm from minimum preexposure rates, and in 1 subject in group II, whose pulse slowed from 60 to 46. Ventilation during exposure averaged 8.2 L/min (± 2.7) and after exposure increased to 9.2 L/min (± 1.2) for both groups (table 2).

Uptake rate, u_t, was determined from the differences between 42M-9 concentrations in inhaled (C_{in}) and mixed exhaled air (C_{ex}) times pulmonary ventilation ($\dot{V}$); the retained dose (D) was determined as the sum of products of uptake rates and time intervals between samplings (t):

$$u_t = \dot{V}\ (C_{in} - C_{ex}) \qquad D = \Sigma u_t t \qquad (I)$$

The relative uptake $\frac{100\ (C_{in} - C_{ex})}{C_{in}}$ at the

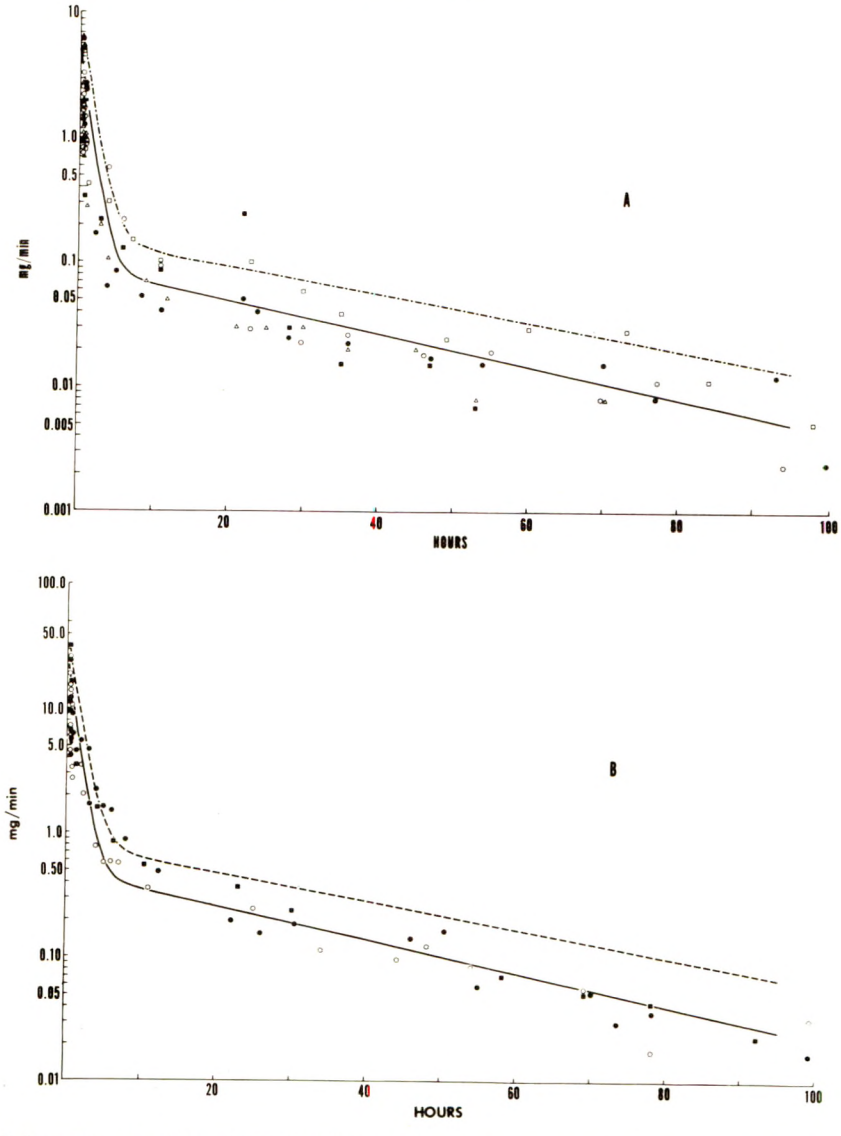

FIG 3. Pulmonary excretion of 42M-9. The excretion rate (mg/min) is plotted against the time after the end of the exposure (hours). Lines are predicted curves: dash lines assume no metabolism (metabolic coefficient equals zero), solid lines account for metabolism (metabolic coefficient = 2.6 L/min). [See text for definition of "metabolic coefficient."] The points represent all measured values in 5 volunteers inhaling for 1 hour 0.047% 42M-9 (A) and in 3 volunteers, inhaling 0.24% (B).

end of 1 hour of exposure approached 43 (± 8.8) percent in both groups (table 2).

42M-9 concentrations in arterial blood averaged 1.8 mg % in group I and 8.5 mg % in group II.

Pulmonary desaturation (table 2) averaged 60 (± 16) percent of the dose. There was no statistical difference between the 2 groups (fig 3).

The parameters of representative desaturation curves described by the sum of 3 exponential functions were determined by searching for optimal fit to the experimental data[7] for each group, using a NONLIN program.* Half-times determined from exponents derived in this manner were 5 minutes, 124 minutes, and 27 hours. There were no significant differences in half-times between the 2 groups (by *t*-test).

A significant increase of *fluoride ion in urine* was observed during the first 5 post-exposure days. In group I, the increase of

*NONLIN is a program for parameter estimation, supplied through the courtesy of Dr. C. M. Metzler of the Upjohn Company.

*Calculated as 42M-9, 3 fluorine atoms in molecules: mg F $\times \frac{189}{3 \times 19}$.

†The amount of fluoride excretion was doubled because of skeletal uptake of fluoride.

‡Includes pulmonary and renal excretion of 42M-9 and its fluorinated metabolites and skeletal uptake of fluoride.

fluoride was equivalent to 11 percent of administered 42M-9, and in group II, the increase represented 5.3 percent. By *t*-test, this difference is not statistically significant because of large coefficients of variation. Combining the groups, an average of 9 (±5) percent of 42M-9 uptake was excreted as urinary fluoride (table 3). The maximum excretion rate occurred in urine samples collected during the first 12 postexposure hours. The maximum excretion rate in group I was 6.4 mg/12 hr and in group II was 16 mg/12 hr. After the excretion rate reached its peak, the excretion rate in both groups decremented exponentially with a half-time of 24 (± 10) hours.

Organic fluorine in urine in the combined groups was equivalent to 11.4 (± 6) percent of total uptake of 42M-9. It followed closely the excretory pattern of fluoride. The maximum excretion rate occurred in the first 12-hour fraction, and equaled 11 mg/12 hr for group I and 56 mg/12 hr for group II. The half-time of the average excretion curve was 15 (± 8.8) hours. There was no difference between results obtained by the method for nonvolatile fluorine and that for total fluorine.

Fluoride in blood peaked within 2 hours after the end of exposure. The maximum increase of fluoride concentration in blood averaged 13 μg % in the 1st group and 20 μg % in the 2nd group (table 3).

42M-9 in urine was measurable only in urines voided shortly after exposure, and the concentration did not exceed 0.7 mg/L.

DISCUSSION

This study had 3 goals: (1) To determine the uptake, excretion, and biotransformation of 42M-9 in man, (2) to determine the effect

of inhaled concentration on extent of metabolism, (3) to investigate the possibility of utilizing the information from studies of metabolism and pharmacokinetics of new drugs for prediction of biologic effects and their duration. To achieve these goals, all data on uptake and pulmonary and urinary excretion were submitted to mathematical analysis.

The physical properties of 42M-9 are similar to those of methoxyflurane. Its blood/air partition coefficient is 8 and fat/air is 560.[6] As expected, its uptake is great and pulmonary desaturation slow.

The uptake and excretion of unchanged 42M-9 indicate that 42M-9 is metabolized and that the fraction metabolized is independent of inhaled concentration in the range studied, the mathematical analysis of pulmonary desaturation curves indicating that the concentration of 42M-9 in inhaled air affects only the values of intercepts but not the values of the rate constants (fig 3). This is in agreement with a mathematical model of uptake and excretion of inhaled drugs described by 1st order reactions.[10,11]

A differential matrix equation, describing a linear 4-compartmental model,[10] was used for prediction of uptake and desaturation of 42M-9 at a constant inhaled concentration. Considering the lung as the only excretory pathway,[11] the predicted total uptake was lower than the measured total uptake, and the predicted pulmonary desaturation (100%) was greater than the measured desaturation (60%) as demonstrated in table 2. The same observation was made comparing predicted and measured rates of pulmonary desaturation (fig 3, dashed line). The increased uptake and lower desaturation have been attributed previously to metabolic clearance.[10,12] Since only a negligible amount of unchanged 42M-9 was excreted in urine, it is postulated that 40 percent of the dose was metabolized during or following exposure.

The rate of 42M-9 metabolism (mg/min) was estimated from the difference between pulmonary uptake rate at the end of 1 hour of exposure, determined according to equation I, and the calculated retention rate of 42M-9 in tissues of 3 major pharmacokinetic compartments after 1 hour exposure to the measured arterial concentration.[10-12] The mean metabolic rate equaled 9 mg/min in group I and 48 mg/min in group II. The metabolic coefficient (which is the ratio of metabolic rate to inhaled concentration expressed as mg/L),[12] was equal to 2.6 L/min for both groups. The direct dependence of rate of metabolism on inhaled concentration supports the assumption of a 1st order reaction in the range of concentrations studied. This is further supported by the close agreement between the measured rate of pulmonary washout and a desaturation curve predicted by a mathematical model which assumes metabolic clearance to be a 1st order reaction, the rate constant of which is derived from a metabolic coefficient[10] of 2.6 L/min (fig 3).

The fraction excreted as metabolites in urine accounted for 20 percent of uptake and was independent of inhaled concentration, in the range of concentrations used in these studies. The ratio of amounts of 42M-9 exhaled and excreted in urine was the same in groups I (3.34 ± 0.76) and II (3.24 ± 0.51). This supports the conclusion made above from analysis of uptake and pulmonary washout, namely that in the range of concentrations tested, there was no concentration-dependent effect on the extent of metabolism.

Increased fluoride concentration was observed in blood and urine of volunteers exposed to 42M-9. Fluoride concentrations in blood and urine and the pattern of fluoride clearance in group II are comparable to those observed in patients receiving enflurane anesthesia[7] and are smaller than those observed in patients receiving methoxyflurane anesthesia.[8] However, since the concentration of 42M-9 would be twice that used in group II, and as an anesthetic would be used for a longer period, renal impairment similar to that which follows methoxyflurane anesthesia[1,2] might occur.

Increased fluoride was also found in skeletons of mice and rats anesthetized for 2 hours by IP-administered 42M-9. Using a procedure described previously,[13] 1.3 percent of fluorine administered in the form of 42M-9 was recovered from skeletons of mice 48 hours after injection. In similar experiments, 0.6 percent of the dose administered to rats was recovered in skeletons. In these animal studies, the extent of biodegradation to fluoride was not effected by Na-phenobarbital pretreatment.*

The other metabolite, determined in this study as a nonvolatile organic fluorine, was excreted rapidly, and was equivalent to 11 percent of uptake. In terms of latency of

†Excretion curves exhibit two time constants.

peak excretion and half-time, it is one of the most rapidly excreted metabolites of any anesthetic agent in use (table 4). Another postulated metabolite of 42M-9 is bromide.[6] Our attempt to quantitate its urinary excretion failed because of inadequacy of available analytical methods and because bromide is excreted very slowly and does not follow a regular excretion curve, its excretion being dependent on metabolism and excretion of chloride.[14]

Despite the large availability of 42M-9 for biotransformation, the compound was metabolized to a small extent compared with other soluble anesthetic agents. The major clearance pathways vary for different anesthetic agents, depending on their physical and chemical properties. In general, high vapor pressure and low solubility favor pulmonary excretion; high solubility and chemical instability favor metabolism. The rate of pulmonary clearance of a drug is inversely related to its blood-gas partition coefficient.[15] Accordingly, isoflurane[16] and enflurane[7] are removed from the body mainly by the lung, methoxyflurane[8,9] and trichloroethylene[17-19] by biotransformation. The physical properties of fluroxene favor pulmonary excretion; however, only 60 percent is exhaled.[20]

A number of halogenated anesthetics, arranged in order of increasing blood-gas partition coefficient, are compared in table 5 with respect to fraction of uptake exhaled unaltered and excreted in urine. The high solubility of 42M-9 and its low vapor pressure favor retention; its persistence in the body provides optimum conditions for biotransformation. Since similar fractions of uptake (approximately 60%) of fluroxene[20] and 42M-9 are exhaled despite their different physical properties, it is postulated that 42M-9 molecules are more stable than fluroxene. Similarly, we can postulate that 42M-9 resists biotransformation more than methoxyflurane and trichloroethylene since, despite similar physical properties, a considerably larger fraction of 42M-9 is exhaled than of methoxyflurane[8] and trichloroethylene.[17]

Recovery studies of volatile anesthetics in man have never accounted for 100 percent excretion (table 5). The unrecovered fractions of uptake of the fluorinated volatile anesthetics are related to the quantity of urinary metabolites recovered (table 5) and inversely related to the exhaled fractions. The unexcreted fraction of isoflurane,[16] which is metabolized very little[21] or not at all,[16] is small and could be attributed to experimental errors; but in the cases of enflurane[7] (14%), fluroxene[20] (32%), and methoxyflurane[8] (40%), the unrecovered fraction is so large that another explanation must be given. Other excretory routes, feces[3] and skin,[19,22] were found to be negligible.

It has been shown that as a result of the metabolism of certain drugs[23-31] including

halothane,[5,23-25] reactive intermediates are formed which are covalently bound to tissue components. The covalently bound moieties tend not to be excreted, and to be associated with necrosis[5,23-29] and carcinogenicity.[30,31] It is possible that the unrecovered fraction of halothane[32-34] as well as of other anesthetics may also remain covalently bound in the body. A relatively small fraction of 42M-9 remained unrecovered (11%) in our study.

Exposure of volunteers to subeffective and analgesic concentrations of 42M-9 for 1 hour caused *no clinically significant changes in clinical laboratory tests* and cardiovascular parameters. However, Carrow's group[35] reported that anesthetic concentrations of 42M-9 in human subjects resulted in an unusually high incidence of ventricular arrhythmias, which certainly will interfere with its acceptance as a commercial anesthetic agent.

Cardiovascular Effects of Lidocaine During Acid-Base Imbalance

RONALD W. YAKAITIS, MD*
JOHN D. THOMAS, MD†
JOHN E. MAHAFFEY, MD‡
Charleston, South Carolina§

Although lidocaine HCl is often given to critically ill patients with ventricular tachyarrhythmias, its use is not without hazard. To investigate whether acid-base disturbances and their subsequent effects on molecular ionization influence cardiovascular (CV) response to lidocaine, dogs in normal acid-base balance, metabolic acidosis, respiratory acidosis, and respiratory alkalosis were given 2 or 4 mg/kg lidocaine IV. Heart rate (HR), PR and QT intervals, MAP, LVEDP, LV dp/dt, and LV dp/dt ÷ CPIP were measured at intervals. In all groups a slight increase in mean HR occurred after 2 mg/kg. Generally, myocardial contractile force was depressed in direct proportion to dose. Essentially, the CV response to lidocaine was not altered by any clinically remarkable degree by pH disturbances. Responses differing from those observed during normal acid-base conditions could not be significantly correlated with changes in pH or $Paco_2$. Results suggest that, in the intact animal, the CV effects of lidocaine, administered in therapeutic doses, are not appreciably influenced by clinically encountered states of acid-base imbalance.

THE antiarrhythmic efficacy of lidocaine hydrochloride has been firmly established.[1,2] Although safe in most instances, overdosage may cause profound hypotension, and clinical conditions that reduce distribution volume or hamper metabolism may cause lidocaine accumulation through delayed plasma clearance.[3]

To some extent, the cardiac action of a local anesthetic may be determined by the degree of drug ionization. Such is the case with procaine, as observed in the isolated heart.[4] Ionization is influenced by the relationship between the dissociation constant (pK_b) and the environmental pH.

As some patients given lidocaine may have significant pH disturbances, these experiments studied, in normal intact dogs, the cardiovascular (CV) response to clinically recommended doses of lidocaine given during commonly-encountered states of acid-base imbalance.

METHODS

Twenty-eight mongrel dogs, 12 to 20 (mean 15) kg in weight, were anesthetized with chloralose (50 mg/kg) and urethane (750 mg/kg). Succinylcholine (2 mg/kg) was administered IM to prevent movement during measurements. After intubation, ventilation with air was controlled with a Bird® Mark 8 respirator. Tidal volume was adjusted to maintain $Paco_2$ at 35 to 45 torr. Left ventricular end-diastolic pressure (LVEDP) was measured with a Statham SF-1 catheter-tip transducer inserted

Paper received: 1/7/76
Accepted for publication: 3/15/76

through a femoral artery into the left ventricle. This catheter signal was also channelled through a Statham resistance-capacitance (RC) differentiator for simultaneous display of left ventricular dp/dt. The remaining femoral artery was cannulated to record aortic blood pressure (BP) through a Statham P23 db pressure transducer. Lead II of the ECG was monitored continuously. All pressure and ECG data were recorded on an Electronics for Medicine DR8 polygraph. Arterial blood-gas determinations were made with a Radiometer ABL-1 analyzer immediately after sampling. Rectal temperature in each dog was maintained, with a heat lamp, at 38 ± 1° C.

Initially, each animal was placed in acid-base balance ($Paco_2$ 35 to 45 torr, pH 7.35 to 7.45, base excess ± 5). Control measurements of heart rate (HR), mean aortic blood pressure (MABP), LVEDP, and the first derivative of left ventricular pressure (LV dp/dt) were made. An additional estimate of myocardial contractility (dp/dt ÷ CPIP)* also was calculated. The PR and QT intervals of the ECG were also measured. Lidocaine (1%) was then injected IV, 14 dogs receiving a dose of 2 mg/kg and 14 receiving 4 mg/kg.

Measurements were repeated 1, 5, and 20 minutes after injection. Thirty minutes after the last measurement, a randomly selected state of metabolic acidosis ($Paco_2$ 35 to 45 torr, pH 7.05 to 7.15, base excess <-5), respiratory acidosis ($Paco_2$ 70 to 85 torr, pH 7.05 to 7.15, base excess ± 5), or respiratory alkalosis ($Paco_2$ 10 to 15 torr, pH 7.60 to 7.75, base excess ± 5) was induced. Metabolic acidosis was produced with an infusion of 0.3 M lactic acid. Respiratory acidosis was induced by ventilation with 10 percent CO_2 in air. Hyperventilation with air was employed to create respiratory alkalosis.

The prescribed acid-base state having been attained, a 10 to 20-minute period was allowed for CV stabilization. Cardiac measurements were then made before and 1, 5, and 20 minutes after giving lidocaine. In a random manner, no more than 2 abnormal acid-base states were studied in any dog, and each dog received the same dose of lidocaine for each experiment. The continuity of an acid-base state was monitored throughout the observation period by frequent blood-gas analyses.

Mean values for HR, MABP, LVEDP, LV dp/dt, and dp/dt ÷ CPIP were calculated. Paired *t*-tests were used to determine significant differences from control within individual groups. Unpaired *t*-tests were employed to compare changes observed in normal dogs with changes during aberrant acid-base conditions.

RESULTS

Seventy-two experiments were performed in the 28 dogs. Control values for pH and $Paco_2$ were similar between respective groups at both dosages studied (table 1). Mean values for all CV variables measured are presented in tables 2 and 3. In most instances, the greatest alterations in MABP, LVEDP, LV dp/dt, and dp/dt ÷ CPIP

*dp/dt ÷ CPIP = the ratio of LV dp/dt to a common peak isovolumic pressure (CPIP). The denominator is the highest isovolumic pressure common to both control contractions and those following pharmacologic intervention. This formula gives an estimate of myocardial contractile force while minimizing the influence of HR, preload, and afterload in the intact heart.[5]

occurred within 4 to 5 minutes after injecting lidocaine. In 5 to 20 minutes, these values generally returned toward control levels. Maximum deviations in heart rate tended to be more dispersed throughout the 20-minute observation period. No group demonstrated appreciable ECG changes of either configuration or intervals (table 4).

Response to 2 mg/kg Lidocaine.—Mean HR within each group did not change significantly. However, dogs in respiratory alkalosis experienced a slight slowing of HR instead of the increased rate exhibited by other groups. Although the mean change in HR at 1 minute was highest (+9.6%) during respiratory acidosis, this change was not significantly greater than that demonstrated by dogs in normal acid-base balance.

Changes in MABP were clinically insignificant.

Values for LV dp/dt and dp/dt ÷ CPIP were generally depressed after lidocaine; a slight increase in LV dp/dt and decrease in LVEDP were noted with respiratory acidosis.

Response to 4 mg/kg Lidocaine.—HR was not remarkably affected at this dose. During respiratory acidosis, the progressive fall in HR and decrease in BP were significantly different from those observed after 2 mg/kg. At 1 minute, both indices of myocardial contractility were appreciably reduced in all animals. The degree of depression in each group was of similar magnitude. In response to decreased contractility, all groups manifested a significantly increased mean LVEDP at 1 minute.

DISCUSSION

Given in the recommended bolus dose of 0.5 to 1.5 mg/kg, the therapeutic plasma concentration of lidocaine is 2 to 5 mcg/ml. This dosage does not appear to significantly depress CV function, even in patients with underlying hypertensive, valvular, or coronary heart disease.[1,6,7] Generally, low doses of lidocaine will actually increase heart rate, systemic arterial pressure, and cardiac output. This phenomenon has been ascribed to a central cardiostimulative effect of the drug.[8]

Administration of lidocaine is not entirely without hazard. Central nervous system signs of drowsiness proceeding to convulsions may be the initial indications of toxicity. These signs may become evident at plasma levels as low as 5 to 6 mcg/ml.[9] Rapid injection or absolute or relative overdosage may cause profound hypotension.[10] Electrophysiologic complications such as sinus standstill and A-V block have occurred, even with approved dosages.[11,12]

Several hypotheses for untoward effects may be proposed. First, a single IV injection of 50 to 100 mg of lidocaine has a pharmacologic half-life of 10 to 20 minutes and

an elimination half-life of 1 to 2 hours. Metabolism to inactive products takes place in the liver. With liver dysfunction and volume distribution abnormalities, a substantial prolongation of the elimination phase was found[3] in patients with hepatic cirrhosis or congestive heart failure. Unless total dosage is reduced in the presence of these disease states, cumulative drug effects will occur much sooner than in normal individuals.

Second, it has been shown that the increased extracellular K^+ concentration which surrounds ischemic or infarcted tissues will enhance the depressant properties of lidocaine.[13] Thus, normally therapeutic blood levels may cause toxic manifestations in a hyperkalemic milieu.

Third, the degree of ionization of the molecules of a local anesthetic partially determines its local and systemic effects. Ionized lidocaine is primarily responsible for conduction block inside the peripheral nerve.[14] Using procaine in an isolated heart preparation, elevation of the stimulation threshold and prolongation of conduction time appear to depend upon the concentration of ionized molecules, while the nonionized drug is responsible for negative inotropic activity.[4]

According to the Henderson-Hasselbalch equation, degree of ionization depends on the relationship between pH and pK_a, the pH at which 50 percent of a given drug is ionized. Since local anesthetics are weak bases (lidocaine $pK_b = 7.86$), an acidotic medium will cause more ionization; an alkaline environment maintains the molecule in its lipid-soluble, nonionized form. At pH values of 6, 7, and 8, the percentages of ionized lidocaine in solution are 98.6, 88, and 42 percent, respectively.

In vitro heart studies with lidocaine, similar to those with procaine, have not been reported; however, at least one toxic effect of lidocaine is influenced by pH: the cortical seizure threshold to lidocaine in intact cats is lowered as $Paco_2$ increases.[15] This finding suggests that a high intraneuronal CO_2 concentration may generate enough intracellular acidosis to significantly increase the concentration of the pharmacologically active lidocaine cation.

Critically ill patients often have associated acid-base derangements. In our study, a clinically representative pH spectrum was induced in intact dogs. Administration of 2 and 4 mg/kg of lidocaine to dogs in acid-base balance produced changes in HR, MABP, and myocardial contractile force similar in magnitude to those observed by other investigators.[16] Deviations in pH within the range of 7.1 to 7.7 did not appreciably alter the effect of lidocaine on the CV variables measured.

Dogs in respiratory acidosis tended to be more susceptible to tachycardia and hypotension, respectively, after 2 and 4 mg/kg of lidocaine. However, this sensitivity could not be significantly correlated with changes in either pH or $Paco_2$. Although independent of pH, myocardial contractile force did appear to decline in proportion to the dose of lidocaine. A notable exception was the slight increase in LV dp/dt and subsequent decrease in LVEDP produced by injecting 2 mg/kg during respiratory acidosis. This heightened inotropy may have been apparent only because it was accompanied by a concurrent increase in HR.

It is possible that compensatory mechanisms in the intact animal were responsible for the inability to demonstrate greatly altered responses to lidocaine in the presence of pH abnormalities. Isolated heart studies would be necessary to delineate the direct effects of lidocaine interaction with pH and CO_2. More intricate electrophysiologic analyses might have revealed subtle effects on conduction. Higher doses of lidocaine at greater extremes of pH might also provide other results. However, such conditions are not relevant within the usual realm of clinical experience.

Whether the antiarrhythmic properties of lidocaine are substantially affected by pH alterations remains to be determined. To the extent that animal data may be applied to man, our results suggest that the response of the normal intact heart to lidocaine, administered in currently recommended doses, is not modified to a clinically significant degree by routinely encountered states of acid-base imbalance.

UNEXPLAINED HEPATITIS FOLLOWING HALOTHANE (UHFH). Two hundred and three patients (177 received halothane) developed postoperative jaundice and were evaluated as to etiology by a panel of hepatologists without knowledge of the anesthetic drugs utilized. After excluding all patients with an identifiable cause for the jaundice there remained 76 patients with unexplained hepatitis following halothane (UHFH). Ninety-five percent (71 patients) had been previously exposed to halothane and over half had received the drug within 4 weeks. Of the 76 patients with UHFH 9 had experienced unexplained jaundice after previous halothane exposure and in 7 of these the latent period before the onset of jaundice was shorter during the current episode. Twenty-nine were obese, 52 were aged 41-70 and 53 were female. Twenty patients in the UHFH were subsequently anesthetized without halothane and manifested no hepatic dysfunction although a "halothane free" machine was used in only 1 case. The overall death rate was 23 percent and 20 percent in the UHFH group. The clinical and biochemical features of UHFH were indistinguishable from viral hepatitis. Presence of autoantibodies and esinophilia were increased in patients with UHFH. The authors conclude that reexposure to halothane at short intervals may cause hepatitis but such a complication is rare. *(Walton B, Simpson BR, Strunin L et al: Unexplained hepatitis following halothane. Brit Med J 1:1171-1176, 1976)*

Case History Number 93: Congenital Lobar Emphysema

JOHN T. MARTIN, MD*

IN DECEMBER, 1974, a son was born to healthy parents of an older normal child. The pregnancy, labor, and delivery were medically unremarkable. There was no known family history of congenital anomalies. Within the first month, the diagnosis of Down's syndrome was made, the infant exhibited chronic tachypnea on a routine examination, and his parents reported that his respirations were usually labored or "hard."

At age 8 months, he was hospitalized elsewhere because of "atelectasis" of his right upper lobe (RUL). He recovered after treatment with a chest tube and, perhaps, antibiotics. Neither additional data about his hospitalization nor chest roentgenograms were available from the institution in question.

Because of poor growth and development, the family physician was contacted when the infant was 11 months old. A cardiac murmur was evident at that time, and subsequent cardiac catheterization confirmed the clinical impression of an endocardial cushion defect. Digitalization was begun, for reasons that are uncertain in retrospect.

Evidently the baby was generally healthy until he developed gastroenteritis at age 13 months and was hospitalized with diarrhea, fever, dehydration, and coffee-ground emesis. He was transferred to this Medical Center with the additional diagnosis of pneumonia. He responded to therapy, was subsequently recatheterized to substantiate the diagnosis of endocardial cushion defect, and was maintained on digitalis. The ECG showed a regular sinus rhythm with 1st-degree heart block, right bundle branch block, a left anterior hemi-block, and right ventricular hypertrophy. No comment about chronic respiratory distress was recorded. He was discharged in satisfactory condition.

One month later, at age 14 months, he contracted an upper-respiratory-tract infection. On admission to his home town hospital, congestive heart failure was obvious, and he was transferred to the Medical Center on 30 January, 1976. His weight was 5.2 kg, height 70 cm, rectal temperature 38.3° C, and he had a mild but definite pectus escavatum. The right axillary tube thoracostomy scar was well healed and his liver was enlarged to palpation. Tachycardia, cardiomegaly, and a grade-3/6 pansystolic murmur were evident. Intercostal retraction on inspiration was significant, and medium rales could be heard bilaterally over the lower half of the posterior chest, with coarse, diffuse ronchi throughout all lung fields. His chest x-ray showed bilateral apical infiltrates and right-lower-lobe (RLL) atelectasis. The therapeutic regimen included appropriate antibiotics, furosemide diuresis, postural drainage, chest physiotherapy, 40 percent supplemental O_2 by hood or mask, and continued digitalization.

Respiratory distress continued, with tachypnea (rate 60-80), peripheral cyanosis, progressive atelectasis of the RUL and RLL, and poor aeration of the right hemithorax. Transnasal aspiration of the trachea provoked an ineffective cough and produced minimal amounts of thin, whitish secretions. His conditioned deteriorated slowly. On the 3rd hospital day, because of the onset of respiratory failure with a rate of 110, his trachea was gently and easily intubated transorally with a size-3.5 plastic tube. He received small doses of morphine sulfate IM to permit adequate volumetric ventilation.

To compensate for a poorly fitting endotracheal tube, 100 ml of tidal volume was

This feature conducted by John T. Martin, MD, Associate Editor.

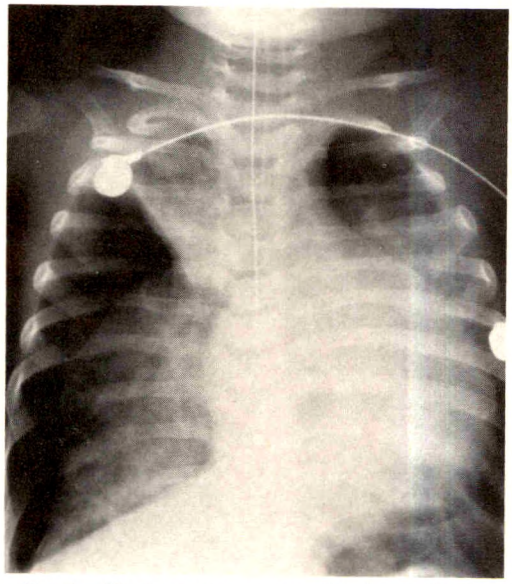

FIG 1. Chest roentgenogram showing collapse of upper and lower lobes. Area lateral to compressed lung tissue showed faint lung markings of hyperinflated RML on original x-ray film.

needed from the respirator. At 35 breaths/min with an F_IO_2 of 0.4, this produced blood-gas values of pHa 7.42, $PaCO_2$ 38 torr, PaO_2 50 torr, SaO_2 88 percent. That evening, the chest x-ray was unchanged, mild respiratory alkalosis was present, borderline hypoxia persisted on the same F_IO_2, a questionable plug of mucus was recovered on tracheobronchial aspiration, his color had improved slightly, and breath sounds were somewhat improved over the right hemithorax. A trial of F_IO_2 0.5 produced little elevation in his PaO_2 (50 up to 54), which his attending pediatric cardiologist attributed to his congenital cardiac defect. An end-expiratory pressure (PEEP) of 3 cm H_2O was added to the ventilatory circuit.

The following morning (hospital day 4) blood-gas values were pHa 7.51, $PaCO_2$ 24 torr, PaO_2 60 torr, on F_IO_2 0.4. Physical examination and chest x-ray were unchanged; the working diagnosis was atelectasis of the RUL and RLL, with an intervening pneumothorax. Review of the chest films by an attending anesthesiologist/intensivist introduced the diagnosis of congenital lobar emphysema with a now-isolated right middle lobe (RML) (fig 1). Bronchoscopy and bronchography followed by lobar resection was suggested. Because of the cardiac anomaly, additional consultations were awaited.

On hospital day 6, the baby was gaining weight, had increasing cyanosis and cardiac failure, urine output was decreasing, and blood from a heel puncture indicated that K^+ and BUN levels were rising. The ECG showed slight digitalis effect but no confirmatory evidence of the alleged hyperkalemia, which was then attributed to the presence of tissue fluid in the blood sample as a result of the heel being squeezed to improve blood flow at the puncture site.

Ketamine-succinylcholine-O_2 anesthesia was administered to permit bronchoscopy and bronchography, which demonstrated an obstructed RML. No foreign body could be found, and the procedure did not improve the RUL and RLL atelectasis. Resection of the RML was agreed upon but was delayed until better control of the baby's fluid and electrolyte status could be achieved. After the bronchoscopy, good diuresis was obtained from furosemide, a mild but compensated respiratory alkalosis was present, and the PaO_2 was acceptable.

Early in the morning of the 7th hospital day, 15 hours after bronchoscopy, the infant began to struggle against the respirator. Since the endotracheal tube was properly positioned, pancuronium in incremental doses up to a total of 0.08 mg/kg was used to restore respiratory control. Tracheal aspirations recovered small amounts of whitish secretions. Good ventilation was evident over the left hemithorax thereafter. Fifteen minutes later, the nurses observed a sudden onset of severe bradycardia, which then became asystole. Resuscitation was begun with 100 percent O_2, delivered by controlled manual ventilation from an anesthesia bag, and closed-chest cardiac compression was started. The heart rate promptly returned to more than 100/min, though the color did not improve. During the resuscitation, the endotracheal tube was briefly displaced into the right mainstem bronchus, was suspected and confirmed by x-ray, and was repositioned into the lower trachea and reconfirmed by x-ray. Following resuscitation, the color remained poor, the pupils were sluggish, the baby was listless without sedation, the hyperkalemia became more intense, and he could be ventilated without requiring pancuronium relaxation.

By midmorning his abdominal girth had begun to increase, unclottable blood was recovered in small amounts when the tracheobronchial tree was aspirated, breath sounds deteriorated over the left lung, and he became mildly hypothermic despite extrinsic

heating. Bradycardia recurred and closed-chest cardiac compression was begun to assist his impaired cardiac output. Shortly thereafter, the heart ceased beating and no effective rate or rhythm could be restored despite all resuscitative drugs, ventilation with 100 percent O_2, and electric shock for 3 episodes of ventricular fibrillation. Necropsy did not define the reason for the obstructed middle lobe bronchus.

DISCUSSION

Hyperinflation of lung tissue as the result of a functioning one-way valve mechanism in the tracheobronchial tree is, fortunately, infrequent. Possible in either the infant or adult, it may present as a respiratory emergency or may unexpectedly complicate the administration of an anesthetic. Awareness of the etiology and pathophysiology of the lesion permits the anesthesiologist to suspect its presence and to modify his management accordingly.

In the adult, hyperinflation of a segment, lobe, lobes, or an entire lung may occur if a functional check-valve develops in an air passage, permitting gas flow on inspiration but obstructing on expiration and trapping gas behind it. The pulmonary tissue distal to the obstruction is gradually pumped up to encroach upon neighboring lung lobes, shift the mediastinum and heart, and, perhaps, to cross the mediastinum and compress portions of the contralateral lung. Symptoms obviously depend upon the amount of hyperinflation and the basic competence of the remaining lung tissue. Whether, and at what point, pulmonary perfusion is impaired is uncertain, but a ventilation/perfusion mismatch can easily be presumed.

At some point, the ability of the check-valve to open on inspiration is undoubtedly terminated by the overexpanded tissue, and the offending portion of the lung becomes bronchially isolated. While controlled ventilation at this point might not further overexpand that portion of the lung, introduction of an anesthetic gas, such as N_2O could easily, were perfusion intact, cause molecular diffusion into the isolated area, thereby increasing its pressure and undoubtedly its volume. Little imagination is needed to understand the undesirable potential of such a process.

Knowledge about congenital lobar emphysema is not new. Meyer[1] reported the entity in 1858, as did Nelson[2] in 1932. Treatment by lobectomy was described by Leahy and Butsch[3] in 1949 and by Robertson and James[4] in 1951. The ball-valve process, which produces hyperinflation as described above, was recognized. However, diagnosis and therapy may be delayed, as in the case presented, if an unwarranted controversy develops over whether the process is primary atelectasis with "compensatory" overexpansion or whether the expansion is primary and collapses adjacent tissue secondarily. Were the former true, one would expect to see a loss of volume in the atelectatic hemithorax with an elevated diaphragm and a mediastinal shift toward the lesion. When, as in the baby presented, the diaphragm of the involved side is flattened and the mediastinum is shifted away from the pathologic process, no case can be made for loss of volume, and the mechanics of the situation becomes clear.

Etiologically, lobar emphysema is not a simple entity. Bronchial obstruction may result from local inflammation, a foreign body, mucosal flaps,[5] softened bronchial cartilages[2,6] which permit bronchial collapse, external compression[7,8] by vessels or tissue masses, anatomically narrowed bronchi,[9] a mucus plug[10] unrecoverable by tracheobronchial aspiration, or a luminal adenoma. No evidence reliably associates congenital lobar emphysema with overvigorous infant resuscitation[10] as has been the case with pulmonary interstitial emphysema.[11,12] Difficulty in demonstrating bronchial obstruction at autopsy permits consideration of the possibility that emphysema has occurred primarily, but this does not account for the clinical picture of overdistension and encroachment. A more detailed etiologic debate is available in Murray's excellent review.[10]

The association of congenital lobar emphysema and heart disease has been well documented.[13,14] In 1 series[14] eight of fourteen cases had heart disease; in another,[13] fourteen of seventeen. Stanger and coworkers[15] demonstrated that either enlarged pulmonary arteries or an enlarged left atrium can compress bronchi. Particularly vulnerable are the left mainstem bronchus and the left upper and right middle lobar bronchi. Associated with this extrinsic bronchial compression is marked softening of the collapsed cartilagenous rings. The two most frequently associated congenital heart lesions are ventricular septal defect (VSD) and patent ductus arteriosus; each produces an increase in pulmonary blood flow.[13] While both the cardiac and the pulmonary lesion may be

severe, hyperinflation is generally the more disruptive situation, and its correction is usually required before cardiac surgery can be contemplated. Pierce's group[13] reported 4 cases of overdistension without adjacent lobe collapse or mediastinal shift, in which they repaired the cardiovascular pathology (2 cases of patent ductus, 1 VSD with pulmonary atresia, 1 Tetralogy of Fallot with absent pulmonary leaflets), with subsequent nonsurgical resolution of the pulmonary the chances of an accidental fluid overload.

Symptomatic congenital lobar emphysema is most frequently treated by surgical excision of the involved lobe(s). Murray[10] reports a mortality rate of 50 percent for nonsurgical "conservative" therapy, with 75 percent of the survivors developing persistent emphysema. Operative mortality in his review was 7 percent. Needle aspiration of the hyperinflated lobe has been tried without acceptable results, or with fatalities.[10] Following lobectomy, most patients enjoy normal growth and development unless hampered by other congenital defects.

Several further problems with the case presented merit comment. Whether the syndrome was present in a mild form shortly after birth is unclear; suspicion that it was is supported by the parents' report of "rapid" and "hard" breathing as a chronic characteristic. Review of the chest roentgenograms from the first admission of this infant to the Medical Center (age 13 months) shows the middle lobe to be hyperinflated and the lower lobe partially collapsed but without flattening of the diaphragm or mediastinal shift (fig 2). The presence of congenital heart disease and pectus excavatum implies vascular compression of the RML bronchus as the etiologic factor in a ball-valve mechanism. It also suggests secondary bronchial chondrodysplasia, and may be a reason for the absence of a pathologic diagnosis of bronchial obstruction at necropsy. Intercurrent respiratory infection undoubtedly was the event that provoked the overt respiratory failure by accentuating underlying pathology in the remaining pulmonary tissue or by obstructing a RML bronchus that was only partially occluded and not previously productive of hyperinflation and encroachment.

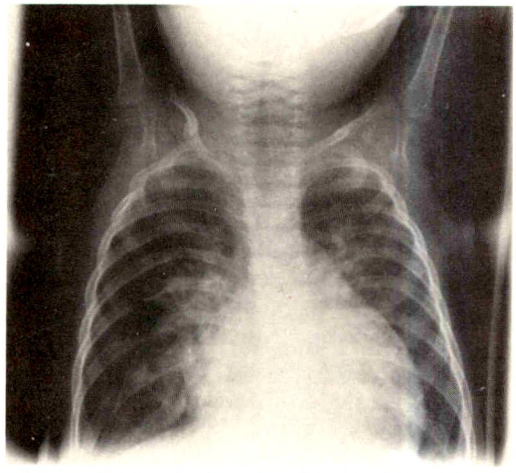

FIG 2. Chest roentgenogram from earlier admission showing partial collapse of RLL with lung markings of encroaching RML visible laterally.

The "pneumothorax" which was treated by a chest tube at age 8 months can be postulated to have been an overdistended RML that was deflated by the chest tube. It is tempting to propose this as a form of decompressive therapy, but literature experience with such an approach has not been encouraging.[10]

Because this infant was intubated and placed on mechanical ventilation without acute worsening of the encroachment, one can presume that the inflammation had fully occluded the RML bronchus by that time. The perfusion status of that lobe is uncertain because hypoxemia can be anticipated from the congenital heart disease and might easily mask shunts attributable to a $\dot{V}/\dot{Q}$ mismatch. Assuming perfusion and shunting to be present, however, one can readily understand why N_2O would be an unwise and rapidly disastrous addition to any anesthetic technic proposed for the infant.

The differential diagnosis of pneumothorax vs congenital lobar emphysema might be difficult under certain circumstances. In this instance RUL and RLL collapse with RML hyperexpansion rendered the right apex and base relatively radiopaque (fig 1), while the intervening area was radiolucent and contained definite but faint lung markings. A pneumothorax usually opacificies the deflated lung, which extends out from the hilum toward a clear periphery, with no lung markings in the radiolucent area, and with a smooth contour for the visceral pleura of the collapsed whole lung. Hyperexpansion of lobes of the left lung may be harder to differentiate from a pneumothorax, but the presence of lung markings in the radiolucent area should cause strong diagnostic suspicion. Should radiolucency extend from the hyperinflated side across the mediastinum without evidence of pneumomediastinum or

subcutaneous emphysema, little danger exists of confusing lobar emphysema with pneumothorax.

Reliance upon blood samples derived from stab wounds in the heel for blood-gas and electrolyte data is not infrequent in pediatric ICU practice. If the heel is not warmed to arteriolize, as nearly as possible, the capillary blood before the stab wound is made, or if it must be squeezed to obtain enough blood for the specimen and tissue fluid is inadvertently obtained, the values obtained may be confusing or misleading. In situations as tricky as in this infant, it would seem that a strong case can be made for an arterial indwelling sampling port to permit accurate measurements with little trauma to the patient. Great concern should be directed toward knowing the exact volume of crystalloids infused into that arterial line, however, and use of a constant-volume pump for this purpose will lessen the chances of an accidental fluid overload.

The demise of this infant was not thought to be an hypoxic event but more likely to be due to electrolyte imbalance, diffuse intrapulmonary hemorrhage, and intractable heart failure. Whether thoracotomy could have been successful immediately after bronchoscopy and bronchography is impossible to deduce retrospectively. Were a similar situation to arise in the future, however, I doubt that the valid reasoning applied to this infant would delay thoracotomy and lobar resection despite the critical nature of the patient's condition.

Lobar emphysema, then, is an infrequently occuring entity which may pose significant problems for the anesthesiologist. Either a mechanical respirator or manual ventilation during anesthesia may worsen a slightly symptomatic hyperinflated lung segment. Should a patient with a bronchially isolated pulmonary subdivision, as existed in the infant discussed here, be anesthetized with N_2O, the probability exists that diffusion of the gas into the isolated alveoli via intact perfusing vessels would augment the hyperinflation and intensify its acute disruptive pathophysiology. Awareness of these situations and of their mechanics might help avoid otherwise potentially fatal respiratory misadventures.

Bronchial Blockade in a Child with a Bronchopleural-Cutaneous Fistula Using A Balloon-Tipped Catheter

WILBUR F. CANT, MD*
JOHN H. TINKER, MD
SAIT TARHAN, MD
Rochester, Minnesota§

BRONCHIAL blockade has often been used for airway isolation during thoracic surgery. Whenever infectious processes are combined with the surgical requirement that the diseased hemithorax be positioned uppermost, blockade of the offending bronchus seems desirable. Magill-type blockers, tampons, and other devices previously used are seldom found in operating rooms today. Bronchial blockade in children, involving considerably smaller airways than in adults, has in the past been thought very difficult. It may, in fact, be more important to attempt bronchial blockade in infected pulmonary cases in children than in adults, due to the shorter distances for infectious material to travel to contaminate other pulmonary structures.

The following case is reported to call attention to the ease with which bronchial blockade can be achieved with the Fogarty balloon-tipped arterial embolectomy catheter, and also to illustrate its effectiveness not only in blocking secretions but also in allowing adequate positive-pressure ventilation of the remainder of the lung. Further, the case serves to illustrate that a gastight seal can be achieved with this method.

REPORT OF A CASE

Our patient was a 3-year-old girl weighing 13 kg who was apparently well until approximately 1 year prior to operation, when she developed what was diagnosed as a hemophilus influenza pneumonia. This subsequently became an empyema requiring open drainage. She was discharged with an empyema tube bandaged in place (open to

ANESTHESIOLOGIST NEEDED—Board Certified desired with supervisory experience, now have three anesthesiologists and thirteen CRNAs doing all types surgery except open heart. Involved in intensive care, respiratory care, pain clinic, school for CRNAs and student and resident training cooperating with Jefferson Medical School. Lovely family community area. Call (412) 539-9711, ext. 273, or send resume to Mr. K. D. Bowman, Assistant Administrator, Latrobe Area Hospital, Latrobe, Pa. 15650. An equal opportunity employer.

CALIFORNIA—ANESTHESIOLOGISTS. Excellent opportunity to practice and participate in academically oriented program. Delightful California city. Favorable plan of remuneration and time off will be worked out. We can pay your professional liability insurance. Send curriculum vitae in first letter to: Jerome S. Harris, M.D., Director of Medical Affairs, Valley Medical Center, 445 S. Cedar, Fresno, California 93702.

ANESTHESIOLOGIST: Board certified/eligible to join newly formed group of anesthesiologists and nurse anesthetists in New Orleans. Fee for service private practice at 650-bed general hospital and newly opened Pediatric hospital. Write or call Metropolitan Anesthesia Associates, 4520 Melpomene, New Orleans, La. 70185. (504) 822-9331.

FACULTY POSITIONS

Department of Anesthesiology, Charity Hospital, New Orleans, affiliated with LSU and Tulane Medical Schools, has three faculty positions open for board certified/eligible anesthesiologists at Associate-Assistant Professor, Instructor levels. Duties involve teaching, research, clinical supervision. Salaries negotiable. Send inquiries and curriculum vitae to: M. Naraghi, M.D., Director, Department of Anesthesiology, Charity Hospital, New Orleans, Louisiana 70140.

MARYLAND: Positions on the Anesthesia Staff at Baltimore City Hospitals. Excellent fringe benefits and salary. Residency fully integrated with the Johns Hopkins Medical School program. Send CV to Peter Chodoff, M.D., Anes-in-Chief, Baltimore City Hospitals, 4940 Eastern Ave., Baltimore, Maryland 21224.

2 American anesthesiologists, eligible for oral boards in April 1977 from world-famous midwestern center, desire to relocate in Ohio or other state if center is attractive. Extensive experience in vascular, neuro and cardiovascular anesthesia. Contact Box 11-76-A in care of I.A.R.S.

ANESTHESIOLOGIST, 38, ABA certified, university trained, excellent references, seeks assoc. partner or group. No geographic preferences, prefer city or suburb. Available June 1977. Write to Box 11-76-B c/o I.A.R.S.

ANESTHESIOLOGIST—LOCUM TENEMS— 1/77 - 3/77 in multispecialty center in NW lower Michigan. Excellent skiing and winter sports area. Michigan licensure necessary. Practice includes cardiac anesthesia and respiratory care. Share call with three other Board certified anesthesiologists. Contact: J. R. Rasmussen, M.D., c/o Burns Clinic Medical Center, P.C., 560 W. Mitchell, Petoskey, Michigan 49770.

ANESTHESIOLOGIST—BOARD CERTIFIED OR ELIGIBLE to assume position as director of and/or consultant to a hospital anesthesiology department in a new, rapidly growing, 171-bed Midwestern hospital; service area covers 150,000 residents and responds to a medical staff of 50-60 physicians; progressive city of 35,000 with excellent schools, cultural activities, and recreational oppotunities; salary $80,000 base and excellent compensation plan. Send c.v. and references to Michael L. Wintory, Director of Personnel, St. Mary's Hospital, 3333 N. Seminary St., Galesburg, IL 61401.

Rates for classified advertising are $3.00 per line, minimum 5 lines. Box number ads $3.50 per line. Classified Display rates on request. Copy deadline 6 weeks prior to publication. Current Researches, 3645 Warrensville Center Rd., Cleveland, Ohio 44122.

CLASSIFIED ADVERTISING

ANESTHESIOLOGY CHAIRMAN

The Hospital Center at Orange has an exceptional opportunity for a Board Certified or Board eligible Anesthesiologist with a minimum of 10 years experience to coordinate the activities of our Department of Anesthesiology as the Department Chairman. An affiliation with Medical School for a student and house officer training program is being pursued. The selected candidate will be considered for academic appointment to the New Jersey College of Medicine and Dentistry.

A competitive compensation package consisting of administrative fee or salary plus fee-for-service income will be available.

The Hospital Center has approximately 400 beds consisting of two units; namely The Orange Memorial Hospital and The New Jersey Orthopaedic Hospital Unit located in suburban N.J. offering convenient access to New York City and Philadelphia.

Send curriculum vitae to:
Arthur T. Dunn, President
THE HOSPITAL CENTER AT ORANGE
188 South Essex Ave.
Orange, New Jersey 07051
Equal Opportunity Employer

CHIEF OF ANESTHESIOLOGY

Major Midwestern medical center with a medical school affiliation is seeking an outstanding Anesthesiologist to head the Department of Anesthesiology. This is an immediate opportunity to restructure and/or build upon our current team. Our compensation package is exceedingly attractive and the working conditions are excellent as a result of our recently completed, multi-million-dollar expansion program. Please send curriculum vitae to: John D. Silbar, M.D., Chairman, Anesthesia Search Committee, Mount Sinai Medical Center, 950 North 12th Street, Milwaukee, Wisconsin 53233.

LOUISIANA—Tulane University, New Orleans. Immediate positions available for Academic Anesthesiologists in new Department of Anesthesiology. Positions in all anesthetic subspecialties, intensive care and respiratory therapy in new university teaching hospital. Tulane University is an Affirmative Action/Equal Opportunty employer. Curriculum vitae to: Robert R. Kirby, M.D., Department of Anesthesiology, Tulane University School of Medicine, 1430 Tulane Ave., New Orleans, Louisiana 70112.

PEDIATRIC ANESTHESIOLOGY RESIDENCY

Childrens Hospital of Los Angeles

Three-phase program: Clinical, Academic, Investigative, emphasizing practical aspects of anesthesiology related to infants and children.

AMA approval for third-year residency. Positions available from two months to one year.

Apply: George B. Lewis, Jr., M.D.
Head, Division of Anesthesiology
Childrens Hospital of Los Angeles
4650 Sunset Boulevard
Los Angeles, California 90054
Phone (213) 660-2450, Ext. 2262

DIRECTOR/SCHOOL OF NURSE ANESTHESIA. Immediate opening for CRNA with Masters Degree. We have a two-year program with university and medical school affiliation leading to a B.S. degree and CRNA certification. Ability to work independently in curriculum formation and school supervision is essential. Excellent salary and benefit package. If you are seeking a challenging position and career in a large medical teaching center, send resume with salary history and requirements to: Mrs. Anna Barker, Employment Manager, Medical Center Hospitals, Norfolk General Hospital Division, 600 Gresham Drive, Norfolk, Virginia 23507.

FACULTY POSITIONS

New University Department of Anesthesiology seeks full-time faculty (all levels) with interests in intensive care, ambulatory and obstetrical anesthesia. Also, full-time director of pediatric (not neonatal) intensive care and respiratory therapy. Challenging positions for those genuinely interested in teaching students and residents, research and development of a new Department. Pleasant university oriented community of 1,000,000. Excellent schools and living areas. Salaries negotiable. Send curriculum vitae to: R. Bryant Roberts, M.D., Professor and Chairman, Department of Anesthesiology, Wright State University School of Medicine, Dayton, Ohio 45431.

CHIEF ANESTHESIOLOGIST for 200-bed hospital—five modern OR's. All surgical services except open heart and neurosurgery. Excellent job challenge. Salary based on past experience and type of appointment. No malpractice insurance required. For information call or write to Dr. Zwemer, Chief Surgeon, Phoenix Indian Medical Center, 4212 North 16th Street, Phoenix, Arizona 85016. (602) 263-1200. The Indian Health Service is a Federal Employer and Federal Civil Service or Public Health Commissioned Corps benefits and requirements apply. Preference is given to qualified Indian or veteran applicants. IHS is an equal opportunity employer.

adherence of part of the cuff to the underlying tube, causing puckering of the rest of the cuff—this is especially true in older tubes and when the cuff is wet; (4) vocal cord paralysis from muscle relaxant administration during intubation, with recovery of normal cord function during extubation.

We believe all the above factors contributed to our problem.

The clinician should be aware that flange formation can occur not only in cuffs with a large residual volume but also in those with low residual volume if tubes are old or worn. Therefore, all cuffed tubes should be examined closely prior to insertion. Selection of a smaller and newer tube would probably have prevented our problem.

ACKNOWLEDGMENT

The authors express their gratitude to Mr. S. Weiss for the photography and to Ms L. Stock for secretarial assistance.

Humidity Output of the Columbia Pediatric Circle

SIVAM RAMANATHAN, MD*
JACK CHALON, MD†
PETER RAND‡
HERMAN TURNDORF, MD§
New York, New York‖

Rackow and Salanitre[1] have stated that infant circles generate enough moisture (through the neutralization of soda lime by CO_2) to satisfy the humidity requirements of *all* pediatric patients. To verify this assumption, we studied the humidity output of this system on a model patient. Variation in inhalation limb humidity at the Columbia valve,[2] in relation to $\dot{V}CO_2$ and fresh gas inflow, are described and discussed during and after a 2-hour period of stabilization. Recommendations for further humidification, when required, are made.

MATERIALS AND METHODS

A model patient was constructed (fig 1) by attaching a 1 or 2-L anesthetic bag to the patient end of the Columbia valve of a Columbia pediatric system, and flowing CO_2 from a calibrated metered source through the tail end of the bag. A Cascade humidifier** was inserted in the expiratory limb of the circle near the valve. A hygrosensor, connected to a Hydrodynamics Electric Hygrometer Indicator,†† was placed at the valve end of the inspiratory limb. Thermistor probes connected to a Yellow Springs multichannel telethermometer‡‡ were placed: (1) near the hygrosensor in the inspiratory limb, (2) at the outlet of the Cascade, and (3) in ambient air. The thermostat of the humidifier was regulated to maintain outlet temperature at 32° C (the mean temperature measured in the

A Steen valve on the inspiratory limb is not shown.

endotracheal tube of 10 anesthetized children at the level of the incisor teeth or gums). Ventilation was provided by an Ohio pediatric anesthesia ventilator* (series 300/DO).

Four sets of experiments were conducted using fresh dry systems and CO_2 inputs of 15, 30, 45, and 60 ml/min (3 ml/kg body weight),[3] figures estimated respectively to be the $\dot{V}CO_2$ of children weighing 5, 10, 15 and 20 kg. Ventilator settings, using commonly employed ventilatory parameters, were adjusted as follows: (1) Vt = 50 ml, f = 24; (2) Vt = 100 ml, f = 22; (3) Vt = 150 ml, f = 20; and (4) Vt = 200 ml, f = 18, for the 5, 10, 15, and 20-kg model children, respectively.

All experiments were run with fresh gas inflows (FGI) of 1, 3, and 5 L/min. The canister was filled with 900 gm of soda lime USP. Humidity and temperature measurements were recorded at 15-minute intervals. A 1-L anesthetic bag was used at the patient end of the system for the 5 and 10-kg models and a 2-L bag for the 15 and 20-kg models. Room temperature was recorded throughout the study. All experiments were repeated 5 times. Results represent the mean of 5 individual measurements recorded under identical conditions.

RESULTS

The humidity output of the Columbia pediatric circle *after a 2-hour period of stabilization* ranged from 3 mg/L H_2O with a $\dot{V}CO_2$ of 15 ml/min and an FGI of 5 L/min (fig 2) to 20 mg/L H_2O with a $\dot{V}CO_2$ of 60 ml/min and FGI of 1 L/min. Humidity readings at the onset of all experiments ranged between 2 and 3 mg/L H_2O, reaching approximately 50 to 60 percent of stabilized values within 1 hour. Room air remained at 22 and 24° C throughout all experiments.

DISCUSSION

The humidity output of the Columbia pediatric circle, which ranges from 3 to 20 mg/L H_2O after a 2-hour period of stabilization, is generally within acceptable levels.[4] At an FGI of 1 L/min, all humidity values (fig 2) are above 12 mg/L so long as the $\dot{V}CO_2$ attains or exceeds 30 ml/min. The system should, therefore, be further humidified by vaporizers incorporated into the circuitry when it is used on infants weighing 5 kg or less. The FGI should always be kept around 1 to 3 L/min, as at an FGI of 5 L/min, all humidity values fall short of the minimum recommended level.[4]

Despite these mild disadvantages, the construction of the system is sound. With the exhalation tube placed inside the inhalation tube for a distance of 4 cm, the Columbia valve allows it to act as a heat and moisture exchanger, thus further elevating inspired humidity. The absorber contains a trap which drains out of the system the water formed by the reaction of neutralization, thus preventing encrustation within the apparatus. In addition, all gases exhaled into the system are subjected to the germicidal effect of the lime[5] before reaching the ventilator (or bag), thus reducing respiratory cross-contamination.

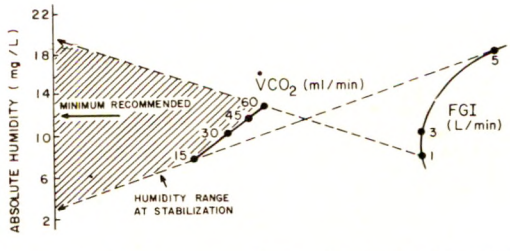

FIG 2. Nomogram predicting the inspired humidity of a child placed on the Columbia circle *after 2* hours of use in relation to $\dot{V}CO_2$ and FGI. Shaded area indicates humidity range of system. To estimate inspired humidity, join FGI value (extreme right) to $\dot{V}CO_2$ (center) and prolong to intersection with humidity line (left.) Read absolute humidity at that point. After 1 hour of use, humidity values are between 50 and 60% of figures derived from this nomogram.

Modification of a Bird® Mark-14 Anesthesia Ventilator for Greater Versatility

C. S. JONES, MB, ChB*

THIS anaesthetic machine (figure)† is a Bird® Mark 14 positive-phase ventilator powered via a Bird N_2O-O_2 blender. The selected gas mixture is delivered through a Fluotec® Mark 2 or any other vaporizer of low internal resistance. A ventilation meter is incorporated in the delivery line to monitor ventilating volumes.

When the patient breathes spontaneously, the machine can be set to assist each respiration to the degree judged necessary by the anesthesiologist. The machine can also be programmed to control ventilation.

Adaptation to enable entrainment of the selected gas mix presently involves gas bleed-off from the common line to a reservoir bag. In the primitive form shown, this bleed-off volume is considerably greater than is necessary and a needle valve control could with profit be installed in the bleed-off line to reduce waste.

If the O_2 supply fails, or gas source pressures vary so greatly that the accuracy of the blender is impaired, an audible signal is emitted and the ventilator will not cycle. Under proper working conditions, the blender will not deliver O_2 in less than 25 percent concentration.

†The apparatus described utilizes principles explored and enunciated by Dr. McKesson 65 years ago.

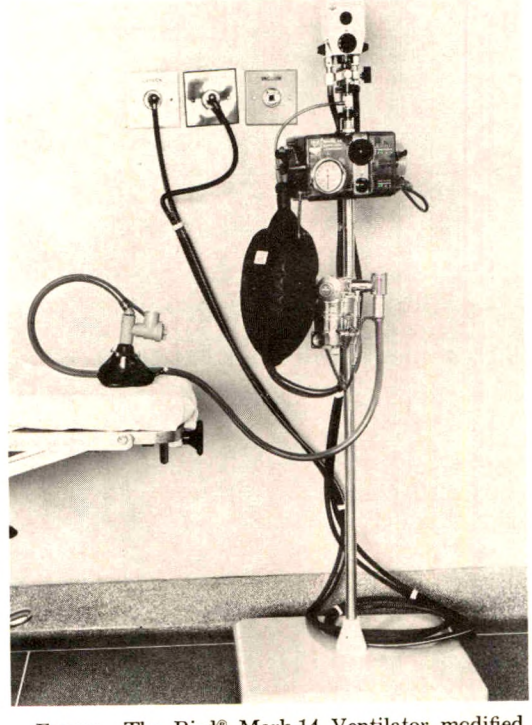

FIGURE. The Bird® Mark-14 Ventilator modified for routine use as a demand-feed anesthetic machine.

This apparatus has been used successfully for over three years, for more than 1000 patients, and for a wide variety of surgical procedures.

Decreased Arterial Oxygenation During Sodium Nitoprusside Administration for Intraoperative Hypertension

JOSEPH L. SELTZER, MD*
JOSEPH B. DOTO, JR, MD†
JAY JACOBY, MD, PhD‡
Philadelphia, Pennsylvania§

UNDESIRABLE hypertension is sometimes associated with morphine-N_2O anesthesia for cardiac surgery. Two common approaches to control of such hypertension are the use of chloropromazine[1,2] and the addition of inhalation agents.[3] In the present study, we used sodium nitroprusside to obtain normal blood pressures intraoperatively, finding this procedure generally useful, with one possible hazard.

METHODS

Seven patients who developed hypertension under morphine-N_2O anesthesia for coronary artery surgery were studied. All had received at least 1 mg/kg of morphine sulfate (range 1.06 to 1.6 mg, mean 1.37 mg), d-tubocurarine, and N_2O-O_2 (50:50). Hypertension was considered present when systolic pressure was 50 torr greater than the highest pressure recorded preanesthetically, or was greater than 200 torr. Heart rate, arterial blood pressure, central venous pressure, and arterial blood gases were recorded before and 15 to 30 minutes after the lowering of the blood pressure with 100 μg/ml of sodium nitroprusside in 5 percent dextrose and water.

The drip was started at 20 μg/min and increased until the desired effect was obtained. The mean rate required to control hypertension was 105.7 ± 19.9 μg/min (range 90 to 150 μg/min). The mean total dose at the time of blood-gas drawing was 2.2 ± 0.7 mg (range 1.5 to 3 mg).

TABLE

Mean ± SD (and Range) of Arterial Blood-Gas Tensions and pH Values for 7 Patients Before and After 15 to 30 Minutes of Sodium Nitroprusside Treatment for Intraoperative Hypertension

	Before	After
Pa_{O_2}	219.1 ± 47.9 (134-275)	143.1* ± 34.1 (100-185)
Pa_{CO_2}	33.7 ± 7.7 (21-46)	34.8 ± 7.4 (20-43)
pH	7.42 ± 0.05 (7.36-7.53)	7.44 ± 0.07 (7.38-7.55)

*$p<0.01$.

RESULTS (table)

Mean Pa_{O_2} values decreased 76 torr ($p<0.01$). Pa_{CO_2} and pH did not change significantly. In 4/7 patients, the infusion was required during bypass also. None had any difficulties in terminating the perfusion procedure, and none had any postoperative recall of the procedure.

DISCUSSION

Arens and associates,[1] in 200 patients who received 1.5 to 3 mg/kg of morphine, had 36 patients with hypertension for whom chloropromazine was used after finding droperidol to be ineffective. Conahan's group[2] also reported the use of chloropromazine to treat hypertension associated with morphine anesthesia. Stoelting and coworkers[3] added low concentrations of halothane to 1 mg/kg

of morphine and N_2O. Although chloropromazine has been found effective in lowering blood pressure, it is an alpha-adrenergic blocking agent and may cause prolonged hypotensive effects which might hamper termination of bypass. Also, patients may sleep for prolonged periods postoperatively after the large doses necessary to lower blood pressure for a prolonged operation. Halogenated hydrocarbons may also prove undesirable because of their myocardial-depressant effects and their possible potential for visceral toxicity.

Sodium nitroprusside offers a valuable alternative because of its rapid onset and prompt termination of action. Styles and colleagues[4] reported an increase in cardiac output in patients under anesthesia in whom sodium nitroprusside was used to induce hypotension to about 45 torr below control; the blood-gas analysis in their study showed a statistically insignificant decrease in Pao_2. Wildsmith's group[5] reported a marked decrease in Pao_2 in patients given sodium nitroprusside to induce hypotension to a systolic pressure of 50 to 60 torr below halothane-N_2O anesthesia.

The marked fall in Pao_2 in our patients, without changes in pH or $Paco_2$, can be best explained by postulating the opening of intrapulmonary shunts and therefore a change in the ventilation:perfusion ratio. Chatterjee and coworkers[6] demonstrated a decrease in pulmonary vascular resistance and pulmonary artery filling pressures in patients with myocardial infarctions receiving sodium nitroprusside. Another possible explanation would be a fall in cardiac output, which has been reported[7] in unanesthetized hypertensive and normotensive subjects receiving sodium nitroprusside.

An Anesthetic Gas Scavenger for the Jackson-Rees System

KENNETH J. CESTONE, MD*
WILLIAM P. RYAN, CRNA†
CHARLES D. LOVING, RN‡
Bennington, Vermont§

WE HAVE developed a Plexiglass® gas evacuator‖ (figure) for pediatric systems that vent exhaust gases from the tail of the reservoir bag. It is extremely simple, requiring no additional apparatus, and fits directly into the bag tail, while standard wall-suction tubing fits directly over the outlet at a right angle to the valve. It

‖Manufactured by Anesthesia Associates, Inc, Hudson, New York.

FIGURE. Plexiglass® Gas Evacuator.

incorporates a bag tail overflow valve, enabling the anesthetist to manually control bag distention and inflation pressures at customary gas flows. The unit is most suitable for modified Jackson-Rees systems.

The evacuator is constructed to prevent the suction from either collapsing the bag or affecting gas flow to the patient; only gases exhausted by the pop-off valve are evacuated. With gas flows of 4 to 10 L/min and inflation pressures below 40 torr, no leakage was detected using moderate wall suction.

We have employed the unit clinically and have found it safe, light, effective, and convenient when used as described. It should not be autoclaved, but may be gas or cold-sterilized.

A Method for Inserting the Carden Tube

JAMES E. COOKE, MD*
JUDITH B. HOOD, MD†
JOHN D. THOMAS, MD‡
Charleston, South Carolina§

PREVIOUS investigators[1] have reported difficulty in inserting the Carden tube. Where anatomic abnormality exists, both trainees and attending anesthesiologists often encounter extreme difficulty. We have developed a safe, relatively easy method for inserting the Carden tube when microlaryngoscopy is planned.

We removed 6 cm of the plastic insulation from a 12-gauge copper wire and formed a "U" bend in the wire at the 6 cm point. The wire was then shaped to follow the natural curve of the patients' airway. The exposed copper wire was lubricated and placed in the Carden tube (figure).

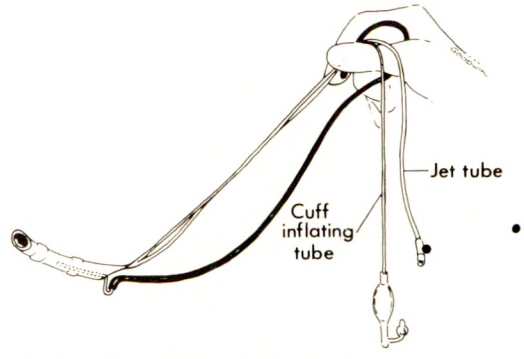

FIGURE. Technic for inserting Carden tube; described in text.

The position of the Carden tube on the stylet is important. The tip end of the stylet should be 1.5 cm from the distal end of the endotracheal tube to prevent injury to the trachea by the stylet. The hump in the stylet is placed at the furthest end of the tube facing posteriorly. This prevents the tube from sliding and turning on the stylet, an additional precaution against injury.

Paper received: 2/13/76
Accepted for publication: 3/29/76

During insertion, the cuff tube and jet tube are held between the fingers at the proximal end of the stylet. Under direct vision, the trachea is exposed and the Carden tube inserted to a position with the proximal end just below the vocal cords. The tubes are released, the cuff inflated, and the stylet removed. The cuff is always inflated before removal of the stylet, to avoid accidental dislodgement of the tube.

We have found our insertion technic to be quite simple and to avoid previously-described difficulties. First-year anesthesia residents have found placement of the Carden tube with stylet as easy as insertion of a standard endotracheal tube. We believe use of the stylet is as safe as and more successful than use of Magill forceps or uterine packing forceps.

Comparison of Dot Test and Digit-Symbol Test for Street Fitness of Outpatients

JOSEPH G. RITTER, MD*
NANCY ANDERSON, MA†

THE Trieger Dot Test has been described[1] as an adequate measure of street fitness for discharge of same-day surgery patients. This test is essentially an adaptation of design 4 of the Bender-Gestalt Visual Motor Test. Since the directions were altered from the original procedure of copying the design and require that the patient connect the dots with a measure of variance used to determine pre- and postoperative scores, previous studies of normal and deviant populations on this test cannot be used to establish the validity and reliability of the test. In addition, scoring of the Trieger is time consuming. Other authors have also suggested criteria for street fitness.[2-5]

As gross motor coordination after anesthesia returns to baseline values more rapidly than fine motor coordination, a measure of fine motor coordination meets one of the criteria essential to establishing the validity of the test. Selection of a widely used and well standardized test would permit the application of already established normative data and reliability studies. Other criteria are that it be short in duration and relatively easy to administer and score. The Digit-Symbol subtest of the WAIS‡[6] and the Coding (Digit-Symbol) subtests of the WISC‡-R[7] and WISC[8] appear to meet these criteria.

METHOD

A 60-day trial was instituted during which both the Trieger Dot Test and the Digit-Symbol Tests were administered to all outpatients for general anesthesia. For the 6-to-8-year age group, the WISC-R Coding Test A (Digit-Symbol); for the 8-to-16-year age group, the WISC Coding B (Digit-Symbol); and for the over-16 group, the WAIS Digit-Symbol subtest were used.

The younger children make 1 or 2 horizontal or vertical lines or a circle inside stars, triangles, etc, in imitation of 5 completed symbols. The adolescent and the adult groups place symbols below prescribed digits duplicating the digit-symbol combinations shown at the top of the test paper. These 2-minute timed subtests provided a measure of speed and accuracy on a routine task yielding a score based on visual discrimination, short-term memory, and fine motor coordination functioning—all basic skills necessary for street fitness. The use

Paper received: 8/1/75
Accepted for publication: 2/20/76

of scaled scores rather than raw scores takes advantage of the extensive standardization of both the WISC and the WAIS tests.

The Digit-Symbol Test is administered with the patient seated at a table or in an armchair with a flat surface available and directions are read aloud by the person administering the test. Following a sample practice section, the patient copies the symbols appropriate to the numbers as rapidly as he can during the 2-minute period. The raw score (total number of correct responses) is converted to a scaled score as per the norms established for each age group.[6-8]

After the return to normal of the patient's vital signs and orientation to hospital, doctor, and room number, the same test is administered to the patient under the same conditions. The raw score is converted to a scaled score as per the norms and the result compared with the preoperative scaled score. If the postoperative scaled score is below the preoperative, the patient is retained and the identical test repeated in ½ hour.

Since repeated testing with the same test form with normal subjects results in slightly improved scores, the question of re-test reliability arises. However, in this case the physician is interested in a return of functioning related to street fitness. For improvement in test performance to occur as a result of increased practice, the functions of visual discrimination, short-term memory, and fine motor coordination would have to return to preoperative levels. Thus, repeated testing with the same form can be conducted at ½-hour intervals without interfering with the validity of the measure.

RESULTS

During the period October 1, 1974, to May 30, 1975, 257 outpatients for general anesthesia were tested with the Dot Test. During April and May 1975, 82 outpatients for general anesthesia were given both the Dot Test and the Digit-Symbol Test, according to age. Since June 1, 1975, the Digit-Symbol Tests have been used exclusively on 847 patients.

The subjective evaluation of the staff in the Short Procedure Unit as to ease of testing and ease of scoring was recorded. Variability in the comparative scoring systems for the Dot Test and the Digit-Symbol Test were evaluated, as was the time for arrival in the recovery room until satisfactory scoring was achieved.

In subjective evaluation of ease of administration, the Digit-Symbol Testing required the use of a nurses' aide or ward clerk to administer the test over the 2-minute period prescribed. This time was compensated for, however, by the greater ease of scoring the Digit-Symbol Test. An evaluation of the degree of error is not necessary with the Digit-Symbol Testing as with the Dot Test. In comparing the results of the 2 tests, there were no instances where the Digit-Symbol Test consistently produced a score which mitigated against discharge of the patient, while in ± 10 percent of the cases, the Dot Test consistently produced a worse score postoperatively than preoperatively. Either repeated testing or other situational factors adversely influence the patient's responses with the Dot Test. Nursing personnel chose the Digit-Symbol Test the more time saving and more accurate in evaluating street fitness.

Average time from recovery room to discharge was 286 minutes during the period when the Dot Test was used, 322 minutes when both tests were used, and 175 minutes with the Digit-Symbol test alone.

CONCLUSIONS

Our studies suggest that the Digit-Symbol Tests are easier than the Dot Test to administer, easier to score, provide a better measure of street fitness, and allow for earlier safe discharge of the patient from the ambulatory unit.

Acute Maxillary Sinusitis Complicating Nasotracheal Intubation: A Case Report

T. JAMES GALLAGHER, MD*
JOSEPH M. CIVETTA, MD†
Miami, Florida‡

ACUTE maxillary sinusitis is frequently mentioned as one of the complications of nasotracheal intubation. Arens and associates[1] recently reported a 2 percent incidence in a retrospective study. In that group all patients complained of pain or had some other definite symptom, and all responded to antibiotic therapy.

In the acutely ill patient, the diagnosis becomes both more difficult and more important. The patient is usually too ill to complain specifically, and the presence of the tube prevents vocalization. An elevated temperature is of no diagnostic value in a setting of many possible causes. Therefore, in evaluating sepsis, patients with nasotracheal tubes should have sinus films taken as soon as feasible. If the source is not discovered, hematologic seeding[2] and sepsis may occur. The following case exemplifies these problems.

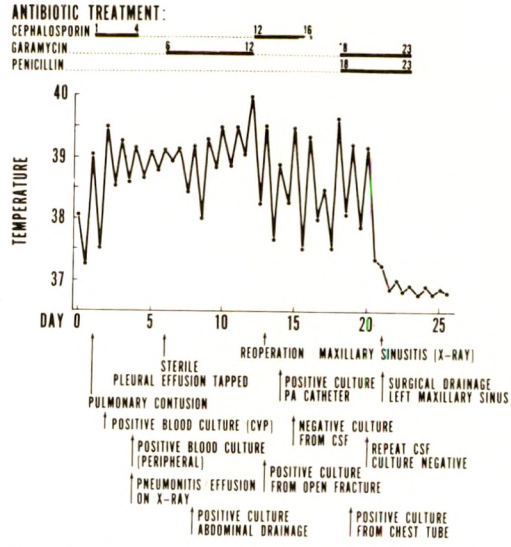

FIG 1. Temperature spikes, with appropriate antibiotics used according to new culture results.

REPORT OF A CASE

A 49-year-old man was hit by a truck, sustaining a pulmonary contusion, partially lacerated pancreas, and an open fracture of the right ulna. Prior to induction of anesthesia for abdominal exploration, an 8.5-mm low-pressure cuff was placed through the nares. No mucosal-shrinking agents were used.

His postoperative course (fig 1) was complicated by respiratory failure, treated by intermittent mandatory ventilation and positive end-expiratory pressure. He became febrile from the time of operation, potential sources including his contused lung, the Swan-Ganz catheter, and the site of his open fracture. Pancreatitis was also considered because of persistent abdominal drainage with high amylase content. Blood cultures grew Streptococcus; Proteus and Herellea were identified in tracheal secretions, and the abdominal drainage contained Enterococcus. Cerebrospinal fluid cultures were negative. As each new positive culture was obtained, sensitivities were checked to insure appropriate antibiotic coverage.

On the 13th postoperative day, abdominal exploration was performed in an attempt to find the source of sepsis. None was discovered, but during the course of anesthesia, a purulent discharge was noted from the right naris. At this time, the nasotracheal tube

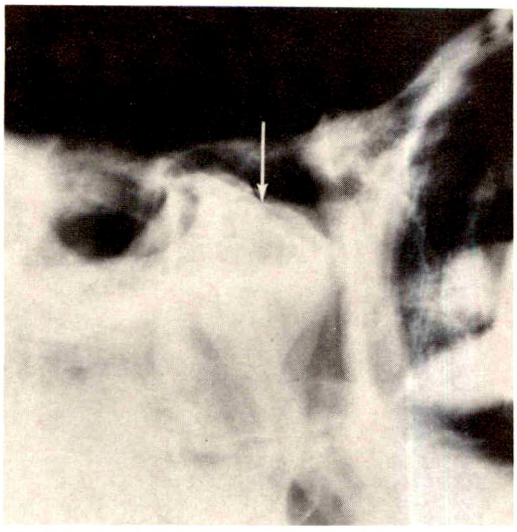

FIG 2. Arrow demonstrates air-fluid level in the maxillary sinus while in the supine position.

was exchanged for an orotracheal tube. This discharge revealed Proteus, Klebsiella, and Citrobacter when cultured.

Postoperatively, the fever continued in spite of appropriate antibiotic therapy. Sinus films were obtained after physiologic stability permitted transport. An air-fluid level was seen in the maxillary sinus (fig 2). There was no evidence on routine films of a maxillary fracture. The sinus cavity was drained shortly thereafter of 30 ml of foul-smelling pus. Proteus, Klebsiella, and Citrobacter were subsequently grown from the cultures. His temperature returned to normal on the following day.

COMMENT

This patient had multisystem failure and the path to the final diagnosis was quite complicated. There is need for a complete and exhaustive search to identify the source of sepsis in the severely ill patient with multiple problems. The case also demonstrates the fallacy of relying on culture reports alone for therapeutic decisions.

The argument that long-term intubation is better tolerated with a nasal tube is not supported by objective data. Since sinusitis as well as other complications[2,3] are more likely to result from nasotracheal intubation, orotracheal intubation may be attended by fewer complications.

SUCTION CATHETERS. This study was undertaken to evaluate mucosal trauma following tracheobronchial suctioning. Four different design suction catheters were evaluated including a beaded tip designed to prevent invagination of tracheal mucosa. The effect of a single suctioning procedure on the airway mucosa was observed and photographed through a fiberoptic bronchoscope. During a single suctioning procedure all catheters performed equally well and were associated with minimal trauma. Tracheal mucosal hemorrhage was not observed. Trauma with repeated suctioning is probably most related to frequency, vigor of catheter insertion, duration and negative pressure. *(Jung RC, Gottlieb LS: Comparison of tracheobronchial suction catheters in humans. Visualization by fiberoptic bronchoscopy. Chest 69:179-181, 1976)*

Supine Hypotensive Syndrome Caused by Intra-Abdominal Mass: A Case Report

JONG MIN KIM, MD*
CHANA BUAKHAM, MD†
FLORENCE McAMIS, RN‡
Kansas City, Kansas§

An obese woman who presented with 3 separate intra-abdominal masses developed a supine hypotensive syndrome following induction of general anesthesia. The hypotension was corrected by positioning the patient in a left lateral tilt and by releasing intra-abdominal pressure. Following decompression of the vena cava, arterial and central venous pressure rose and remained at a high level. Urine output was poor until IV furosemide was administered.

VENA CAVAL compression occurs in over 75 percent of normal term pregnancies, and 10 to 15 percent develop supine hypotensive syndrome.[1] Kennedy and associates[2] reported a 17.7 percent incidence of hypotension in normal vaginal deliveries under low spinal anesthesia. Left uterine displacement was effective in restoring blood pressure (BP) in 93.4 percent of these patients.

Eckstein and Marx[3] reported that elevation of the hip was more effective than mechanical displacement of the uterus in alleviating aortocaval compression. Evidently a large intra-abdominal mass can cause supine hypotensive syndrome similar to that caused by the near-term pregnant uterus.

REPORT OF A CASE

A 24-year-old obese woman, 156 cm in height and weighing 104 kg, was admitted with intrauterine pregnancy of 16 weeks gestation and an intra-abdominal mass. She had gained about 14 kg during her pregnancy and reported having had occasional cramping in hips and thighs, low back pain, episodes of coughing, and dyspnea upon minimal exertion. She denied the occurrence of dependent edema, varicosities, dizziness, or lightheadedness at any time during her pregnancy.

Preoperative laboratory data included: hemoglobin, 10.7 gm/100 ml; hematocrit, 32.9 percent, Na^+ 134; K^+ 3.8; Cl^- 103; and CO_2, 21 mEq/L. Chest x-ray and ECG were within normal limits. Sonography suggested a twin pregnancy and a large ovarian cyst extending into the upper abdominal cavity, measuring 17 x 15 x 15 cm. Despite 16 weeks gestation by history, the patient appeared as a full-term parturient, due to obesity and the intra-abdominal mass.

The patient was premedicated with 10 mg of diazepam and 0.5 mg of atropine, IM. Preoperative BP was 120/75, with a heart rate of 80/min. She was placed in low lithotomy position, 250 mg of thiopental and 80 mg of succinylcholine were administered, intubation was performed, and N_2O-O_2 (3.5:1.5) was started, with intermittent positive-pressure ventilation (IPPV). Following induction, her BP dropped to 60/40 and her heart rate rose to 120/minute. In spite of the hypotension, an additional dose of 75 mg of thiopental and 4 mg of pancuronium were administered to alleviate straining and coughing. The hypotension and tachycardia did not respond either to

increased fluid administration (1000 ml in 40 min) or to IV administration of 0.2 mg of phenylephrine given in 2 divided doses.

At this time, supine hypotensive syndrome was suspected, and the operating table was tilted to the left approximately 30 degrees. During the next 5 minutes, BP gradually rose to 110/50; heart rate remained elevated at 110/min. In an effort to determine if the hypotension was caused by vena caval compression, we restored the patient to the level position; this resulted in a BP drop to 80/60. As left lateral tilt was again resumed, the BP rose to 110/75 and remained stable until the peritoneum was opened, at which time her CVP was 3.5 cm H_2O.

The operation began 40 minutes after induction, with the patient in the left lateral tilt and low lithotomy position. She received 1000 ml of 5 percent dextrose in lactated Ringer's solution; during the same period, urine output was only 50 ml. Upon complete release of vena caval compression by opening the peritoneum, the BP and CVP rose to 150/90 and 17 cm H_2O, respectively, and heart rate fell to 100/min. The lateral tilt was removed without a change in either BP or heart rate.

In addition to a 16-week pregnant uterus, 2 large ovarian masses were found. The larger was a serous cystadenoma from the left ovary, measuring 15 x 20 x 20 cm; the smaller was a multilocular teratoma from the right ovary, measuring 10 x 10 x 12 cm. The left ovarian cyst was pushed into the upper abdominal cavity by the firm right ovarian teratoma and the pregnant uterus, and filled the entire epigastrium and upper abdominal cavity. Approximately 1500 ml of serous fluid was aspirated from the cystadenoma. Thereafter, BP and CVP stabilized at 140/90 and 14 cm H_2O, respectively.

Because of her high CVP and relatively poor urine output (175 ml for the 2-hour period, during which 1800 ml of fluid was given), 20 mg of furosemide was administered IV. This increased urine output from 175 to 1400 ml and decreased CVP to 7 cm H_2O, reduced BP from 140/90 to 110/60, and heart rate from 100 to 90/min within an hour.

The operation lasted 2.5 hours. Estimated blood loss was 1000 ml, replaced by the same amount of whole blood. Total fluid input was 2000 ml of 5 percent dextrose in lactated Ringer's solution. Anesthesia was maintained throughout with N_2O-O_2, supplemented with fractional doses of IV pancuronium (11 mg total dose) and fentanyl (0.3 mg total dose). The patient awoke in the operating room and the postoperative course was uneventful.

DISCUSSION

The clinical manifestations of vena caval compression by a pregnant uterus depend upon the degree of obstruction and the patient's ability to compensate. The mild decrease in venous return can be compensated by peripheral vasoconstriction and tachycardia without significant BP change. When these mechanisms become inadequate, supine hypotensive syndrome may develop, occasionally associated with bradycardia.[4] Compensatory mechanisms may be disturbed by either general or regional anesthesia.

In our patient, moderate vena caval compression by the intra-abdominal masses was well compensated preoperatively without significant clinical manifestations. However, when the intra-abdominal pressure was acutely raised by the tightening of the abdominal and thoracic muscles in the presence of inadequate muscle relaxation during induction of anesthesia, and venous return was impeded by IPPV, vena caval compression was acutely augmented. This impeded venous return beyond the patient's compensatory ability and was manifested as severe hypotension.

Rubinson and colleagues[5] demonstrated the marked narrowing of the inferior vena cava in dogs without significant change in arterial pressure when an inferior vena caval pressure gradient of 28 torr across the diaphragm was created by acute increase in intra-abdominal pressure. Further increase in intra-abdominal pressure to 35 to 40 torr resulted in a significant fall in arterial pressure. Lee[6] reported a patient who developed acute hypotension during laparoscopy when the intra-abdominal pressure reached 40 torr due to intraperitoneal CO_2 insufflation; BP returned to preoperative levels upon releasing intra-abdominal pressure.

When hypotension developed in our patient, fluid and vasopressor administration were not effective. Considering the overdistended abdomen and hypotension unresponsive to conventional therapy, we suspected the supine hypotensive syndrome. Left lateral tilt, with subsequent release of the intra-abdominal pressure upon opening the peritoneum, were effective in restoring blood pressure.

Epstein and Panter[7] described a patient in whom the arterial pressure and CVP rose following evacuation of a giant ovarian cyst, attributing the rise in BP and CVP to retained fluid distal to vena caval compression thrown into the systemic circulation. The initial BP and CVP elevations in our patient could be explained by a similar mechanism, but these pressures stayed high with relatively poor urine output. Furosemide decreased both and resulted in profuse diuresis. This suggested that decreased renal excretion of water, commonly associated with vena caval compression,[4] was not of postrenal origin. If postrenal obstruction was a causative factor, removal of the obstruction should increase urine output, as did rising BP.

Davis and colleagues[8] reported that when acute constriction of the proximal abdominal vena cava creates a sustained high venous pressure distally, aldosterone secretion is progressively elevated. Also, a smaller intra-arteriolar volume in the afferent arteriole of glomerulus stimulates the renin release.[9] In normal pregnancy, plasma renin activity and aldosterone concentration are increased.[10] The sodium-conserving effect appears about an hour after the IV administration of aldosterone.[11]

The time between induction of anesthesia to the opening of the peritoneum was about an hour. During that period, significant vena caval compression may have stimulated aldosterone and renin secretion, which had been increased by pregnancy. This could contribute to a sustained high CVP with relatively poor urine output.

TRIMETHAPHAN. The effect of trimethaphan produced hypotension (systolic blood pressure 60-65 torr) on blood glucose and serum potassium was measured in 10 patients. Anesthesia was with nitrous oxide-halothane and d-tubocurarine neuromuscular blockade. Compared with normotensive patients, those receiving trimethaphan manifested an attenuated hyperglycemic response and a small but significant decrease of serum potassium. These responses are mostly likely due to trimethaphan's ganglionic blocking properties. *(Fahmy NR: Changes in serum potassium and blood glucose concentrations after trimethaphan administration in man. J Lab Clin Med 87:999-1004, 1976)*

Twelfth Annual Becton, Dickinson and Company Oscar Schwidetzky Memorial Lecture

WILLIAM K. HAMILTON, MD

DR. WILLIAM K. HAMILTON, Professor and Chairman of the Department of Anesthesia, University of California, San Francisco, will deliver the 12th Annual Becton, Dickinson and Company Oscar Schwidetzky Memorial Lecture at the 51st Congress of the International Anesthesia Research Society, to be held at the Diplomat Resort and Country Club, Hollywood, Florida, March 6-10, 1977.

Widely known and admired among anesthesiologists, Bill Hamilton brings to our podium a unique blend of academic insight, clinical expertise, and personal common sense.

He was born and educated in Iowa and advanced from Clinical Instructor in Anesthesiology to Professor and Chairman of the Department of Anesthesiology at the University of Iowa in Iowa City. After nine years in the latter post, he moved to San Francisco in 1967 to assume his present duties and his second departmental chairmanship. Under his capable direction, the University of California Department of Anesthesia has continued its evolution into one of the most prominent clinical, educational, and research facilities in our specialty.

Included in Dr. Hamilton's busy schedule have been membership in many University of California School of Medicine committees, as well as such national posts as Past President of the American Board of Anesthesiology, membership on the Liaison Committee on Graduate Medical Education, membership on the Surgical Study Section A of the National Institutes of Health, and past presidencies of both the Association of University Anesthetists and the Society of Academic Anesthesia Chairmen. While this would completely preoccupy, if not overwhelm, most people, Bill Hamilton still finds time to participate in research and in daily clinical anesthesia. From such varied activities, he brings to his teaching efforts a blend of intellectual preparedness and clinical practicality that has won him respect from students and practitioners alike.

At the 51st Congress of this Society, Dr. Hamilton's topic will be "Pharmacology, Pressures and People."

The Fifteenth Annual Baxter-Travenol Lecture

ARTHUR C. GUYTON, MD

ARTHUR C. GUYTON, M.D., Professor and Chairman of the Department of Physiology and Biophysics at the University of Mississippi, will present the Fifteenth Annual Baxter-Travenol Lecture at the 51st Congress of the International Anesthesia Research Society, to be held at the Diplomat Resort and Country Club, Hollywood, Florida, March 6-10, 1977.

Long a leader in the fields of physiology and biophysics, Dr. Guyton is particularly recognized for his unique ability to reduce complex issues to simple diagrams and statements. His textbooks, embodying this attribute, have become major instructional assets to countless classes of students of various disciplines.

Dr. Guyton qualifies strongly as a "hometown boy," as he was born, educated through college (top honors at each level), and has subsequently taught in Oxford, Mississippi. However, he received his M.D. degree at Harvard Medical School (honors there also) and was exposed to the discipline of surgery at both Massachusetts General Hospital, and, during World War II, at the National Naval Medical Center. Since 1948, he has held his present post at the University of Mississippi Medical Center in Jackson.

A list of Arthur Guyton's awards, honors, and society offices reads like a roll call of available distinguished recognitions. Particularly noteworthy are a Presidential Citation (1956) for the development of aids for the handicapped; selection by the U.S. Junior Chamber of Commerce as one of the Ten Outstanding Young Men in America (1951); the Ross McIntyre Award for contributions to Medical Teaching and Research (1972); the Teaching Award of the Association of Chairmen of Departments of Physiology (1975); named lectureships of various specialty societies; presidencies and chairmanships of societies and committees; and editorial board activities on behalf of half a dozen scientific journals, including *Circulation Research* and the *American Journal of Physiology*.

The topic of Dr. Guyton's presentation to the 51st Congress of this Society will be "A Composite Analysis of Cardiovascular Regulation."

We Salute . . . .

Richard George Barton Gilbert, M.B., B.S., F.R.C.P.(C)

"Given a government with a big surplus and a big majority and a weak opposition, you would debauch a committee of archangels."—Sir John A. MacDonald, First Prime Minister of Canada.

A SON OF the Manse, which instilled patience, wit, and understanding, Dick Gilbert was educated at Haileybury College, England, and the University of London, graduating from St. Thomas' Hospital in 1933. These were lean years, but Dick devoted his postgraduate studies to internal medicine, then to anesthetics, at the Postgraduate Medical School, Hammersmith, followed by private practice prior to the outbreak of hostilities in Europe.

He served with distinction in the Second World War as a specialist in anesthetics in England, Northwest Europe, and in the Burma campaign in the Far East, retiring with the rank of Lieutenant Colonel in 1946. During these war years, he came in contact with the 3rd Canadian Division in Combined Operations, which influenced his decision to immigrate to Canada with his family in 1946.

From 1948 to the present, Dick has been clearly identified with McGill University, in Montreal. He had the good fortune of coming under the tutelage of two of the pioneers in Canadian anesthesia—Dr. Wesley Bourne and Dr. Harold Griffith. At the same time, he came under the persuasive spell of the late Dr. Wilder Penfield, noted neurosurgeon and founder of the Montreal Neurological Institute. From 1950, Dick devoted his energies to improving the science of neurological anesthesia, and from 1957 to 1970 as chairman of the university department, fostering postgraduate education and research in the specialty through the McGill Diploma Program and the autonomous Anaesthesia Research Department.

Dick has had the distinction of serving both the Society of Anaesthetists of Quebec and the Canadian Anaesthetists Society as President, and for many years acted as a wise and fatherly examiner for the Royal College of Physicians and Surgeons of Canada as well as the Quebec College. Following a sabbatical year at Montpellier University, in France, in 1970, Dick has continued in his post of Professor of Anaesthesia at McGill. Charismatic, always of good humor, Dick has been a counsellor to many and a friend to all in time of need, both here and abroad.

The Society is pleased to "Salute" Dick and his gracious wife, Eunice, and to wish them future health and happiness.

"Every man is a volume, if you know how to read him."—Channing.

METHOD TO IDENTIFY A CERVICAL ESOPHAGEAL DIVERTICULUM DURING GENERAL ANESTHESIA

To the Editor:

Occasionally, the surgeon may have difficulty in identifying a small esophageal diverticulum during an operation under general anesthesia with a cuffed endotracheal tube properly placed. A simple maneuver that we have found effective is to pass a nasal catheter into the oropharynx (figure) and, after closing the lips and nostrils, gently introducing air. As the air pressure increases, the weak spot in the esophageal wall will distend and the diverticular sac can be seen as it expands into the operative field.

Although the illustration shows the air being introduced from a large syringe, one of us (MJN) prefers to blow his expired air into the catheter, as the pressure can be better evaluated and the potential usable volume is large enough to maintain a steady, small air pressure in the oropharynx.

It may be helpful to have the surgeon apply backward pressure on the cricoid cartilage, compressing the esophagus (Sellick maneuver) against the body of the vertebrae before introducing the air. This is not necessary if the operation is performed under cervical plexus block, for then the patient can be asked to swallow, thus increasing the oropharyngeal pressure, which will cause the diverticular sac to distend.

ACCURACY, BREVITY, CLARITY: THREE PRINCIPLES OF GOOD MEDICAL WRITING

To the Editor:

The article, "Righting the Wrongs of Writing: Copy Editors Speak Out," by Alexander and Wall,[1] contains some useful advice to authors, but one of the authors' final suggestions, "Write the way you talk," demands comment. This suggestion touches on a root cause of the low quality of medical writing that you, Sir, have done so much to correct by publishing helpful contributions concerning medical writing, such as Dr. Charles Roland's series, "Thoughts About Medical Writing"—and indeed the article by Alexander and Wall.

Alexander and Wall advise authors to write the way they talk. This is fine—provided authors talk well. But a fundamental reason why medical writing is frequently poor is precisely the fact that physicians write using words that they are comfortable with in communicating with their colleagues *orally*—and as a generalization, such words when printed lack effectiveness and interest. The corridor conversation and the grand rounds presentation are not a good basis for excellence in medical writing.

Alexander and Wall, in recommending

that authors should write the way they talk, also say that "people don't usually talk in five-syllable words." I disagree, if physician authors are included among such people. The trend in medical conversation or oral reporting is indeed toward use of polysyllabic words. Thus, the result of a physical examination may be said to be "noncontributory" (6 syllables), and "hepatosplenomegaly" (8 syllables) may or may not be said to be "nonsignificant" (five). Again, a patient may require "hospitalization" (six) because of "cardiorespiratory" (eight) "decompensation" (five). It is therefore not at all surprising that so many manuscripts submitted to medical journals are replete with benumbing polysyllabic words.

Good advice to authors is difficult to formulate, but Alexander and Wall have provided some helpful words of wisdom. It is more difficult to act on because writing is so personal and subjective an art. Writing, too, requires discipline, time, and hard work; and, as an editor, I sympathize with the busy physician who has to write when this is not necessarily a priority. What the physician therefore requires is the general assurance and understanding that to write well means that, in the long term, manuscripts take less time and effort to prepare —and may even be a pleasure to write. The physician author welcomes rules of thumb but to these must be added advice about the steps required in writing well.

Medical writing should seek to achieve what writing of any type should provide: effective communication between author and reader. True, the technical content of medical writing makes medical writing different from some other types of writing, but this should not deter the physician author; although great pains are required in order to select the right word so that the intended meaning is in fact conveyed, such care should come easily to anyone scientifically trained—and, in fact, such care is a plus because it makes for good rather than poor writing. With this in mind, one can offer 3 principles of good medical writing: accuracy, brevity, and clarity.

The need for *accuracy* should not surprise anyone, for "truth" is essential to all scientific work; and the description of a medical technic or the instructions relating to the administration of a drug *must* be accurate.

The need for *brevity* also should not surprise, though editors frequently receive manuscripts that are excessively long. But the adage, "Half as long is twice as good," is a useful one, not only because readers prefer to read short rather than long articles, but also because to be brief means to use simple and direct language. By cutting through the tangled undergrowth of redundancy, circumlocation, abstract terms, passive voice, and jargon, one avoids boring the reader and can set about interesting the reader instead.

And *clarity?* There is no shortcut to this *sine qua non* of writing, and one can only realize that, if one is to be sure of conveying one's message so that it is received, one must be clear. Clear thinking, a logical approach to organization, choice of the right word, relation of sentences to each other and of paragraphs to each other—these are the keys to clarity, but to achieve clarity one must be motivated to write well. Rules, then, are most helpful but help is required in their application.

How does one learn to write well? Recognition of the need to learn to improve one's skills is one step. A second step is motivation to learn—to learn through reading about writing, through attending workshops on writing such as those organized by, for example, the American Medical Writers Association, and through reading and studying the writing of good writers, particularly those who are known for their excellence of style. Only in this way can one become sensitized to what is good and what is poor. And the final step is to write, rewrite and write again, yet never to be completely satisfied. Writing well is an art that, like medicine, is a life-long one.

Communication is important in medicine, as it is in any field of social activity. Effective communication demands good writing, and, because so much of medical writing is technical in content and deals with the well-being of patients, the need for good medical writing is paramount. Good medical writing is not simply a virtue having its own reward; it may be an urgent need, as a recent case report showed.[2] In this instance a patient died after the labeling on a vial of chloramphenicol was misinterpreted. I agree therefore that "Righting the Wrongs of Writing" is an important matter, but I would like to emphasize that it is even more important at times than most of us realize.

WRITE TO INFORM, NOT TO IMPRESS

To the Editor:

I have been following the articles in Anesthesia and Analgesia on how to improve medical writing and after much rumination of the subject, I feel it is a love's labor lost.

Doctors write and speak the way they do with their consummate love for clichés and tautology because they can do nothing else. Nor do I think it is very important that they should.

Somerset Maugham points out in one of his essays that the greatest writers like Tolstoy or Joseph Conrad never mastered the technical aspects of the art of writing and that they made errors in composition such as a sophomore would never make.

We read the great writers not for their perfection of style or clarity of diction but for the stories they tell, the images they conjure up, for their philosophic asides, etc —not for their perfect grammar or composition.

Can it truly be claimed that if a new discovery tantamount to Jenner's vaccination were made, the world would not recognize or hasten to accept it because the discoverer's account included a cliché or a tautological expression? I doubt it.

USE OF MONITOR FOR KETAMINE IN RADIOTHERAPY

To the Editor:

In the description of their low-dose ketamine technic for radiotherapy,[1] Amberg and Gordon do not mention their monitoring equipment. We found[2] that viewing the patient through the observation port and closed-circuit television were inadequate and adapted conventional monitors to this special application. Perhaps the acceptance of their technic might be hastened by using one of the several monitors of pulse and respiration mentioned in our paper.

Alfred Feingold, MD
Department of Anesthesiology
University of Miami School of Medicine
Miami, Florida

To the Editor:

Thank you for giving me an opportunity to reply to Dr. Feingold's letter.

During the course of treatment, we initially monitored the ECG via the observation port. We also took blood pressures while in the treatment room. After several treatments, we simplified this down to radial pulse monitoring and close observation of respiratory movements. We felt that one of the great advantages of ketamine was the preservation of protective reflexes, especially with the low dosages we were using. The other problem with placing multiple monitoring devices is the time factor. With low dosages and minimal pretreatment stress, placement of devices takes time away from treatment periods. With inhalation anesthesia, these monitoring devices are needed, but with low-dose ketamine, we feel they are not.

WHAT ROUTE OF ADMINISTRATION FOR K^+ SOLUTIONS?

To the Editor:

I cannot agree with Dr. Myron B. Laver's statement, "Potassium solutions must never be administered through a peripheral IV," which appeared in your March-April, 1976, issue.[1]

We all give potassium-containing solutions in peripheral veins every day (lactated Ringer's, Normosol-R, Ionosol B, etc). It

is true that solutions containing greater-than-physiologic concentrations of K^+ are most irritating to peripheral veins and must be given with care, but this does not preclude their being administered by this route. To insist, for instance, that a solution like Ionosol B (25/mEq L of K^+) be given through a central venous line would be submitting thousands of patients each day to the potential hazards of central venous catheterization. This would be a needless risk in most situations, and should remind us of the old caveat: *primum non nocere*.

Gary L. Fanning, MD
The McFarland Clinic
Ames, Iowa

REFERENCE

1. Laver MB: Questions and Answers. Anesth Analg 55:276, 1976

To the Editor:

Dr. Fanning is quite right in his criticism of the wording in my comment. It is true that solutions containing higher-than-physiologic concentrations of K^+ (in fact as high as 80 mEq/L or 0.08 mEq/L) have been and are being given into "peripheral" veins without apparent difficulty. He also states that substantially higher-than-physiologic (ie >0.005 mEq/ml) can cause "irritation" of peripheral veins.

However, what Dr. Fanning apparently has ignored is the fact that a number of patients, like the one in the query, may need substantial intravenous K^+ replacement before or during operation without the benefit of additional free water or electrolytes. For example, if a patient were to require a total of 100 mEq/L K^+ supplement, then according to Dr. Fanning's formula, using Ionosol B, one would have to administer no less than 4L of water plus other electrolytes. I do not consider this sound medical practice.

Careful reading of my answer to the question referred to will indicate that I suggested use of KCl, not "potassium-containing" solutions, for this purpose. What I did not state (and here Dr. Fanning is correct) is that these are *concentrated* solutions, mixed usually at 40 or 80 mEq/ml of K^+ with 5 percent glucose in water, in which case the K^+ concentration is 0.16 or 0.24 mEq/ml of K^+.

Whether this latter technic is to be used in an open ward or confined to an ICU or operating room is a different matter. The final decision must rest with the patient's physician. Acute changes in serum K^+ do occur with great frequency in the course of major operations. The method described is the one I prefer if intraoperative K^+ supplement is required.

The limitations as to hourly dosage still apply: 0.2 to 0.25 mEq/kg/hr K^+ and, without exception, these concentrated solutions must be administered via a central venous line. It is also good practice to include a commercially available graduated cylinder in the system (eg, Metriset®) and fill it only with the hourly dose of the K^+-containing solution, to prevent infusion of excessive quantities of the ion.

The manner in which K^+ supplementation is provided varies enormously. The success of commercially premixed solutions containing added K^+ suggests that in most cases it is an effective and safe mode of therapy. Unfortunately, there are situations in which this is convenient but not necessarily intelligent medicine. I wonder how Dr. Fanning would consider replacement in an elderly patient, in atrial fibrillation, on chronic digitalis therapy and not dehydrated who, prior to emergency operation, is found to have a K^+ of 2.5 mEq/L? How many liters of Ionosol B would it be safe to infuse peripherally to provide adequate K^+ replacement before his *primum non nocere* dictum becomes questionable?

Myron B. Laver, MD
Department of Anaesthesia
Massachusetts General Hospital
Boston, Massachusetts

To the Editor:

Thank you for sending me a copy of Dr. Laver's reply to my letter. A few additional comments are in order.

First of all, I did not state nor did I imply that Ionosol B should be used for the treatment of all K^+ deficiencies. I merely pointed to it as a fluid containing greater than physiologic concentrations of K^+ that is being given to thousands of patients every day via peripheral venous routes. Likewise, I did not state and did not mean to imply that all potassium-containing solutions should be given in peripheral veins. Obviously, there are many indications for using quite concentrated solutions of K^+, as pointed out by Dr. Laver, and these, I would

agree, are more properly given through a central venous catheter.

HOW DO BENEFITS OF HEMODILUTION BALANCE O_2 REDUCTION?

To the Editor:

The data from the recent paper by Gordon and associates,[1] regarding the effects of hemodilution on hypotension during cardiopulmonary bypass raise a disturbing issue on which the authors did not comment in their discussion: How does one balance the reputed benefits of hemodilution against the very real reduction in O_2 delivery to the patient that hemodilution must entail? I realize that Dr. Gordon's group did not set out to address this issue, but the degree of hemodilution they employed in several of their patients was of a magnitude that requires some justification by these gentlemen.

I have taken the information contained in table 2 of their article and rewritten it to express O_2 delivery per minute to the patient from the pump oxygenator (table). In making these calculations, I assumed that:

TABLE

Patient	Oxygen delivery in ml/min
1	370 ml/min
2	176
3	437
4	443
5	314
6	407
7	351
8	462
9	386
10	425
11	427
12	241
13	554
14	333
15	387
16	353
17	595
18	446
19	425
20	483

(1) hemoglobin (Hb) was fully saturated and had an O_2 binding capacity of 1.39 ml/gm; (2) a hematocrit of 3 percent corresponded to an Hb value of 1 gm/100 ml; (3) a body surface area was 1.8 sq m for all patients; and (4) that dissolved O_2 amounted to 1 ml/100 ml of blood.

Two patients would then have had a total O_2 delivery of less than 250 ml/min and 3 others would have received between 250 and 350 ml/min. Available O_2 is, of course, significantly less than this at 31° C. At this temperature, Hb is still 50 percent saturated at a PO_2 of 19 torr, and 25 percent saturated at 12 torr. Even assuming that O_2 requirements were reduced by a third at 31° C and still further by the anesthetic agents employed, it is unlikely that total O_2 consumption was much less than 150 ml/min. If the latter value is taken to be correct, patient 2 would have a mixed venous saturation of 17 percent and a mixed venous PO_2 of about 10 torr. Patient 12 would have a mixed venous saturation of 42 percent and a venous PO_2 of about 16 torr. The happy circumstance that both these patients apparently survived what can only be described as a severe physiologic challenge does not alter the fact that they were subjected to the risk of dangerously low reserves of O_2 for the very marginal benefits of reduced blood utilization and greater ease of perfusion.

Dr. Frank Gollan, in his discussion of this paper, concluded by noting that these patients did much better than theoreticians would have predicted, and that experimental and clinical evidence remain the guidelines for future work. I am afraid that I must respectfully disagree. The mere fact that one can "get away" with a theoretically unsound procedure is not sufficient justification for its use unless risk/gain advantages clearly argue in its defense.

Such is not the case here. Hemodilution to an Hb level of 4 gm/100 ml combined with only moderate hypothermia (30° C) and a perfusion level of 2.2 L/sq m represents a dangerous technic, and I believe Drs. Gordon and Ravin should say so.

To the Editor:

Dr. Gordon is in England, so I take the liberty of replying to the letter from Dr. Aaron Kopman in response to our article.

We would like to emphasize that the data referred to in table 2 of our paper apply only to the period immediately after the start of bypass. These abnormally low hematocrit values rapidly rose following a marked diuresis. It is also clear from table 1 that no special effort was made to induce hemodilution in patients 2 and 12; their pump primes are similar to those of the other 18 patients. The low hematocrit values following onset are clearly suggestive of hypovolemia. The degree of hypothermia we employed decreases O_2 need by approximately 50 percent. Finally, we are only making observations and not recommending any technic. But Dr. Kopman's analysis does indicate the importance of monitoring hemoglobin content during perfusion.

EFFECT OF P_{aCO_2} ON O_2 CONSUMPTION DURING CARDIOPULMONARY BYPASS

To the Editor:

The recent paper by Patterson[1] on the effect of P_{aCO_2} on O_2 consumption during cardiopulmonary bypass, while otherwise well conceived, is, I am afraid, marred by a serious error in methodology.

In theory, the difference in O_2 content between arterial and mixed venous blood ($A\text{-}V_{DO_2}$) can be calculated from measured P_{O_2}, P_{CO_2}, pH, and hemoglobin (Hb). In practice, the results so obtained are not reliable for the following reasons:

The most serious problem with calculating Hb saturation and hence O_2 content from blood-gas determinations is that very small errors in the measurement of blood O_2 tension become greatly magnified as one goes along. If, for example, the $P\bar{v}_{O_2}$ is reported as 37 torr when it is in fact 5 torr higher, the calculated saturation will be 70 percent instead of 77 percent. Even assuming that arterial blood is fully saturated, this 5-torr error in the determination of mixed venous O_2 tension will result in almost a 25 percent error in the calculated $A\text{-}V_{DO_2}$.

Another potential source of trouble lies in assuming that the patient's O_2:Hb dissociation curve has a normal P_{50}. In the presence of prior anemia or blood transfusion, for example, considerable shifts in P_{50} can and do occur. Even after corrections are made for temperature, pH, and base excess, the actual value of P_{50} is subject to significant variation. An increase in P_{50} of only 2.5 torr is equivalent to a 10 percent increase in effective P_{O_2}.

Finally, the O_2-binding capacity of Hb may also vary by a considerable amount. While in theory, 1 gm of Hb carries 1.39 ml of O_2 when fully saturated, in practice this value is rarely achieved. DeVillota's group[2] found in normal subjects a mean value of 1.36 (range 1.33 to 1.41) for this parameter, while in heavy smokers the figure was 1.3 (range 1.21 to 1.41). Obviously, any arbitrary figure selected is likely to be wrong much of the time unless carboxyhemoglobin is also measured and accounted for.

If reliable values for $A\text{-}V_{DO_2}$ are to be obtained, O_2 content must be either measured volumetrically or calculated from measured Hb saturation, if the former is not feasible. It is, therefore, unfortunate that, while the author's data on O_2 consumption *may* be accurate, it is difficult to put much faith in the figures reported. I would very much like to see this study repeated with more rigorous attention to the problems discussed above.

Aaron F. Kopman, MD
Department of Anesthesiology
Long Island Jewish-Hillside
Medical Center
New Hyde Park, New York

2. DeVillota ED, Carmona MTG, Barat G, et al: The influence of carboxyhemoglobin on the oxygen binding capacity of blood. Br J Anaesth 48:111-117, 1976

To the Editor:

Thank you for relaying Dr. Kopman's letter to me.

In reply:

In the preparation of the table of results, it was not obvious that there was a need to

tabulate all of the arterial and mixed venous blood-gas values. Had this been done, it would have been apparent from the tension decreases as CO_2 was added that an increased quantity of O_2 was being removed even though the total O_2-carrying capacity may have been constantly impaired.

Contributing to the belief that changes in $\dot{V}O_2$ were actually occurring were the findings that essentially the same results were obtained whether, from the initial state, CO_2 was added or subtracted; the fact that the trend of the changes was similar regardless of the absolute constant temperature during the study; and also, though not a part of the study, when the same bypass occurred for long periods at 2 different temperatures, $\dot{V}O_2$ was markedly higher at the higher temperature.

Dr. Kopman is correct in pointing out that in precisely deriving content from tension, total O_2-carrying capacity and Hb:O_2 affinity must be known. Dissatisfaction with the available methods of calibrating the co-oximeter (as well as the variability in the calculated factors, also mentioned in the last paragraph of the paper by DeVillota), precluded a systematic evaluation of carboxyhemoglobin (COHb) in this study.

However, the range of COHb values to be expected during our study conditions is indicated by a separate study, where we measured COHb spectrophotometrically. Immediately prior to commencing bypass, patient COHb averaged less than 3 percent. Sampling the initial pump prime disclosed a wide range of values, 2.2 to 6.5 percent. There was a progressive decline in COHb during bypass; at the end of 1 hour, the average value was <2 percent.

Since actual volumetric measurements of O_2 consumption on a minute-to-minute basis show a 6 to 10 percent coefficient of variation around a mean steady-state value, it was considered that the assumptions made in this study contributed to a lesser percentage of error in $\dot{V}O_2$ estimation than that inherent, in that the overall average value may differ from the discrete value of a particular sampling period. More precise values for $\dot{V}O_2$ during bypass can be obtained by adapting the method of measuring $\dot{V}O_2$, which we are currently using in patients in situations where collection of all expired gas is feasible (with subsequent analysis of inspired and expired respiratory gases by mass spectrometry and minute-to-minute on-line computation of $F_{E}N_Z/F_{I}N_Z$, RQ, and $\dot{V}O_2$); steady-state conditions are clearly designated, and the requirement of measuring P_{50} and the O_2-carrying capacity of Hb is obviated.

Thank you again for your continuing interest. From the large number of reprint requests, we believe that perhaps others will be stimulated to look more closely at some of the circulatory changes occurring during bypass.

CORRECTION

The illustration accompanying the *Correspondence* item entitled "Plastic-Covered Wire Stylet," which appeared on page 755 of the September-October issue was incorrect. The correct illustration is:

In each issue of the Journal an article of particular interest and value to anesthesiologists, which has been published elsewhere, will be presented. Primarily the material will contain fundamental basic information which has been presented by anesthesiologists, physiologists, pharmacologists, and others and, on occasion, by commercial firms. In the last instance, these reprintings are not to be construed as an endorsement of the particular commercial firm or its product by Anesthesia and Analgesia—Current Researches.

Retrospectroscope . . . the Soul of Wit

ABRAHAM LINCOLN, on November 19, 1863, delivered his Gettysburg Address, one of the most elegant, famous, and widely quoted of modern speeches. Delivered on a Civil War battlefield, it was almost finished before the crowd became quiet. Few in the audience heard all or much of it. The Address contained only 272 words and, in print, was a single paragraph.

As a schoolboy, I (and I suppose all school-children throughout America) memorized Lincoln's Address and recited it in the classroom. Never in my later scientific training, however, has anyone ever suggested that I memorize and recite a scientific article. I'm sure no candidate-article was as eloquent as Lincoln's Address, but some important discoveries or concepts were presented about as briefly. Here are a few; they include only complete accounts that stood alone and not abstracts that were enlarged upon later in a full article.

Benjamin Franklin, foremost scientist in the American Colonies, communicated in a one-page letter (one paragraph, 342 words, excluding his salutation) the details and conclusions of his famous kite and key experiment by which he demonstrated for the first time the "sameness" of lightning and "electric matter" stored in a Leyden jar (figure 1).

Korotkoff, in 1905, wrote a single paragraph describing how he modified Riva-Rocci's method to permit measurement of diastolic blood pressure and accurate recording of systolic pressure; his 1905 technic is essentially that used today. This paragraph is all that Korotkoff ever published on the subject (267 words in the English translation):

ON THE SUBJECT OF METHODS OF DETERMINING BLOOD PRESSURE

(From the clinic of Prof. S. P. Fedorov)

DR. N. S. KOROTKOFF:

On the basis of his observations, this reporter has arrived at the conclusion that a completely compressed artery in a normal condition does not produce any sound. Taking advantage of this situation the reporter proposes the sound method for determining the blood pressure in humans. The sleeve [cuff] of Riva-Rocci is placed on the middle 1/3 of of the arm toward the shoulder. The pressure in the sleeve is raised quickly until it stops the circulation of the blood beyond the sleeve. Thereupon, permitting the mercury manometer to drop, a child's stethoscope is used to listen to the artery directly beyond the sleeve. At first no audible sound is heard at all. As the mercury manometer falls to a certain

Reprinted with permission from American Review of Respiratory Disease and the author.

Oct. 19, 1752.

AS frequent mention is made in the news papers from *Europe*, of the ſucceſs of the *Philadelphia* experiment for drawing the electric fire from clouds by means of pointed rods of iron erected on high buildings, *&c.* it may be agreeable to inform the curious that the ſame experiment has ſucceeded in *Philadelphia*, though made in a different and more eaſy manner, which is as follows:

Make a ſmall croſs of two light ſtrips of cedar, the arms ſo long as to reach to the four corners of a large thin ſilk handkerchief when extended; tie the corners of the handkerchief to the extremities of the croſs, ſo you have the body of a kite; which being properly accommodated with a tail, loop, and ſtring, will riſe in the air, like thoſe made of paper; but this being of ſilk is fitter to bear the wind and wet of a thunder guſt without tearing. To the top of the upright ſtick of the croſs is to be fixed a very ſharp pointed wire, riſing a foot or more above the wood. To the end of the twine, next the hand, is to be ty'd a ſilk ribbon, and where the ſilk and twine join, a key may be faſtened. This kite is to be raiſed when a thunder guſt appears to be coming on, and the perſon who holds the ſtring muſt ſtand within a door, or window, or under ſome cover, ſo that the ſilk ribbon may not be wet; and care muſt be taken that the twine does not touch the frame of the door or window. As ſoon as any of the thunder clouds come over the kite, the pointed wire will draw the electric fire from them, and the kite, with all the twine, will be electrified, and the looſe filaments of the twine will ſtand out every way, and be attracted by an approaching finger. And when the rain has wet the kite and twine, ſo that it can conduct the electric fire freely, you will find it ſtream out plentifully from the key on the approach of your knuckle. At this key the phial may be charged; and from electric fire thus obtained, ſpirits may be kindled, and all the other electric experiments be performed, which are uſually done by the help of a rubbed glaſs globe or tube; and thereby the ſameneſs of the electric matter with that of lightening completely demonſtrated.

B. F.

height the first short tones appear, the appearance of which indicates the passage of part of the pulse wave under the sleeve. Consequently, the manometer reading at which the first tones appear corresponds to the maximum pressure. With a further fall of the mercury in the manometer systolic pressure murmurs are heard which change again to a sound (secondary). Finally, all sounds disappear. The time at which the sounds disappear indicates a free passage of the pulse wave; in other words, at the moment the sounds disappear, the minimum blood pressure in the artery exceeds the pressure of the sleeve. Consequently, the reading of the manometer at this time corresponds to the minimum blood pressure. Experiments on animals gave positive results. The first sound-tones appear (10-12 mm) sooner than the pulse, for the perception of which (r. art. radialis) the breakthrough of a greater part of the pulse wave is required.

Cooke and Barcroft, in 1913, recorded the first measurement of O_2 saturation of human arterial blood (four paragraphs, but only 180 words). Although Hürter had performed arterial puncture in Germany a year earlier, Barcroft took advantage of the then-current clinical technic for transfusion (inserting a cannula into the donor's artery and running arterial blood directly into the recipient's vein) to obtain blood without exposure to air or contamination with anesthetic gases. A year later, Hustin in Belgium hit upon citrate as a safe anticoagulant and indirect transfusions of venous blood replaced the artery-to-vein technic. Widespread use of arterial puncture for diagnostic purposes or physiologic investigation didn't surface until World War II.

Adolph Fick (1870) wrote only two paragraphs on the measurement of cardiac output; in the first, he outlined his principle, and in the second, gave a sample calculation based on reasonable data:

> Herr Fick had a contribution on the measurement of the amount of blood ejected by the ventricle of the heart with each systole, a quantity the knowledge of which is certainly of great importance. Varying opinions have been expressed on this. While Thomas Young estimated the quantity at about 45 cc, most estimates in modern textbooks, supported by the views of Volkmann and Vierordt, run much higher, up to 180 cc. It is surprising that no one has arrived at the following procedure by which this important value is available by direct determination, at least in animals. One measures how much oxygen an animal absorbs from the air in a given time, and how much CO_2 it gives off. One takes during this time a sample of arterial and a sample of venous blood; in both samples oxygen content and CO_2 content are measured. The difference of oxygen content gives the amount of oxygen each cubic centimeter of blood takes up in its passage through the lungs; and as one knows how much total oxygen has been taken up in given time, one can calculate how many cubic centimeters of blood have passed through the lungs in this time, or if one divides by the number of heartbeats during this time, how many cubic centimeters of blood are ejected with each beat. The corresponding calculation with CO_2 quantities gives a determination of the same value, which provides a control for the other calculation.
>
> Since for the demonstration of this method two gas pumps are needed, your reporter unfortunately is not in a position to communicate experimental data. He will only give, therefore, a calculation of blood flow in man according to this method, based on more or less arbitrary data. According to the experiments of Scheffer in Ludwig's laboratory, dog's arterial blood contains 0.146 cc oxygen per cc (measured at 0° C and 1 atm pressure); 1 cc of venous blood contains 0.0905 cc oxygen. Each cc of blood therefore takes up 0.0555 cc oxygen in its passage through the lungs. Let us assume the same in man. Assume, further that a man absorbs in 24 hours 833 grams of oxygen. This will occupy a space of 433,200 cc at 0° C and 1 atm pressure. According to this, 5 cc of oxygen would be absorbed by the lungs of a man each second. In order to effect this absorption, 5/0.0555 cc of blood must perfuse the lungs per second, that is, 90 cc. Assuming, finally, 7 systoles in 6 seconds, each systole would then eject 77 cc of blood.

Note Fick's statement that "It is surprising that no one has arrived at the following procedure by which this important value is available by direct determination," but he did no experiments because he had no "gas pumps" for measuring the O_2 or CO_2 content of blood. The first experimental determination based on his principle was reported 16 years later by Gréhant and Quinquaud (in a one-page paper); they reported measurements in 6 dogs.

William Dock in 1929 adapted the then-new cathode ray oscillograph to monitor and to record ECG (229 words); the CRO monitor is now routine in all operating rooms and intensive care units and, as such, is quite familiar to avid TV viewers.

Others who reported important discoveries in one page or less were the following:

Faraday (1818), who reported that inhalation of ether vapor produced effects similar to those of nitrous oxide.

O'Shaughnessy (1832), who discovered severe fluid and electrolyte disturbances in patients with cholera; within a year his work led to the first rational therapy of this scourge by Latta.

Pasteur (1882), who recounted his successful vaccination of sheep against anthrax; 100 percent of those not vaccinated died, while 100 percent of those vaccinated up to 8 months previously lived.

Hektoen (1907), who suggested that mixing blood of donor and recipient and examining the mixture for agglutinated red blood cells could eliminate transfusion reactions.

Carrel (1911), who described his technic of repeatedly passing tissue fragments cultured *in vitro* from an old to a fresh medium; this technic later became important in many fields, particularly in the culture of polio virus and preparation of polio vaccine.

Guthrie (1919), who demonstrated that blood vessels do not survive as such when transplanted from one animal to another but do provide a scaffolding or bridge for ingrowth of new tissue derived from the host.

Joliot and Curie (1934), who first announced the transmutation of one element to another (the alchemist's dream). They changed boron, magnesium, and aluminum into radionitrogen, radiosilicon, and radiophosphorus, respectively, and won a third Nobel Prize for the Curie family.

Alvarez and Cornog (1939), who first produced tritium in the Berkeley cyclotron.

Pattle (1955), who observed stable pulmonary edema foam and speculated that the surface tension of lung bubbles is zero.

Lehmann (1946), who noted that pathogenic tubercle bacilli have an increased uptake of O_2 in the presence of salicylates and first used para-amino salicylic acid as a bacteriostatic agent against tubercle bacilli.

Somewhat more verbose were the following:

- *Hooke* (1667), who required a page-and-a-half to present proof that rhythmic movements of the lung were not necessary for life if the lungs were inflated by a stream of air (figure 2). Hooke missed the one-page-or-less category because he also included in his article a bit about artificial ventilation, a technic for continuous positive airway pressure (though scarcely applicable clinically because he pricked the outer layer of the lungs with the "slender point of a very sharp penknife" to maintain a continuous flow of air *through* the alveoli), proof that pulmonary blood flow without ventilation could not maintain life and a suggestion that extracorporeal oxygenation of blood was feasible (really *aeration,* since there was no oxygen in 1667).

Henry (1803), who required two pages to present his law relating partial pressure of a gas in a liquid to the quantity dissolved in it.

Von Behring and Kitasato (1890), who needed one-and-a-half pages to tell the medical world of immunization against diphtheria and tetanus; they were awarded the Nobel Prize in 1901 for this work.

Curie, Curie, and Bémont (1898), who used two-and-a-half pages to announce the discovery of radium in pitchblende (another Nobel Prize-winning discovery).

Hering (1924), who took two pages to describe the carotid sinus reflex.

Bayliss and Müller (1928) who needed two pages to describe and illustrate their rotary, roller pump, later known by a variety of names, such as the DeBakey pump (three pages).

Urey, Brickwedde, and Murphy (1932), who used one-and-a-half journal pages to announce the preparation of deuterium.

Stanley (1935), who needed one-and-a-half pages to announce the isolation from infected tobacco plants of a crystalline protein with the properties of tobacco-mosaic virus.

Enders, Weller, and Robbins (1949), who expended one-and-three-quarter pages to present the cultivation of polio virus in human embryonic tissue, which led to the Nobel Prize for them and polio vaccine for all.

Clements (1957), who took one-and-a-half pages to quantify the surface-tension lowering properties of pulmonary surfactant ("anti-atelectasis factor").

Some wrote very long articles that are known today largely for a single paragraph. Henry Head's 70-page paper "On the regulation of respiration" (1889) is remembered mainly for one paragraph on page 13, in which he parenthetically described "Head's paradoxical reflex." And Christian Bohr's 33-page paper (1891) is remembered by most for his equation for respiratory dead space, stated in a few lines on page 248.

It's pretty hard nowadays to join this very select club of those who have written (and had published) a very short, important paper. You can try but I doubt that you'll succeed. Editorial boards resist accepting either long papers or very short papers (unless the latter are carefully segregated in a special section, suggesting that they are

An Account
*of an Experiment made by M.*Hook, *of Preſerving Animals alive by Blowing through their Lungs with Bellows.*

I Did heretofore give this *Illuſtrious Society* an account of an Experiment I formerly tryed of keeping a Dog alive after his *Thorax* was all diſplay'd by the cutting away of the *Ribbs* and *Diaphragme*; and after the *Pericardium* of the Heart alſo was taken off. But divers perſons ſeeming to doubt of the certainty of the Experiment (by reaſon that ſome Tryals of this matter, made by ſome other hands, failed of ſucceſs) I caus'd at the laſt Meeting the ſame Experiment to be ſhewn in the preſence of this *Noble Company*, and that with the ſame ſucceſs, as it had been made by me at firſt; the Dog being kept alive by the Reciprocal blowing up of his Lungs with *Bellowes*, and they ſuffered to ſubſide, for the ſpace of an hour or more, after his *Thorax* had been ſo diſplay'd, and his *Aſpera arteria* cut off juſt below the *Epiglottis*, and bound on upon the noſe of the Bellows.

And becauſe ſome Eminent Phyſitians had affirm'd, that the *Motion of the Lungs* was neceſſary to Life upon the account of promoting the Circulation of the Blood, and that it was conceiv'd, the Animal would immediately be ſuffocated as ſoon as the Lungs ſhould ceaſe to be moved, I did (the better to fortifie my own *Hypotheſis* of this matter, and to be the better able to judge of ſeveral others) make the following additional Experiment; *viz.*

The Dog having been kept alive, (as I have now mentioned) for above an houre, in which time the Tryal had been often repeated, in ſuffering the Dog to fall into *Convulſive* motions by ceaſing to blow the Bellows, and permitting the Lungs to ſubſide and lye ſtill, and of ſuddenly reviving him again by renewing the blaſt, and conſequently the motion of the Lungs: This, I ſay, having been done, and the Judicious Spectators fully ſatisfied of the reallity of the former Experiment; I cauſed another pair of Bellowes to be immediately joyn'd to the firſt, by a contrivance, I had prepar'd, and pricking all the outer-coat of the Lungs with the ſlender point of a very ſharp pen-knife, this ſecond pair of Bellows was mov'd very quick, whereby the firſt pair was alwayes kept full and alwayes blowing into the Lungs; by which means the Lungs alſo were alwayes kept very full, and without any motion; there being a continual blaſt of Air forc'd into the Lungs by the firſt pair of Bellows, ſupplying it as faſt, as it could find its way quite through the Coat of the Lungs by the ſmall holes pricked in it, as was ſaid before. This being continued for a pretty while, the Dog, as I exſpected, lay ſtill, as before, his eyes being all the time very quick, and his Heart beating very regularly: But, upon ceaſing this blaſt, and ſuffering the Lungs to fall and lye ſtill, the Dogg would immediately fall into Dying convulſive fits; but be as ſoon reviv'd again by the renewing the fulneſs of his Lungs with the conſtant blaſt of freſh Air.

Towards the latter end of this Experiment a piece of the Lungs was cut quite off; where 'twas obſervable, that the Blood did freely circulate, and paſs thorow the Lungs, not only when the Lungs were kept thus conſtantly extended, but alſo when they were ſuffer'd to ſubſide and lye ſtill. Which ſeem to be Arguments, that as the *bare* Motion of the Lungs *without freſh Air* contributes nothing to the life of the Animal, he being found to ſurvive as well, when they were not mov'd, as when they were; ſo it was not the ſubſiding or moveleſneſs of the Lungs, that was the immediate cauſe of Death, or the ſtopping the Circulation of the Blood through the Lungs, but the *want* of a ſufficient *ſupply of freſh Air*.

I ſhall ſhortly further try, whether the ſuffering the Blood to circulate through a veſſel, ſo as it may be openly expoſed to the freſh Air, will not ſuffice for the life of an Animal; and make ſome other Experiments, which, I hope, will throughly diſcover the *Genuine uſe of Reſpiration*; and afterwards conſider of what benefit this may be to Mankinde.

grade B and not grade A contributions). I suspect that today some of those mentioned earlier in this article would have received letters from the editor such as these:

Dear Dr. Korotkoff:

Thank you for permitting us to read your interesting manuscript. We regret that we cannot publish it in its present form. You may wish to resubmit it after you have (1) compared data obtained by your method with that obtained by the Riva-Rocci method in a large number of subjects of different ages and different arm circumferences, (2) verified the accuracy of your method against direct measurements of systolic and diastolic arterial blood pressure in animals, and (3) done statistical analysis of the data.

Sincerely,
The Editors

Dear Professor Fick:

Thank you for sending us your interesting suggestion for measuring cardiac output. We regret that we do not publish ideas unsupported by data and are returning your paper forthwith.

Sincerely,
The Editors

Dear Dr. Hooke:

We have read your communication entitled "Preserving animals alive by blowing through their lungs with bellows." We note that you have been sending us a number of short communications, none of which has been suitable for publication. We suggest that you consider combining all of these into one longer, more substantial manuscript that might contain enough new information to make it worthy of acceptance.

Respectfully,
The Editors

The Physician & The Law

Informed Consent Suit Against Anesthesiologist

A TRIAL court's decision in favor of an anesthesiologist should be reversed because the court failed to instruct the jury on the anesthesiologist's duty to inform the patient of risks inherent in treatment, the Vermont Supreme Court ruled. The case was remanded for a new trial.

The patient underwent surgery. Halothane was used as the general anesthetic. Later, the patient developed what was diagnosed as halothane hepatitis. Claiming she had not been informed of the possibility of hepatitis when she consented to the surgery, she brought an action against the anesthesiologist. A jury found in favor of the anesthesiologist, and the patient appealed.

The Vermont Supreme Court said that the trial court's instruction to the jury was too restrictive. The jury had been instructed that the anesthesiologist must disclose risks to the patient according to prevailing medical practice in the community. The supreme court stated that a physician must give a patient all information material to the decision to undergo the proposed treatment. The standard by which materiality is measured is the significance that a reasonable person would attach to the risks involved.

The real dispute in the case involved whether there was such a condition as halothane hepatitis, the court said. Evidence was introduced to show that there was not, and consequently there was no duty to warn of it. The possibility of halothane sensitivity was also disputed. Medical testimony indicated that the patient's condition was probably part of a postoperative depression due to the bilateral mastectomy plus a flare-up of her chronic colitis.

An osteopath who examined her initially diagnosed her condition as having its source in her colitis and not her liver. He later changed his mind after reviewing medical literature and material on halothane. Although it was the first time he had ever made such a diagnosis, he concluded that her condition was halothane hepatitis. Testimony indicated that the symptoms were non-specific and could have been caused by colitis or surgical trauma.

The anesthesiologist testified that he had not informed the patient of the possibility of halothane hepatitis. Under Vermont case law, if a reasonable person would not have consented to the operation had he been informed of the risk of halothane hepatitis, then the anesthesiologist was negligent for not furnishing the information.

The trial court's judgment was reversed and the case remanded for a new trial.—*Small v. Gifford Memorial Hospital,* 349 A.2d 703 (Vt.Sup.Ct., Nov. 24, 1975)

Questions and Answers

We invite you to submit questions to the Editorial Office, Kahler East, Suite C, Rochester, Minnesota 55901. The names of those submitting questions will remain anonymous if so desired.

The answers will be prepared by competent authorities, and their names will or will not appear, according to their specific wishes.

QUESTION: *My question concerns "balanced anesthesia," about the interpretation of which we are having differences of opinion in the Anesthesia Department. May I ask you to give the proper definition of this term? Also, which agents do you feel are usually combined during the use of this type of anesthesia (including different inhalation, as well as intravenous and intramuscular agents).*

The point in question here is whether two or more agents generally considered strong anesthetic agents each in its own right (such as enflurane, methoxyflurane, halothane, and/or ether) can be used simultaneously, mixed with N_2O and O_2, in low concentrations. Would this be considered, academically speaking, an accepted procedure in giving "balanced anesthesia?"

MD, Korea

ANSWER #1: The term, "balanced anesthesia," has no strict definition and thus has been used to describe many different drug combinations. Nevertheless, balanced anesthesia most often denotes anesthetic maintenance with N_2O plus neuromuscular blockers and supplementation with injectable but not with potent inhalation anesthetic drugs. The logic for considering a N_2O-narcotic-barbiturate-relaxant combination a balanced anesthetic, while not applying the same label to anesthetic maintenance with N_2O-halothane-relaxant, is not sound. Ideally, anesthetic drugs should be used in doses sufficient to produce desirable responses such as amnesia and analgesia, while neuromuscular blockers provide appropriate skeletal-muscle relaxation. Thus, neuromuscular blockers are not used to cover inadequate doses of anesthetic drugs nor should excessive concentrations of depressant drugs be used in attempts to produce profound muscle relaxation.

It would seem logical to abandon the term "balanced" to denote some undefinable anesthetic technic or drug combination. Instead, one should state the drugs used for anesthetic maintenance in each patient. True balanced anesthesia is the concept of drug use to obtain maximal beneficial effects with minimal undesirable responses. Thus, anesthetic maintenance with appropriate doses of either inhalation and/or injectable anesthetic agents, with or without neuromuscular blockers, represents balanced anesthesia.

Robert K. Stoelting, MD
Department of Anesthesia
Indiana University School
of Medicine
Indianapolis, Indiana

ANSWER #2: My experience and contacts in anesthesia for many years would indicate that rarely would the mixture of inhalation anesthesia agents, as suggested in the question, be what would come to the mind of most anesthesiologists as associated with the term "balanced anesthesia." Certainly to give these agents together is an acceptable procedure, but as to whether reference to same as "balanced anesthesia" is usual and customary, I would have to say possibly such usage would create a false impression. I have been unable to decide from the literature who first referred to "balanced anesthesia," (possibly John Lundy) but the common use of the term was, and is, most often associated with thiopental, N_2O, and a relaxant, either with or without a narcotic

added. Now many other drugs are used or added to the basic mixture. Any combination of drugs that in the hands of the individual administrator gives the desired anesthetic effect and does so in a physiologically benign manner and permits restoration of the preanesthetic state rapidly is a "balanced anesthetic." While the last point of the questioner is unanswered by this, it can be stated that the practice described is acceptable and commonplace anywhere and may be called whatever seems appropriate to the anesthesiologist.

Roy D. Wilson, MD

Baylor College of Medicine
Houston, Texas

CONTINUOUS POSITIVE AIRWAY PRESSURE. The noninvasive use of continuous positive airway pressure (CPAP) avoids the hazards of tracheal intubation. Arterial blood gases were determined before and after CPAP in 14 patients in acute respiratory distress. Criteria for CPAP were an ability to follow commands, $PaCO_2$ <45 torr and PaO_2 <65 torr (FIO_2> .6). The PaO_2 increased from a mean of 51 torr without CPAP to 87 torr with CPAP. In 8 patients the increase in PaO_2 was adequate to permit continued CPAP while tracheal intubation was performed in the remaining 6. Changes in $PaCO_2$ were variable but in one patient hypoventilation ($PaCO_2$ 69 torr) was significant. Complications of CPAP include increased work of breathing, potential aspiration and discomfort from the tight mask fit. These data suggest CPAP can be effectively delivered without endotracheal intubation in selected patients. *(Greenbaum DM, Millen JE, Eross B et al: Continuous positive airway pressure without tracheal intubation in spontaneously breathing patients. Chest 69:615-620, 1976)*

Books Received

Title	Author/Editor	Publisher	Pages	Price
Monographs in Anaesthesiology Volume 3: Muscle Relaxants	Ronald L. Katz (Editor)	New York American Elsevier Publishing Co. 1975	401	$49.95

This book provides basic information for the rational use of muscle relaxants.

The Anesthesiologist's Role in Pediatric Acute Care	Eric B. Furman (Editor)	Boston Little, Brown and Company 1975	231	

Problems of resuscitation, airway control, blood replacement and general supportive measures are more and more frequently becoming the responsibility of the anesthesiologist. This book provides basic knowledge for such acute care of children.

Physiological Basis of Anaesthesiology: Theory and Practice	W. W. Mushin J. S. Severinghaus M. Tiengo S. Gorini (Editors)	Padua, Italy Piccin Medical Books 1975	367	$20.00

This interesting and informative book is a compilation of material presented at the First International Seminar by internationally recognized participants.

Neurosurgical Anaesthesia 2nd Edition	A. R. Hunter	Philadelphia J. B. Lippincott Company 1975	344	$35.00

The first edition of this book was informative and useful. This second edition has required almost a total revision to bring it up-to-date.

Self Assessment in Anesthesiology	A. W. Grogono T. Hilary Howells	Chicago Year Book Medical Publishers, Inc. 1975	145	

This compilation of multiple-choice questions provides a useful adjunct for learning by the beginners as well as the more advanced student. Each question is supported by an answer.

Basic Physics in Anesthesiology: A Programmed Approach	L. Ivan Epstein Bernard A. Kuzava	Chicago Year Book Medical Publishers, Inc. 1976	388	

This book is written for the student with little or no prior knowledge of physics. Will be a useful source of information.

Clinical Use of Drugs in Renal Failure	Robert J. Anderson John G. Gambertoglio Robert W. Schrier	Springfield Charles C Thomas, Publisher 1975	251	$19.50

This book was written to assist physicians in taking care of patients with renal failure. The chapter on analgesic and soporific agents is important and useful.

Title	Author/Editor	Publisher	Pages	Price
Fundamentos de Anestesiologia 2a. edición	Guillermo Lopez Alonso	Mexico City La Prensa Medica Mexicana 1976	320	

Printed in Spanish, this book should be of real interest and value to our Spanish speaking colleagues.

Biotransformation of Local Anesthetics, Adjuvants, and Adjunct Agents	Gianfranco Dal Santo (Editor)	Boston Little, Brown and Company 1975	192	

Biotransformation and such related processes as distribution, elimination and protein binding of a number of agents are ably dealt with. Book warrants our attention.

Sleep 1974: Instinct, Neurophysiology, Endocrinology, Episodes, Dreams, Epilepsy and Intracranial Pathology	P. Bevin W. P. Poella (Editors)	New York S. Karger AG 1975	525	$76.50

This is a compilation of papers presented at the 2nd European Congress on Sleep Research held in Rome in 1974. To those interested in this particular subject, there are many hours of interesting reading.

Principles of Sedation, Local and General Anesthesia in Dentistry	Sylvan Myron Elliot Shane	Springfield Charles C Thomas, Publisher 1975	371	$19.00

The author, a dentist, has very ably drawn upon his own experience to write this text for dental anesthetists. Warrants reading.

Basic Problems in Burns	R. Vrabec Z. Konícková J. Moserová (Editors)	New York Avicenum, Czechoslovak Medical Press 1975	224	$25.00

This volume comprises the reports presented at the Symposium on the Treatment of Burns held in Prague September 1973. Several chapters are devoted to anesthesia and analgesia and resuscitation.

Local Anesthetics: Mechanisms of Action and Clinical Use	Benjamin G. Covino Helen G. Vassallo	New York Grune & Stratton 1976	173	$13.50

An interesting and informative little text on local anesthetic agents, starting with the discovery and use of cocaine brought up-to-date.

Tracheal Intubation	Edward L. Applebaum David L. Bruce	Philadelphia W. B. Saunders Company 1976	97	$9.50

This well-presented monograph, with very good illustrations and line drawings, will be interesting and useful for all medical and paramedical personnel involved in airway maintenance.

Anesthesia for the Uninterested	Alexander A. Birch John D. Tolmie	Baltimore University Park Press 1976	187	

A concise, frequently amusing, nicely illustrated, evening's reading.

Clinical Pharmacology in Dentistry	R. A. Cawson R. G. Spector	New York Churchill Livingstone 1975	254	$13.50

Dental practitioners must have a basic knowledge of pharmacology to use drugs to the advantage and benefit of their patients. This book concisely provides useful information.

	Author/Editor	Publisher	Pages	Price
1975 Year Book of Anesthesia	James E. Eckenhoff (Editor) David L. Bruce Edward A. Brunner H. Steele Holley Harry W. Linde (Associate Editors)	Chicago Year Book Medical Publishers, Inc. 1975	383	$18.50

Another informative addition to a series.

Anaesthesia for Eye, Ear, Nose and Throat Surgery	William F. K. Morrow James D. Morrison (Editors)	New York Churchill Livingstone 1975	149	

A small book containing much information. Will be particularly useful to students in training, but also will be helpful to more advanced consultants, both in our specialty and otorhinolaryngology.

Anaesthesie und Reanimation in der Kinderneurologie	Heinz Schoeppner Rosemarie A. Dietze Ursula Mielke	Leipzig VEB georg Thieme 1975	316	

An interesting and informative presentation of a subject about which most of us know too little.

Anesthesiology and the University	Nicholas M. Greene	Philadelphia J. B. Lippincott Company 1975	174	$10.00

An interesting and thought-provoking presentation by an outstanding author and anesthesiologist. Warrants your time for reading.

An Historical Account of Pharmacology: To the Twentieth Century	Chauncey D. Leake	Springfield Charles C. Thomas, Publisher 1975	210	$12.50

A very interesting personal historical dissertation on the development of our knowledge of drugs.

Current Topics in Critical Care Medicine	W. C. Shoemaker B. M. Travarese (Editors)	New York S. Karger, AG 1976	181	$36.00

This little paperback presents the proceedings of the Third International Symposium on Critical Care. Timely and useful information.

Intravenous Anaesthesia	John W. Dundee Gordon M. Wyant	Edinburgh Churchill Livingstone 1974	341	$28.50

An excellent comprehensive presentation of a special facet of our specialty. Much useful information.

Pediatric Anesthesia Case Studies	John G. Adams	Flushing, N.Y. Medical Examination Publishing Company, Inc. 1976	191	$10.00

Twenty-nine case histories followed by questions based on information furnished, plus the correct answers, with appropriate references. Readers may not agree with all the answers.

Title	Author/Editor	Publisher	Pages	Price
Self-Assessment of Current Knowledge in Anesthesiology	David L. Trickey	Flushing, N.Y. Medical Examination Publishing Company, Inc. 1976	180	$10.00

This volume comprises 1,142 multiple choice questions and answers referenced to current journal articles. An excellent guide for self-evaluation and continuing education.

Respiratory Therapy in Critical Care	Hugh S. Mathewson	Saint Louis The C. V. Mosby Company 1976	133	$6.50

Material in this little volume really is oriented toward the needs of the respiratory therapist. This book contains much useful information.

Development of Upper Respiratory Anatomy and Function: Implications for Sudden Infant Death Syndrome	James F. Bosma Jane Showacre (Editors)	Washington, DC US Government Printing Office 1976	279	$7.10

This book followed a symposium on Sudden Infant Death Syndrome. Thirty authors have contributed much information, well illustrated, with each chapter followed by appropriate references.

Evaluations of Drug Interactions Second Edition	—	Washington, DC American Pharmaceutical Association 1976	520	$12.50

Several thousand potential drug interactions are evaluated and discussed in this second edition, which is designed for every-day use by all health care practitioners. A significantly expanded index affords the quick access to information on specific interactions. Trade names are included in the index and are referenced to the appropriate nonproprietary term. This is a valuable source for authoritative, practical and complete drug interaction information.

Monographs in Anaesthesiology Vol. 5: Practical Regional Analgesia	J. Alfred Lee Robert Bryce-Smith (Editors)	New York Excerpta Medica 1976	232	$29.95

This book provides a guide to well-tried and commonly employed local and regional anesthetic technics.

The Human Larynx: A Functional Study	B. Raymond Fink	New York Raven Press 1975	193	

A nicely written, informative, well-illustrated book about an anatomic area about which most of us know too little.

Anesthesia for Open-Heart Surgery	Vieri Wiechman, MD (Editor)	Boston Little, Brown and Company 1976	277	

The physiological and clinical problems, as well as the practical management of different types of patients are ably addressed by authors from leading cardiac centres in Europe.

ANNUAL INDEX

VOLUME 55, 1976

Anesthesia AND Analgesia

.....CURRENT RESEARCHES

Official Journal of the International Anesthesia Research Society

A

A-aDo_2 after open-heart surgery 315-321

Aasheim GM: see Pflug AE jt auth

Abouleish E: Caudal analgesia for quadruplet delivery 61-66

Abouleish E: Postpartum hypertension and convulsion after oxytocic drugs 813-815

Abouleish E, Taylor FH: Effect of morphine-diazepam on signs of anesthesia, and dreams of patients under N_2O for cesarean section 702-705

Abramawitz MD: see Brodsky JB jt auth

Absorption-excretion volume effect, pulmonary 51-56

Acromegaly, laryngeal stenosis 57-60

Acupuncture anesthesia, a clinical study 508-512

Acupuncture, incidence of prolonged pain relief 229-234

Acute abdomen, unrelenting hypotension in a comatose hemophiliac child 346-349

Acute maxillary sinusitis complicating nasotracheal intubation, Brief Reports 885-886

Adams HJ, Blair MR Jr, Takman BH: The local anesthetic activity of tetrodotoxin alone and in combination with vasoconstrictors and local anesthetics 568-573

Adams HR, Mathew BP, Teske RH et al: Neuromuscular blocking effects of aminoglycoside antibiotics on fast-and-slow-contracting muscles of the cat 500-507

Adiposis dolorosa, management of intractable pain with intravenous lidocaine 257-259

Airway difficulties, laryngeal stenosis in acromegaly 57-60

Airway problem, tracheal bronchus, Brief Reports 746-747

Airway resistance, changes following droperidol, hydroxyzine, and diazepam 18-21

Albrecht RF: see Miletich DJ jt auth

Aldosterone, general anesthetic agents, and ouabain, effect on striated muscle contraction in toad 409-414

Aldrete JA: see Geevarghese KP jt auth

Aldrete JA, Tan ST, Carrow DJ et al: "Pentazepam" (pentazocine + diazepam) supplementing local analgesia for laparoscopic sterilization 177-181

Alexander JJ, Wall J: Righting the wrongs of writing: copy editors speak out, Editor's Choice 219-223

Alfonso AE: see Sklar GS jt auth

Allen GW: see Frederickson EL jt auth

Alveolar-arterial O_2 tension difference, factors affecting, open-heart surgery 315-321

Amaranath L, Andersen NB: The effect of general anesthetic agents, ouabain, and aldosterone on striated muscle contraction in toad 409-414

Amberg HL, Gordon G: Low-dose intramuscular ketamine for pediatric radiotherapy: a case report 92-94

Amberg HL: Use of monitor for ketamine in radiotherapy, Correspondence 895

Aminoglycoside antibiotics, neuromuscular blocking effects on the cat 500-507

Anaesthesia, history of ideas, Tenth Annual Becton, Dickinson and Company Oscar Schwidetzky Lecture 467-473

Analgesia, caudal for quadruplet delivery 61-66

epidural, bacteriologic aspects 187-190

local, supplemented by "pentazepam" for laparoscopic sterilization 177-181

methoxyflurane administration for vaginal delivery or cesarean section 415-419

narcotic versus post-thoracotomy intercostal block 542-546

Analgesic activity, butorphanol and morphine 394-401

Anaphylaxis, etiology and guidelines for management 493-499

Andersen NB: see Amaranath L jt auth

Andersen TW: see Lee PKY jt auth

Anderson EF: A potential ignition source in the operating room 217-218

Anderson N: see Ritter JG jt auth

Anesthesia, acupuncture, a clinical study 508-512

acute ethanol intoxication, effect on neonate, Brief Reports 602-603

analysis of tasks and human factors for coronary-artery bypass 374-377

anaphylaxis management 493-499

balanced, Questions and Answers 907-908

Bird® Mark-14 ventilator, Brief Reports 879

cardiac disease 617

circle systems, comparison of efficiency 724-729

clinical use of etomidate for induction 730-733

considerations for pericardectomy in uremic pericardial effusion 378-382

considerations in diffuse bleeding, diathesis of uncertain origin 173-176

cyclopropane, hypercapnia, Brief Reports 439-441

dissociative, ketamine, intraocular pressure 773-775

dissociative, ketamine tolerance 778-791

dosage nomogram for sodium nitroprusside induced hypotension 574-581

doxapram effects on cerebral blood flow and peripheral hemodynamics, goats 279-285

effect of general agents, ouabain, and aldosterone on striated muscle contraction in toad 409-414

electroanesthesia, monkey 536-541

endotracheal, laryngotracheal residue 392-393

enflurane and halothane, a comparative study using systolic time intervals 263-268

enflurane, cardiac decompensation, myotonia atrophica, Case History 433-436

enflurane, changes in blood chemistries 547-549

enflurane, COPD 806-809

enflurane, isoflurane, fluroxene, methoxyflurane and diethyl ether, effect on ouabain tolerance in the dog 360-365

estimation of solubility in blood, Brief Reports 593-595

gas machine hazards 26-33

general for blepharoplasty and rhytidectomy 165-167

general, neutrophil chemotaxis 668-673

general, recall 696-701

halothane and enflurane, absence of autoregulation of cerebral blood flow 100-109

halothane and succinylcholine, massive myoglobinuria 680-682

halothane MAC, effect of isoproterenol and propranolol in dogs 383-387

halothane MAC, phenobarbital in dogs 677-679

halothane, subsequent exposures in animals sensitized to a halothane metabolite, hepatic pathology 235-242

induction, etomidate 286-289

Anesthesia, (continued)
influence of pancuronium on potassium efflux produced by succinylcholine 474-477
isoflurane and halothane, hemodynamic effects, coronary artery disease 135-138
isoflurane, calibration of the Narkotest® gas monitor, Brief Reports 441-442
interaction of epinephrine with enflurane, isoflurane and halothane 709-712
intraoperative awakening for early recognition of possible neurologic sequelae during Harrington-rod spinal fusion 526-528
ketamine, arterial hypoxemia 311-314
laryngeal stenosis in acromegaly 57-60
legal aspects, physician-patient relationship, Questions and Answers 463-464
management in cardiac disease 622-625
modification of response to infection in mice 776-781
narcotic-supplemented, naloxone antagonism 800-805
nitrous oxide, absorption and excretion, pediatrics 95-99
nitrous oxide, effect of morphine-diazepam on awareness and dreams of patients for cesarean section 702-705
nitrous oxide, hepatic clearance of lidocaine in dogs 322-325
no liability for death of patient, Physician and the Law 759
obstetric, training centers in the U.S.A.—1975 839-845
patients early after infarction 640-642
patients with gas gangrene 247-252
patients with heart block and artificial cardiac pacemakers 626-632
preoperative evaluation and preparation of the cardiac 618-621
propranolol 1-5
rapid induction in combat casualties 74-76
regional, bupivacaine 763-768
regional, evaluation of memory 368-373
regional in renal transplantation 69-73
regional, lumbosacral plexus block 350-352
regional versus general, Questions and Answers 277-278
relation of $Paco_2$ to fresh gas flow in a circle system 706-708
respiratory distress with cardiovascular anomaly 481-484
severe hypertension, Wilms' tumor 519-521
simple method for inserting a nasogastric tube, Brief Reports 303-304
spinal, bupivacaine versus tetracaine
spinal, lumbar disc surgery 550-554
sodium nitroprusside-induced hypotension 654-662
theoretic significance of pH dependence of narcotics and narcotic antagonists 253-256
thiamylal-N_2O halothane, influence of pancuronium or d-tubocurarine circulatory responses 484-488
transcervical thymectomy 13-21
vanishing lung syndrome 750-752
Anesthesiologist, informed consent suit, Physician and the Law 906
no negligence in surgeon's failure to supervise, Physician and the Law 459
outpatient evaluation 307-310
Anesthetic, effect of oxygen 734-736
Anesthetic gas scavenger, Jackson-Rees system, Brief Reports 881-882
Anesthetic induction, circulatory changes 77-81
Anesthetic, inhalation, comparative study on pharmacokinetics and metabolism 853-862
Anesthetic, liability of manufacturer, Physician and the Law 202
Anesthetic, new intravenous—etoxadrol hydrochloride (CL-1848C; U-37862A) 335-339
Anesthetic, potency of lidocaine in the rat 818-821
Anesthetic wastes, effect on operating room personnel, Questions and Answers 760
Anesthetist, analysis of tasks and human factors for coronary-artery bypass 374-377
Animals, anesthesia and the modification of response to infection in mice 776-781
anesthetic potency of lidocaine in the rat 818-821
cardiovascular dynamics after large doses of fentanyl and nitrous oxide 168-172
cardiovascular effects of enflurane and halothane, Rhesus monkeys 85-91
effect of doxapram on cerebral blood flow and peripheral hemodynamics, goats 279-285
effect of enflurane, isoflurane, fluroxene, methoxyflurane and diethyl ether anesthesia on ouabain in the dog 360-365
effect of heparin on recovery from ischemic brain injuries in cats 683-687
effect of isoproterenol and propranolol on halothane MAC in dogs 383-387
electroanesthesia, Rhesus monkeys 536-541
halothane MAC, phenobarbital, dogs 677-679
hepatic clearance of lidocaine during nitrous oxide anesthesia in dogs 322-325
neuromuscular blocking effects of aminoglycoside antibiotics on the cat 500-507
preanesthetic evaluation and management of malignant hyperthermia, pigs 643-653
sensitization to a halothane metabolite and subsequent halothane exposure, hepatic pathology 235-242
Announcement: Nicholas M Greene, MD
Antagonism, naloxone 800-805
Antibiotics, aminoglycoside, neuromuscular blocking effects on the cat 500-507
muscle relaxants potentiated 224-228
prolonged epidural catheterization, Questions and Answers 132-133
Antihypertension, sodium nitroprusside 574-581
Anxiety, lorazepam premedication 792-796
Apnea, atypical pseudocholinesterase 243-246
prolonged, succinylcholine, Case History 737-739
Appendectomy, settlement for brain damage, Physician and the Law 45-46
Arterial hypoxemia, intravenous ketamine 311-314
Arterial oxygenation, decreased, sodium nitroprusside, Brief Reports 880-881
Artificial heart implantation, cardiovascular and respiratory effects of isoproterenol 560-567
ASA classification, Questions and Answers 614-615
Aspiration, tracheal 816-817
Atropine, pre-and post-anesthetic use in patients with glaucoma, Questions and Answers 460-461
Atypical pseudocholinesterase 243-246
Ausinsch B, Rayburn RL, Munson ES et al: Ketamine and intraocular pressure in children 773-775

Autoregulation, cerebral blood flow, halothane and enflurane anesthesia 100-109
Awareness and recall, perioperative 513-518
Awareness and dreams, effect of morphine-diazepam, nitrous oxide, cesarean section 702-705

Brief Reports
Fire hazard during CO_2 laser microsurgery on the larynx and trachea 146-147
A new introducer for percutaneous cardiovascular catheters 148-149
Plastic covered solid copper wire stylet 150
An unusual problem in nasotracheal extubation 302-303
A simple method of inserting a nasogastric tube for anesthesia 303-304
Acute cardiovascular collapse after intravenous phytonadione 304-306
Defective disposable endotracheal tube 437
Fatal complication from swallowed denture following prolonged endotracheal intubation 438-439
Hypercapnia during cyclopropane anesthesia 439-441
Calibration of the Narkotest® gas monitor for isoflurane 441-442
Prevention of hypothermia during cystoscopy in neonates 592-593
Estimation of anesthetic solubility in blood 593-595

Brief Reports, (continued)
Significance of Pco_2 within low-pressure endotracheal tube cuffs 595-596
Shearing hazard of intra-arterial Teflon catheters 597-598
Evaluation of larynx and trachea by xeroradiography 598-600
Pneumatocele of the larynx: a complication of percutaneous transtracheal ventilation 600-601
Acute ethanol intoxication and its prolonged effect on a full-term neonate 602-603
A precordial ECG lead for chest operations 740-741
A safety valve for the pediatric Rees system 741-743
Hazards of disposable rebreathing circuits 743-744
A PEEP device for a manual bag ventilator 745
The tracheal bronchus: an unusual airway problem 746-747
Innominate artery compression simulating cardiac arrest during mediastinoscopy: a case report 748-749
Anesthesia for vanishing lung syndrome: report of a case 750-752
Bronchial blockade in a child with a bronchopleural-cutaneous fistula using a balloon-tipped catheter 874-875
Difficult extubation of an endotracheal tube cuff 876-877
Humidity output of the Columbia pediatric system 877-879
Modification of a Bird® Mark-14 anesthesia ventilator for greater versatility 879
Decreased arterial oxygenation during sodium nitroprusside administration for intraoperative hypertension 880-881
An anesthetic gas scavenger for the Jackson-Rees system 881-882
A method for inserting the Carden tube 883-884
Acute maxillary sinusitis complicating nasotracheal intubation: a case report 885-886
Supine hypotensive syndrome caused by intra-abdominal mass: a case report 887-889
Brodsky JB, Abramawitz MD, Mehrez MP: Endobronchial intubation for intraoperative protection of a single functioning lung: a case report 340-342
Bronchial blockade, balloon-tipped catheter, Brief Reports 874-875
Bronchopleural-cutaneous fistula in a child, bronchial blockade, Brief Reports 874-875
Bronchus, tracheal, airway problem, Brief Reports 746-747
Brown EM: Intrathecal cold saline solution for intractable pain, Questions and Answers 131-132
Single-needle lateral approach for lumbar sympathetic block, Correspondence 451-453
Bruner JMR: Safety in operation of rechargeable ECG monitor (Tektronix®), Questions and Answers 613

A WARMER FOR ANTISEPTIC SKIN PREPARATION SOLUTIONS—Charles J. Restall, M.D., and Steven P. Schmidt, CRNA, Rochester, Minnesota.

CANNULATION OF A NON-PALPABLE ARTERY WITH THE AID OF A DOPPLER MONITOR—Chana Buakham, M.D., and Jong Min Kim, M.D., Kansas City, Missouri.

ACUTE PULMONARY EDEMA FOLLOWING HEAD INJURY: TWO CASE REPORTS—Harry B. Cohen, M.D., and G. W. N. Eggers, Jr., M.D., Columbia, Missouri.

PROGESTERONE FOR THE PICKWICKIAN SYNDROME: RESPIRATORY IMPLICATIONS—Ray McKenzie, M.D., FFARCS, and Rajindar K. Wadhwa, M.D., Pittsburgh, Pennsylvania.

FLUCTUATING HYPOXEMIA AND PULMONARY SHUNTING FOLLOWING FATAL HEAD TRAUMA. CASE REPORT—Nathan L. Pace, M.D., Seattle, Washington and Fort Sam Houston, Texas.

A Guide for Authors

Anesthesia and Analgesia . . . Current Researches invites manuscripts on subjects pertinent to the specialty of Anesthesia.

Send manuscripts and illustrations in *triplicate* to:

T. H. Seldon, MD, Editor
Kahler East, Suite C
Rochester, Minnesota 55901

Four categories of reports will be considered for publication.

1. Original articles describing clinical or laboratory research.

2. Brief Reports describing new anesthetic technics, equipment, clinical, or laboratory studies.

3. Case Reports.

4. Letters-to-the-Editor.

EDITORIAL POLICIES

Peer review.—All papers submitted are reviewed by selected referees with respect to validity, pertinence, completeness, and originality. If accepted for publication, editorial revisions may be made to aid clarity and understanding. Edited copy will be submitted to authors for approval before the paper goes to the printer. Pageproofs also will be submitted to the authors for final approval. Reprint order forms will accompany pageproofs.

Cover letter.—A letter must accompany each manuscript, stating that the work has not been simultaneously submitted to another journal or previously published in part or whole. The name and address of the author to whom correspondence may be directed should be given.

Legal and ethical considerations.—Information or illustrations which might permit identification of patients must not be used.

Reports describing data from experiments performed on humans must contain a statement in the Methods section, when appropriate, that written informed consent and/or institutional approval of the investigation has been obtained, and that procedures involving the use of animals was conducted so as to minimize discomfort.

Excerpts from material published elsewhere must be accompanied by written permission from the author and publisher to reproduce the material.

JOURNAL STYLE

Format.—All portions of the manuscript should be typewritten and double-spaced, including lists of reference citations. Each component of the paper (title page, with authors' academic rank and addresses, Introduction, Methods, Results, Discussion, References, Legends) should begin on a separate page. Original articles must be preceded by an Abstract concisely describing the purpose, methods, results, and conclusions. Abstracts should not exceed 1 typewritten page in length. Brief Reports and Case Reports do not require an Abstract, but a Summary at the end may be appropriate.

Original articles should be concise (not over 3000 words) and present new information pertinent to anesthesia. Preliminary reports or fragments of material that may better be included in a single, more detailed, report should not be submitted. Brief Reports describing new equipment or technics should present new advances, with advantages over the alternatives. Descriptions of new equipment must be sufficient to permit the reader to either construct or purchase the equipment. Case Reports should emphasize important clinical conditions or variations in typical patient responses. Letters-to-the-Editor must be brief (250-500 words) and should offer constructive comments on

recently published articles or discuss areas of general interest to anesthesiologists.

Measurement units.—The metric system should be used for all such data as length, mass, volume, and temperatures. Torr should be used in place of mm Hg for partial pressures. Authors are encouraged to adopt the International System of units (moles per liter rather than mg percent) for concentrations or amounts of substances. (See Padmore GRA, Nunn JF: SI Units in relation to anaesthesia. A review of the present position. Br J Anaesth 46:236-243, 1974).

Drug names.—Generic or chemical drug names are required. Brand names may be inserted in parentheses after the generic name, if pertinent.

Abbreviations.—The first time an abbreviation appears it should be preceded by the full word it represents.

Respiratory symbols.—Symbols for respiratory physiology should be defined the first time used and should follow Pappenheimer J et al: Standardization of definitions and symbols in respiratory physiology. Fed Proc 9:602-605, 1950.

References. — References should correspond to Index Medicus style and should be listed in the same numerical order as they appear in the text. Reports that are not accessible to all readers or that have not undergone editorial review (abstracts, correspondence, or personal communications) should not be included in numerical listings but may be footnoted. They should include pertinent addresses as well as source and authors' names.

Illustrations.—Drawings and photographs (unmounted glossy prints) should be numbered in order of appearance in the manuscript and labeled on the back with the first author's name and indicate the top edge of the picture.

Tables.—These should carry a title or caption and should supplement, not duplicate, the text.

PRECISE, ECONOMICAL, SAFE...

RALS POWER UNIT

...INSTANT ATOMIZATION FOR FAST TOPICAL ANESTHESIA

Fast, measured topical anesthesia is ready at your finger tips in a Rals Power Unit. Forget about pumping bulbs, uneven atomization, and limited spraying duration. The Rals Power Unit uses a non-toxic propellant, dichlorodifluoromethane (freon) to activate standard DeVilbiss Atomizers No's. 151, 152 and 163. Instantly, a fine mistlike spray is produced. A graduated solution vial is available for measuring the amount of solution administered.

The Rals Power Unit has been proven effective in cocainization prior to endotracheal intubation, endoscopic instrumentation, laryngotracheal insufflation, and in a variety of nose and throat procedures.

Rals Power Unit #168 are supplied six to a box with adaptor top and metal base. Illustration shows #152 atomizer. All styles in stock.

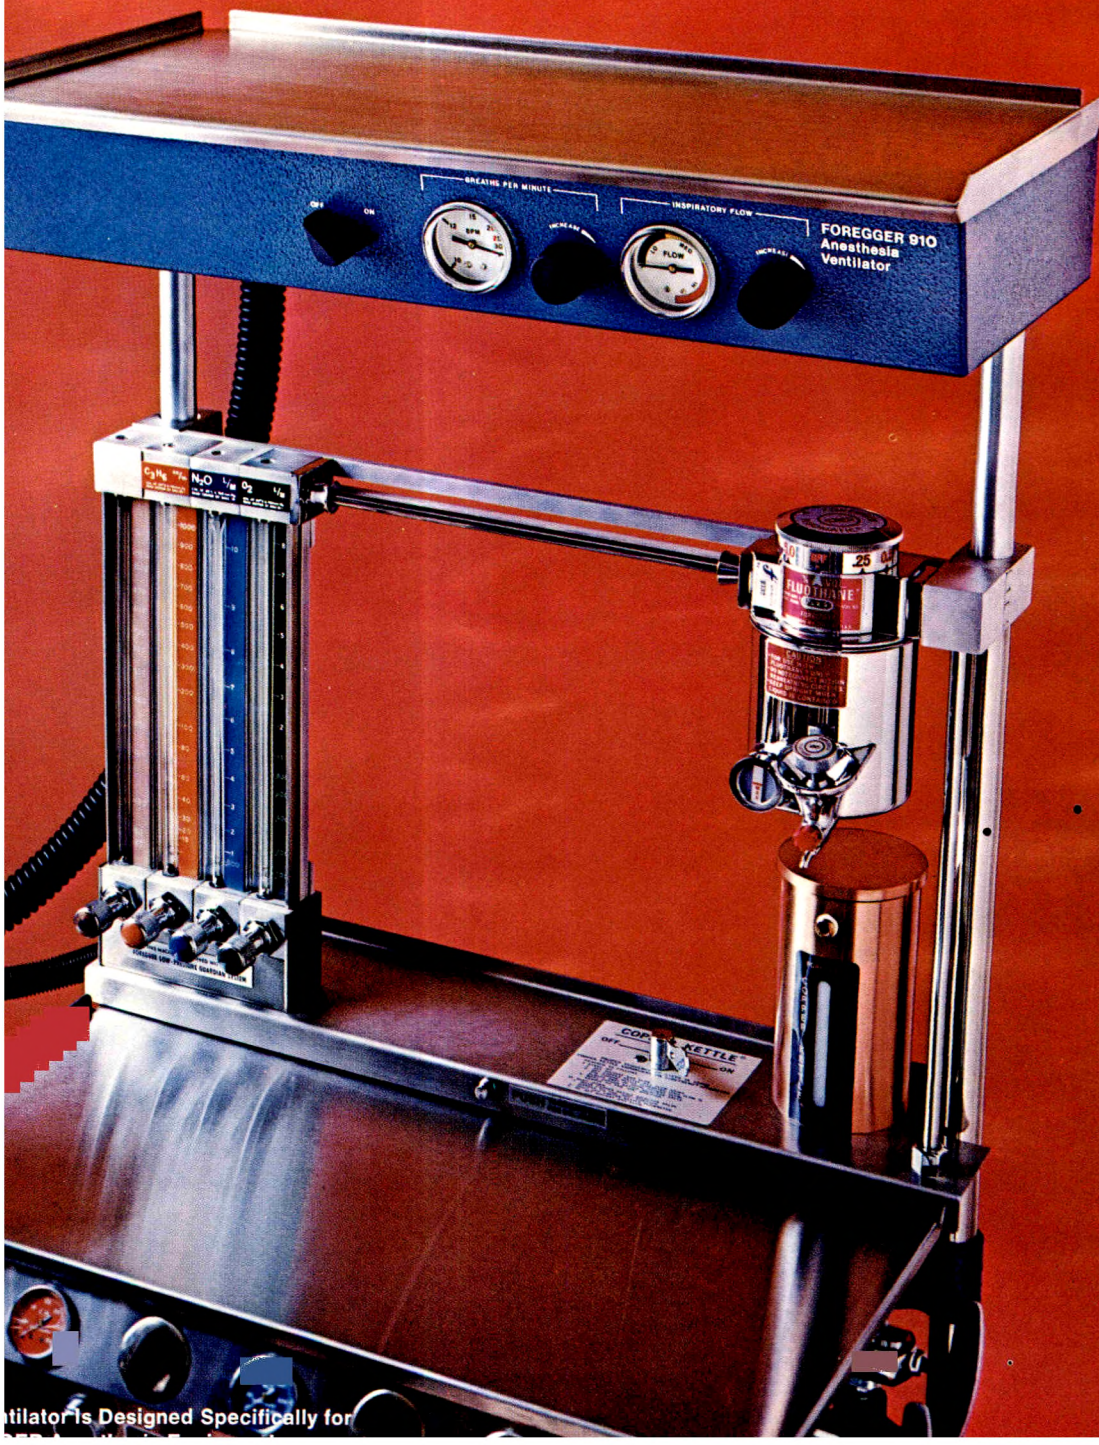
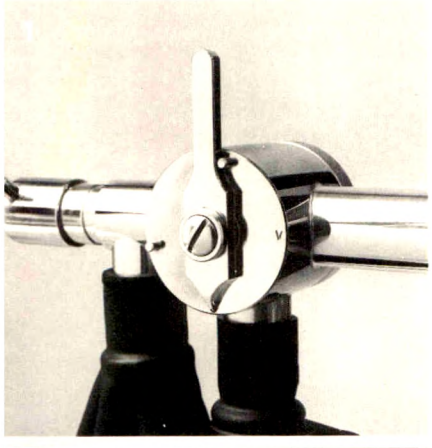
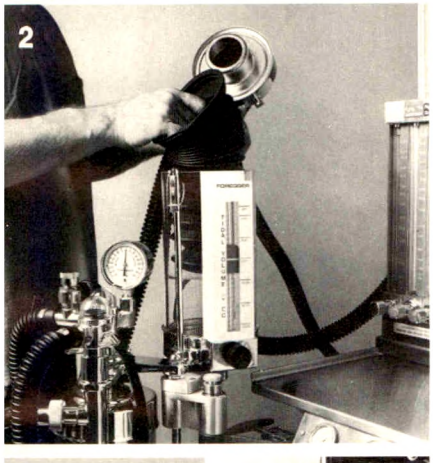
Get Quiet, Simple Performance That's Out of Your Way

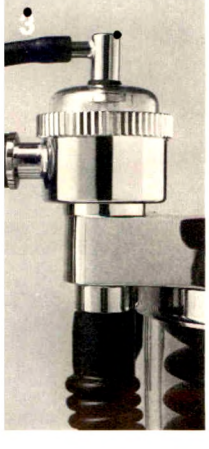


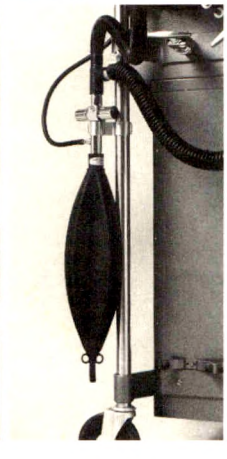
tilator Is Designed Specifically for

The FOREGGER® 910 Anesthesia Ventilator









Your job is complicated enough! You administer anesthesia, chart the patient's vital signs, monitor blood loss and blood gases, regulate the I.V., and much more. In short, you have plenty to do. Therefore, you may use an anesthesia ventilator to help maintain patient control.

But adding on a ventilator can mean adding on distractions, especially if it requires control adjustments for parameters you may not even need. And, you can end up settling for a complicated ventilator arrangement that is inconvenient to use.

So we developed the human-engineered FOREGGER 910 Anesthesia Ventilator. Human-engineered because it gives you just the ventilation control you need in a compact, convenient, uncomplicated package. And it's built-in. So it's accessible, but not in the way.

Simple to operate. Simple to monitor. Simple to clean and maintain. And it's quiet. In addition, the 910 Ventilator helps control OR pollution with an efficient gas collection system.

For additional information contact your Air Products Representative, FOREGGER dealer, or write to Air Products and Chemicals, Inc., Customer Service Department, Box 538 M, Allentown, Pa. 18105.

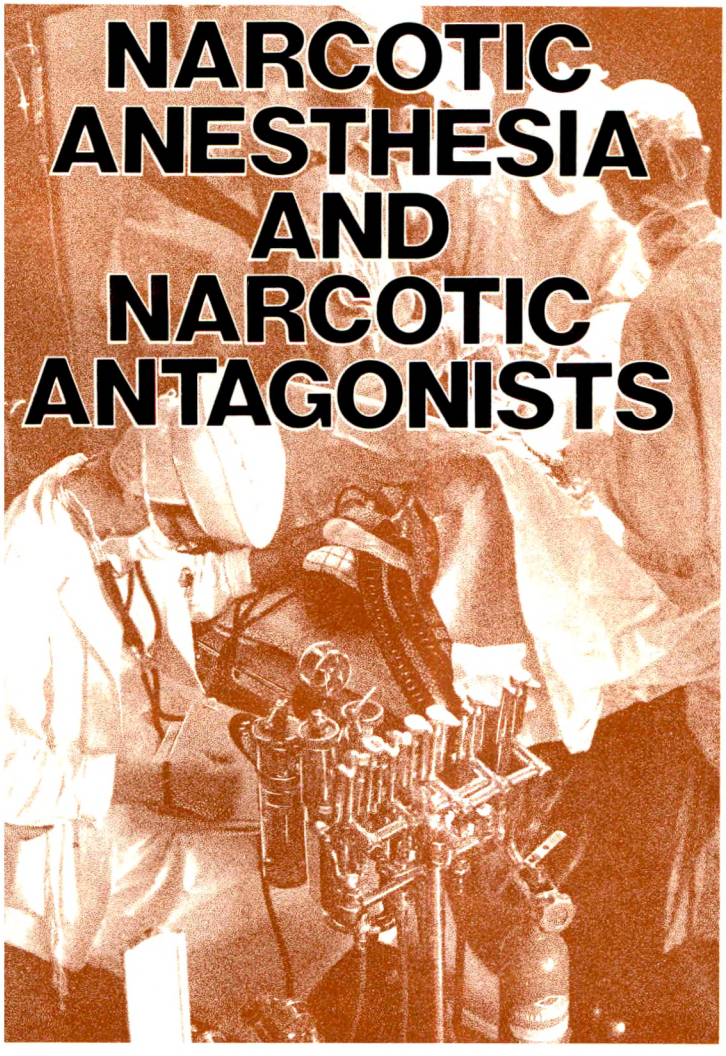
Simple to Monitor because built-in, easy-to-read gauges show Breaths Per Minute, Tidal Volume and Inspiratory Flow at a glance, without clock-watching or computing. And the ventilator control panel is positioned to give you clear visibility and direct control from a comfortable working position.

1. Simple to Operate because it's built-in and requires only five simple steps to initiate and control ventilation. Switches from "bag" to ventilator at a touch.

2. Simple to Clean and Maintain because the bellows and bellows dome container can be easily removed for cleaning, sterilizing and drying purposes. And fluidic circuitry minimizes maintenance.

3. Helps to Minimize OR Pollution because excess gas is automatically vented into a built-in gas evacuator.

Air Products
FOREGGER



NARCOTIC ANESTHESIA

- Despite many advantages, the use of opioids to supplement nitrous oxide anesthesia may be associated with significant postoperative depression.

NARCAN® (naloxone HCl)

- Narcan® in sufficient doses will antagonize opioid effects, including all degrees of respiratory depression and analgesia.
- The degree of narcotic antagonism exhibited by NARCAN® is dose dependent.

A recent study of surgical patients receiving narcotic-nitrous oxide anesthesia was undertaken to determine whether careful titration of naloxone would reverse post-operative narcotic depression and maintain a subjective level of analgesia.[1]

THE OBJECTIVES:

- Restore consciousness
- Reverse narcotic-induced respiratory depression as evidenced by $PaCO_2$
- Maintain *subjective* analgesia

THE METHOD:

- 12 unpremedicated patients received INNOVAR® (fentanyl/droperidol) 5-10 ml I.V. followed by thiopental for induction. Anesthesia was maintained with N_2O-O_2. Increments of 0.1 mg *fentanyl* were given I.V. every 10 minutes during surgery.

Following the procedure, naloxone (0.1 mg/ml) was given in 0.1 mg I.V. increments at 1 minute intervals until the patient was awake, lucid and had adequate tidal and minute volumes. Additional naloxone

eisterkamp DV, Cohen PJ. *Anesth Analg* (Cleve) 53:12-18, Jan-Feb 1974
RCAN® is an Endo registered U.S. trademark; U.S. Pat. 3,254,088

was given I.V. as needed in the first 6 patients; a second group of 6 patients received supplemental naloxone I.M. 30 minutes after the initial I.V. dose.

- 11 patients received 10 mg *morphine* I.M., as well as secobarbital and atropine, 1½ hours preoperatively. Anesthesia was induced by 30 mg morphine given slowly I.V. followed by thiopental and was maintained by N_2O-O_2. Additional morphine was given in divided increments to total 1 mg/kg in the first hour. Further morphine was given as needed. For initial narcotic reversal, naloxone was given as above except at 2 minute intervals. Supplemental naloxone was given I.M. 30 minutes later.

THE RESULTS (fentanyl group):

- When fentanyl was used as the sole narcotic supplement during anesthesia, an I.M. dose of naloxone equal to half the I.V. reversal dose and given ½ hour later provided adequate narcotic reversal.

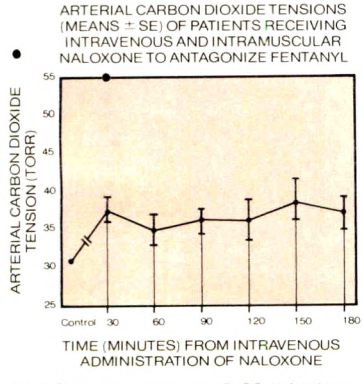


Fig. 1. Control and postoperative $PaCO_2$ in 6 patients receiving I.V. and I.M. naloxone following fentanyl

THE RESULTS (morphine group):

- "After other narcotics, such as morphine, an I.M. dose of naloxone equal to the I.V. dose appears appropriate."

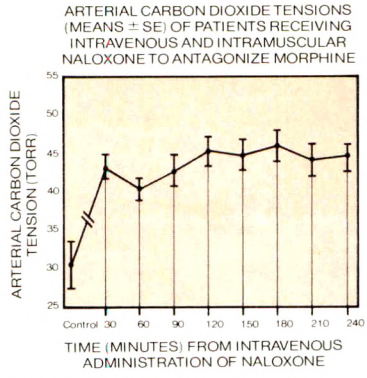

Fig. 2. Control and postoperative $PaCO_2$ in 11 patients receiving I.V. and I.M. naloxone following morphine

THE CONCLUSIONS:

- "Naloxone provides fast, potent, and reliable antagonism to narcotic-induced respiratory depression."
- "By careful titration, this antagonism can be achieved while acceptable analgesia is maintained."
- "Both morphine and fentanyl groups had adequate analgesia, with only 2 patients [of total 21] requiring pain medication in the recovery room."

- **reverses all degrees of narcotic-induced respiratory depression**
- **does not cause narcotic-like effects**
- **does not augment non-narcotic depression**
- **acts rapidly—generally withi 2 minutes following I.V. use and slightly less rapidly whe given I.M.**
- **does not lead to tolerance**
- **does not produce psychotomimetic effects or pupillary constriction**
- **can be repeated if initial dos doesn't produce desired degree of narcotic reversal and improvement in respiratory function**
- **following satisfactory response patient should be observed closely and given repeat doses, if necessary, since the duration of action c some narcotics may exceed that of NARCAN®**

Please see next page for complete prescribing information.

DUPONT

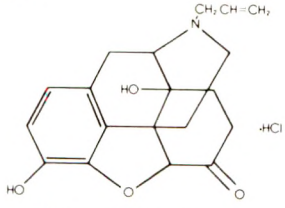
·restored consciousness
·reversed narcotic-induced respiratory depression
·maintained subjective analgesia

NARCAN®
(naloxone HCl)

can reverse narcotic-induced respiratory depression while maintaining subjective analgesia

NARCAN® (naloxone HCl)

DESCRIPTION NARCAN® (naloxone hydrochloride), a narcotic antagonist, is a synthetic congener of oxymorphone. In structure it differs from oxymorphone in that the methyl group on the nitrogen atom is replaced by an allyl group.



NALOXONE HYDROCHLORIDE
(N-allyl-nor-oxymorphone HCl)

Naloxone hydrochloride occurs as slightly off-white crystals, and is soluble in water, slightly soluble in alcohol and practically insoluble in ether.

NARCAN® (naloxone hydrochloride) Injection is available in two concentrations, 0.02 mg and 0.4 mg of naloxone hydrochloride per ml. Each ml of either strength contains 8.6 mg of sodium chloride; and 2.0 mg of methylparaben and propylparaben as preservatives in a ratio of 9 to 1. pH is adjusted with hydrochloric acid.

ACTIONS NARCAN® (naloxone hydrochloride) is an essentially pure narcotic antagonist, i.e., it does not possess the "agonistic" or morphine-like properties characteristic of other narcotic antagonists; NARCAN® (naloxone hydrochloride) does not produce respiratory depression, psychotomimetic effects or pupillary constriction. In the absence of narcotics or agonistic effects of other narcotic antagonists it exhibits essentially no pharmacologic activity.

In the presence of physical dependence on narcotics NARCAN® (naloxone hydrochloride) will produce withdrawal symptoms; it has not been shown to produce tolerance nor to cause physical or psychological dependence.

When NARCAN® (naloxone hydrochloride) is administered intravenously the onset of action is generally apparent within two minutes; the onset of action is only slightly less rapid when it is administered subcutaneously or intramuscularly. The duration of action is dependent upon the dose and route of administration of NARCAN® (naloxone hydrochloride). Intramuscular administration produces a more prolonged effect than intravenous administration. The requirement for repeat doses of NARCAN® (naloxone hydrochloride), however, will also be dependent upon the amount, type and route of administration of the narcotic being antagonized.

INDICATIONS NARCAN® (naloxone hydrochloride) is indicated for the complete or partial reversal of narcotic depression, including respiratory depression, induced by natural and synthetic narcotics, propoxyphene and the narcotic-antagonist analgesic pentazocine.
NARCAN® (naloxone hydrochloride) is also indicated for the diagnosis of suspected acute opiate overdosage.

CONTRAINDICATIONS NARCAN® (naloxone hydrochloride) is contraindicated in patients known to be hypersensitive to it.

WARNINGS NARCAN® (naloxone hydrochloride) should be administered cautiously to persons including newborns of mothers who are known or suspected to be physically dependent on opioids. In such cases an abrupt and complete reversal of narcotic effects may precipitate an acute abstinence syndrome.

The patient who has satisfactorily responded to NARCAN® (naloxone hydrochloride) should be kept under continued surveillance and repeated doses of NARCAN® (naloxone hydrochloride) should be administered, as necessary, since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydrochloride).

NARCAN® (naloxone hydrochloride) is not effective against respiratory depression due to non-opioid drugs.

Usage in Pregnancy Safe use of NARCAN® (naloxone hydrochloride) during pregnancy (other than labor) has not been established. Animal reproduction studies have not demonstrated teratogenic or other embryotoxic effects (See ANIMAL PHARMACOLOGY AND TOXICOLOGY). However, NARCAN® (naloxone hydrochloride) should be administered to pregnant patients only when, in the judgment of the physician, the potential benefits outweigh the possible hazards.

PRECAUTIONS In addition to NARCAN® (naloxone hydrochloride), other resuscitative measures such as maintenance of a free airway, artificial ventilation, cardiac massage, and vasopressor agents should be available and employed when necessary to counteract acute narcotic poisoning.

In an isolated report two patients with pre-existing ventricular irritability requiring lidocaine, and either isoproterenol or epinephrine for hypotension following cardiopulmonary bypass procedures, developed ventricular tachycardia or fibrillation when given NARCAN® (naloxone hydrochloride) I.V. at 9 and 14 hours, respectively, postoperatively for persistent unresponsiveness. Although a direct cause and effect relationship has not been established, NARCAN® (naloxone hydrochloride) should be used with caution in patients with cardiac irritability.

ADVERSE REACTIONS In rare instances nausea and vomiting have been reported in postoperative patients receiving NARCAN® (naloxone hydrochloride) in doses higher than that recommended; a cause and effect relationship has not been established.

DOSAGE AND ADMINISTRATION NARCAN® (naloxone hydrochloride) may be administered intravenously, intramuscularly, or subcutaneously. The most rapid onset of action is achieved by intravenous administration and it is recommended in emergency situations.

Since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydrochloride) the patient should be kept under continued surveillance and repeated doses of NARCAN® (naloxone hydrochloride) should be administered, as necessary.

USAGE IN ADULTS Narcotic Overdose—Known or Suspected The usual initial adult dose is 0.4 mg (1 ml) NARCAN® (naloxone hydrochloride) administered I.V., I.M. or S.C. If the desired degree of counteraction and improvement in respiratory function is not obtained immediately following I.V. administration, it may be repeated intravenously at 2 to 3 minute intervals. Failure to obtain significant improvement after 2 or 3 doses suggests that the condition may be due partly or completely to other disease processes or non-opioid drugs.

Post Operative Narcotic Depression For the partial reversal of narcotic depression following the use of narcotics during surgery, smaller doses of NARCAN® (naloxone hydrochloride) are usually sufficient. The dose of NARCAN® (naloxone hydrochloride) should be titrated according to the patient's response. Excessive dosage of NARCAN® (naloxone hydrochloride) may result in significant reversal of analgesia and increase in blood pressure. Similarly, too rapid reversal may induce nausea, vomiting, sweating or tachycardia.

For the initial reversal of respiratory depression, NARCAN® (naloxone hydrochloride) should be injected in increments of 0.1 to 0.2 mg intravenously at two to three minute intervals to the desired degree of reversal i.e., adequate ventilation and alertness without significant pain or discomfort.

Repeat doses of NARCAN® (naloxone hydrochloride) may be required within one to two hour intervals depending upon the amount, type (i.e., short or long acting) and time interval since last administration of narcotic. Supplemental intramuscular doses have been shown to produce a longer lasting effect.

USAGE IN CHILDREN Narcotic Overdose—Known or Suspected The usual initial child dose is 0.01 mg/kg body weight given I.V., I.M. or S.C. This dose may be repeated in accordance with the adult administration guideline. If necessary, NARCAN® (naloxone hydrochloride) can be diluted with sterile water for injection.

USAGE IN NEONATES Narcotic-induced depression The usual initial dose is 0.01 mg/kg body weight administered I.V., I.M. or S.C. This dose may be repeated in accordance with adult administration guidelines.

HOW SUPPLIED 0.4 mg/ml of NARCAN® (naloxone hydrochloride) for intravenous, intramuscular and subcutaneous administration.

Available in 1 ml ampuls in boxes of 10 and 100.

0.02 mg/ml of NARCAN® (naloxone hydrochloride) NEONATAL INJECTION for intravenous, intramuscular and subcutaneous administration.

Available in 2 ml ampuls in boxes of 10 and 100 ampuls.

ANIMAL PHARMACOLOGY AND TOXICOLOGY In the mouse and rat the intravenous LD_{50} is 150 ± 5 mg/kg and 109 ± 4 mg/kg respectively. In acute subcutaneous toxicity studies in newborn rats the LD_{50} (95% CL) is 260 (228-296) mg/kg. Subcutaneous injection of 100 mg/kg/day in rats for 3 weeks produced only transient salivation and partial ptosis following injections; no toxic effects were seen at 10 mg/kg/day for 3 weeks.

Reproductive studies including fertility, general reproductive performance, embryotoxicity, teratogenicity, and lactation did not show any abnormality in mice and rats at 10 mg/kg/day.

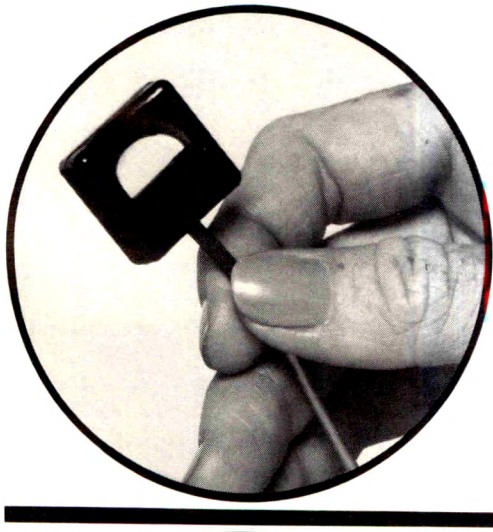
VERSATONE® MULTI-PURPOSE DOPPLER INSTRUMENT

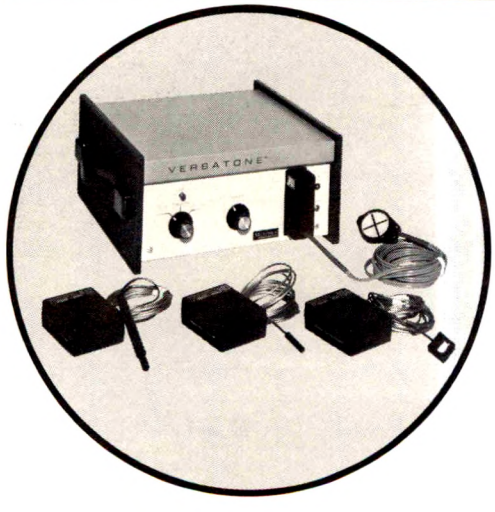


FOR MONITORING DOPPLER SOUNDS OF BLOOD FLOW AND TO TAKE DOPPLER SYSTOLIC BLOOD PRESSURE

This sensitive Doppler probe is easy to tape in position for non-invasive detection and monitoring of arterial blood flow during surgery. Used with an occlusive cuff and manometer, systolic blood pressures may be obtained even on infants and hypotensive patients.

FOR EARLY DETECTION OF VENOUS AIR EMBOLISM

This sensitive wide-angle Doppler probe is particularly well suited for the detection of venous air emboli which may occur during neurosurgical procedures performed with the patient in the upright position. It also detects motion of the heart muscle, heart valves and blood flow.



VERSATONE D8 DOPPLER

The Model D8 VERSATONE Doppler instrument is designed to use interchangeable probes of various frequencies and configurations. It is powered by a rechargeable battery and has a built-in loudspeaker. Options include an electrocautery sensor and cut-out, a molded earset for private listening, and a chart recording circuit. The two probes shown above are particularly useful to the anesthesiologist. Two sizes of pencil shaped probes are also available. These are useful for intraoperative assessment of flow in exposed vessels, as well as for transcutaneous flow detection.

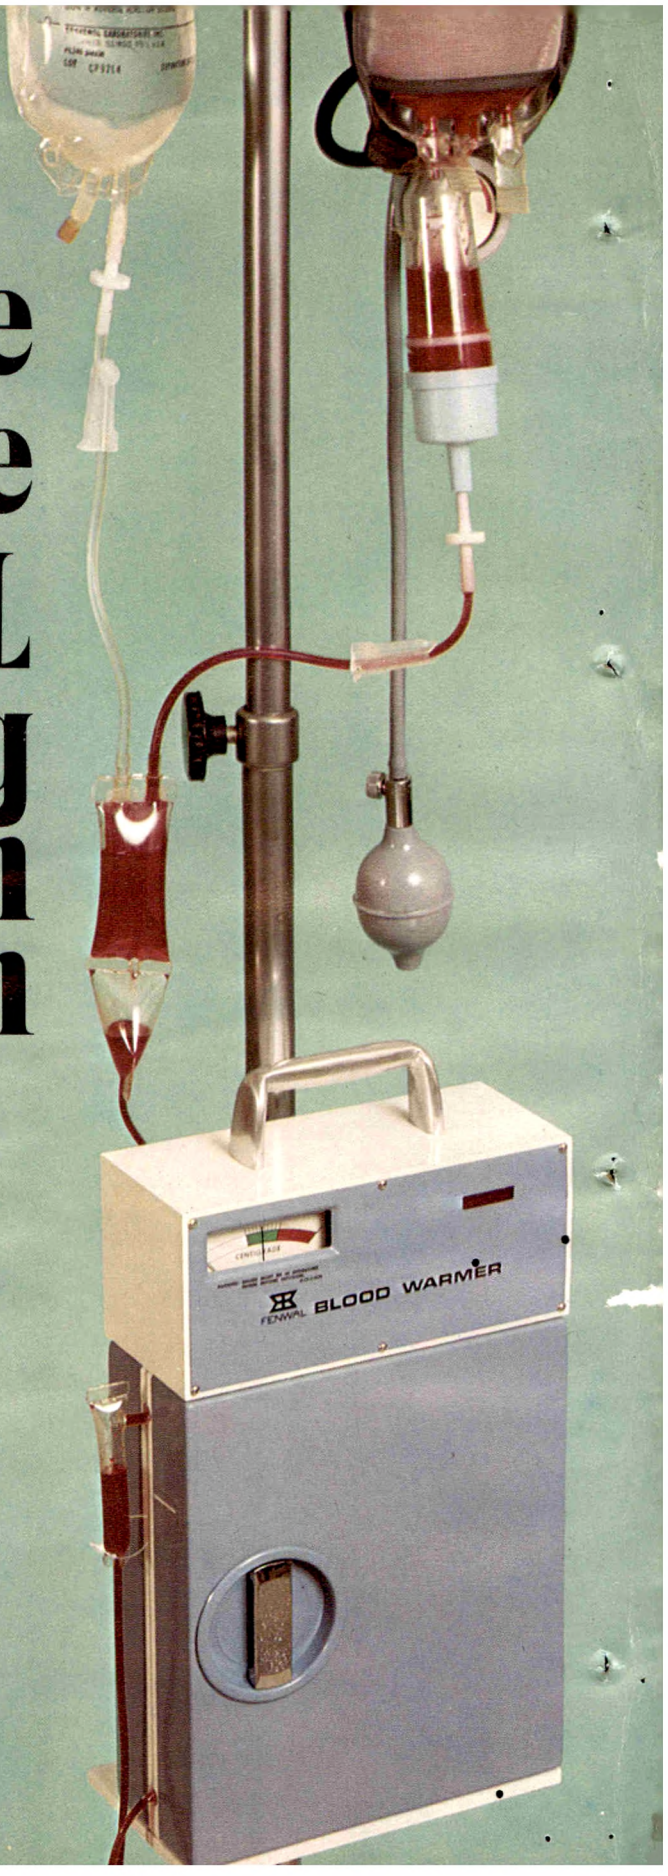
patients
FENWAL BLOOD WARMER

The complete FENWAL operating room system



The Fenwal Dry Heat Blood Warmer is designed for use during single or multiple transfusions when precise regulation of blood temperature and flow rate is indicated. It utilizes a disposable plastic blood-warming pathway.

Fenwal Recipient Sets are available to accommodate your infusion requirements. The Single Lead Set is to be used for the intravenous administration of one unit of whole blood, red cells or plasma. The "Y" Recipient Set is designed to permit dual hookups for simultaneous administration of blood and/or solutions. The Triple Lead Set may be employed in multiple infusion procedures, i.e., blood, solutions, blood components and medication.

The Fenwal Microaggregate Blood Filter is designed to remove microaggregates down to 20 microns in size during intravenous administration of stored whole blood or red cells.

Fenwal Pressure Infusors provide an efficient non-air-dependent method for the rapid infusion of whole blood or red cells.

The Fenwal TYPENEX™ Blood Recipient Identification System ties together the identity of the transfusion candidate, his cross-match request form, blood sample and up to 10 cross-matched units of blood.

The Fenwal Venous Pressure Manometer Set is a disposable, preassembled unit that permits continuous monitoring of the patient's venous pressure while performing one simple hookup.

The Fenwal Platelet Recipient Set is designed specifically for the infusion of fresh blood and pool platelet concentrates.

Our best to you

Fenwal Laboratories has long been identified with innovation in modern blood handling systems. Our knowledge and experience in developing and providing sophisticated blood processing systems have earned a reputation for excellence. Thoroughly researched and tested to meet the demands of the medical profession, you can expect the same quality in Fenwal operating room devices that helped achieve our recognition with the nation's blood banks.

The Fenwal Specialist in your hospital can provide you and the other members of the operating team with completely detailed information on all of our products. Intensive training makes him fully qualified to answer your most involved questions regarding up-to-date blood transfusion procedure. Be sure to see your Fenwal Specialist the next time he visits your department.

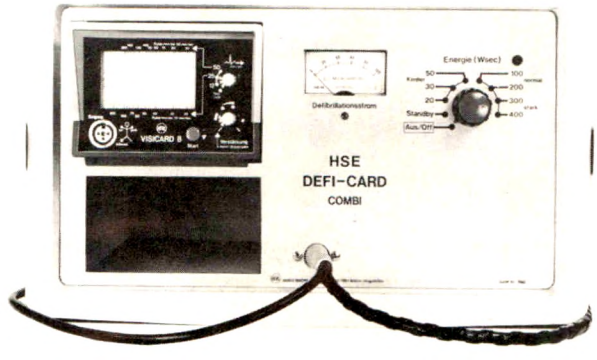
SOMETHING NEW

The Resuscitation Laboratories, Bridgeport, Connecticut, has available the DEFI-CARD-COMBI, a new compact portable battery operated DC defibrillator for emergency use.

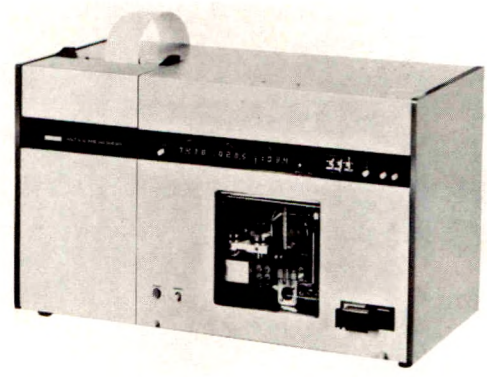
The DEFI-CARD-COMBI may be used in COMBI-nation with the VISICARD 8 for monitoring the patient using the paddles as electrodes. In the "stand-by" position, the ECG is obtained without charging the defibrillator. Cardiac activity may be observed before and after defibrillation.



The self-powered VISICARD 8 may be instantly removed from the DEFI-CARD-COMBI and applied directly to the chest for spot monitoring. Once the defibrillator is charged, a recharging circuit guarantees the availability of the energy regardless of the interval between setting and discharge.

★ ★ ★

American Hospital Supply is introducing Writer Electrode Gel, an ECG electrolyte designed for any area of the hospital which uses a conductive gel for cardiac testing. According to the manufacturer, Writer Gel provides clear traces and rapid baseline stability—but without the use of suspended gritty particles sometimes found in other gels. Writer Gel is slow drying, uses a lanolin base and is lemon scented.



Radiometer's new ABL2 Acid-Base Laboratory is being introduced by The London Company, the exclusive U. S. representative for Radiometer Copenhagen.

This new second generation system features automatic operation, complete analysis with micro samples of blood, patient temperature input, easy-change membranes for the blood gas electrodes, built-in electronic barometer and advanced self-diagnosis testing programs. The ABL2 also contains the advanced features of the ABL1 system which include measured hemoglobin, patented liquid calibration, gas mixer which utilizes a single cylinder of inexpensive CO_2 and room air to furnish precise calibration gas mixtures.

The totally automated operation includes calibration measurement, computation, rinsing and printout.

Direct measurements determine the patient's hemoglobin, pH, Pco_2 and Po_2 from the blood microsample. These measurements are simultaneously used by the computer to calculate additional parameters, including actual bicarbonate, standard bicarbonate, total CO_2, base excess, standard base excess and oxygen saturation. Special patient-temperature conditions can be easily dialed into the ABL2. A permanent record is provided by the built-in printer.

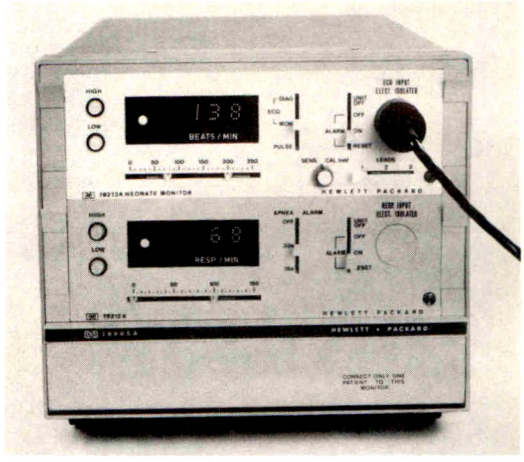
Olympic Medical Corp, Seattle, Washington, has available a new Model 40 Olympic Sterile-Drier with a larger capacity, high speed, bio-clean drier for wet disinfected respiratory therapy and anesthesia equipment. A new concept in drying cabinets, all air entering the Model 40 passes through HEPA (High Efficiency Particulate Air) filters. Each Model 40 Olympic Sterile-Drier is individually tested at the factory with a particle counter and meets standards for Class 100, bio-clean air (no more than 100 particles larger than 0.5 microns per cubic foot of air). The Model 40 will dry 24 tubes and 8 parts trays or converts quickly to dry 48 tubes or 16 parts trays. Double, full-length, see-through doors provide easy access.

Hewlett Packard Medical Electronics Division, Waltham, Massachusetts, has a new neonatal heart-rate monitor, specifically designed to detect ECG signals from infants. The HP 78213A plug-in module, which measures heart rate in the range of 20 to 250 beats per minute, features high sensitivity that allows detection of the often steeply rising, low-amplitude QRS complexes in premature infants.



The neonatal heart-rate monitor has electrically isolated patient input which effectively isolates the newborn from potential hazardous leakage currents. Heart rate is displayed digitally by bright, light-emitting-diode numerals.

Because the vector of the neonate's ECG changes, the module contains a lead selector as standard to allow the attending staff to select the best setup for reliable monitoring. Audible and visual alarms alert the medical staff when the monitored infant's heart rate deviates beyond preselected limits for more than 8 seconds.

The local that gives you the longest anesthesia gives your patient longer postoperative analgesia.

Marcaine® hydrochloride (brand of bupivacaine hydrochloride)—available with or without epinephrine—is the local anesthetic that provides the longest duration of action among commonly used local anesthetics. Which minimizes the problems of "continuous" technique or repeat doses.

Marcaine also provides longer postoperative analgesia. Which reduces the need for postoperative narcotics.

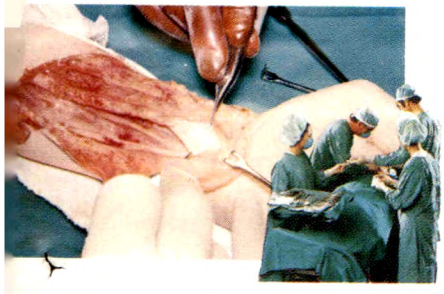
And in data in over 3,000 patients, Marcaine was reported to have excellent or satisfactory results in more than 96% of cases.

Extended anesthesia for the surgeon

In regional blocks, Marcaine, with or without epinephrine, usually provides anesthesia at least 1½ to 2 times longer than lidocaine or mepivacaine. And approximately 20% longer than tetracaine.

In fact, anesthesia may extend up to 9 hours for peridural block and up to 12 hours for peripheral nerve block. This has been established in several thousand surgical and obstetrical patients.[1-4]

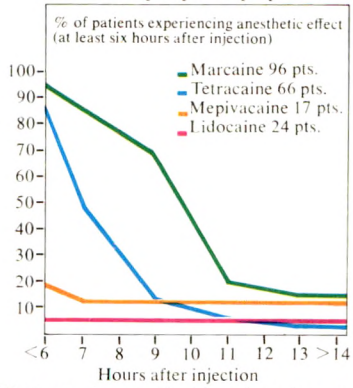
In fact, a single Marcaine epidural injection, with or without epinephrine, may be enough for up to 3½[4] or more[5] hours of anesthesia for surgery, and often provides analgesia that carries over into the recovery room and beyond. When necessary, doses may be repeated up to once every three hours. Caution is advised in administration of repeat doses to patients with severe liver disease. Until further experience is gained, total daily dose of



400 mg. should not be exceeded nor is administration to children under 12 recommended. Also see epinephrine warnings and precautions statements on next page.

This longer anesthetic action can minimize problems of "continuous" technique or repeat doses. Thus, there is the further advantage of a reduced likelihood of introducing infection since injections are less frequent.[6]

Chart I
Duration of anesthesia
Percentage of patients experiencing anesthetic effect—
Comparison of Marcaine with epinephrine and other local anesthetic/epinephrine preparations*



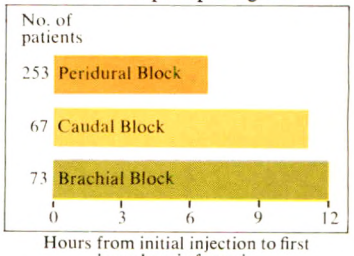
*Equipotent doses used for bilateral, simultaneous blocks of sciatic/femoral, intercostal, or brachial/axillary nerves. Adapted from Moore, D. C.: Data in the files of the Sterling-Winthrop Research Institute.

Extended postoperative analgesia for the patient

Marcaine, with or without epinephrine, gives your patient more—considerably more—postanesthetic analgesia than other local anesthetics in various types of nerve block.[3,4,7,8] An analgesia that persists after the return of motor function and even cutaneous sensation.[7] As a result, you may be able to defer[1,5] and sometimes even eliminate,[5] postoperative narcotics. Chart II illustrates the average duration of time between the initial Marcaine injection and the need for postop analgesics. Many of the 67 patients given Marcaine, with or without epinephrine, caudally for rectal surgery did not complain of pain for 11 hours or longer following induction.

In another group of 40 patients[8] given Marcaine or mepivacaine, both with epinephrine, locally for tonsillectomy, Marcaine pain relief lasted 3 to 5 times longer than that provided by mepivacaine. And in a study[1] of 65 patients given 0.5% Marcaine with epinephrine caudally for rectal or other perineal surgery, complete sensation returned in a mean of 8½ hours for the average patient. And the majority of these patients did not require a narcotic for an additional 1 to 3 hours.

Chart II
Duration of time between injection of Marcaine, with or without epinephrine, and need for postop analgesics†



†Average—exclusion of extremes and failures. Adapted from Lund, P.C., *et al.*: *Anesth. Analg.* 49:103, Jan.-Feb. 1970.

Excellent clinical acceptance

Marcaine, with or without epinephrine, was administered to 3,112 patients for various types of local anesthesia.[9] Of these patients, only 2 experienced a systemic reaction. Although Marcaine has a very wide safety margin, adverse reactions characteristic of those associated with other amide local anesthetics may occur.

Marcaine is indicated for most anesthetic blocks; however, until further clinical experience is gained, paracervical block is not recommended.

See important product information concerning warnings, adverse reactions, patient selection, and prescribing and precautionary recommendations on next page.

Marcaine® hydrochloride

Brand of
bupivacaine hydrochloride

with or without epinephrine 1:200,000

Winthrop

MARCAINE® Hydrochloride
Brand of **bupivacaine hydrochloride**

Indications: Peripheral nerve block, infiltration, sympathetic block, caudal, or epidural block.

Contraindication: Marcaine is contraindicated in patients with known hypersensitivity to it.

Warnings: RESUSCITATIVE EQUIPMENT AND DRUGS SHOULD BE READILY AVAILABLE WHEN ANY LOCAL ANESTHETIC IS USED.

Usage in Pregnancy. Reproduction studies have been performed in rats and rabbits and there is no evidence of harm to the animal fetus. The relevance to the human is not known. Safe use in pregnant women other than those in labor has not been established.

Until further clinical experience is gained, paracervical block with Marcaine is not recommended. Fetal bradycardia frequently follows paracervical block with some amide-type local anesthetics and may be associated with fetal acidosis. Added risk appears to be present in prematurity, toxemia of pregnancy, and fetal distress.

The obstetrician is warned that severe persistent hypertension may occur after administration of certain oxytocic drugs, if vasopressors have already been used during labor (e.g., in the local anesthetic solution or to correct hypotension).

Solutions containing a vasoconstrictor, particularly epinephrine or norepinephrine, should be used with extreme caution in patients receiving monoamine oxidase (MAO) inhibitors or antidepressants of the triptyline or imipramine types, because severe, prolonged hypertension may result.

Local anesthetics which contain preservatives, i.e., those supplied in multiple dose vials, should not be used for caudal or epidural anesthesia.

Until further experience is gained in children younger than 12 years, administration of Marcaine in this age group is not recommended.

Precautions: The safety and effectiveness of local anesthetics depend upon proper dosage, correct technique, adequate precautions, and readiness for emergencies.

The lowest dosage that gives effective anesthesia should be used in order to avoid high plasma levels and serious systemic side effects. Injection of repeated doses of Marcaine may cause significant increase in blood levels with each additional dose, due to accumulation of the drug or its metabolites or due to slow metabolic degradation. Tolerance varies with the status of the patient. Debilitated, elderly patients and acutely ill patients should be given reduced doses commensurate with age and physical condition.

Solutions containing a vasoconstrictor should be used cautiously in areas with limited blood supply, in the presence of diseases that may adversely affect the patient's cardiovascular system, or in patients with peripheral vascular disease.

Marcaine should be used cautiously in persons with known drug allergies or sensitivities, particularly to the amide-type local anesthetics.

Serious dose-related cardiac arrhythmias may occur if preparations containing a vasoconstrictor such as epinephrine are employed in patients during or following the administration of chloroform, halothane, cyclopropane, trichloroethylene, or other related agents. In deciding whether to use these products concurrently in the same patient, the combined action of both agents upon the myocardium, the concentration and volume of vasoconstrictor used, and the time since injection, when applicable, should be taken into account.

Caution is advised in administration of repeat doses of Marcaine to patients with severe liver disease.

Adverse Reactions: Reactions to Marcaine are characteristic of those associated with other amide-type local anesthetics. A major cause of adverse reactions to this group of drugs is excessive plasma levels, which may be due to overdosage, inadvertent intravascular injection, or slow metabolic degradation.

Excessive plasma levels of the amide-type local anesthetics cause systemic reactions involving the central nervous system and the cardiovascular system. The *central nervous system effects* are characterized by excitation or depression. The first manifestation may be nervousness, dizziness, blurred vision, or tremors, followed by drowsiness, convulsions, unconsciousness, and possibly respiratory arrest. Since excitement may be transient or absent, the first manifestation may be drowsiness, sometimes merging into unconsciousness and respiratory arrest. Other central nervous system effects may be nausea, vomiting, chills, constriction of the pupils, or tinnitus. The *cardiovascular manifestations* of excessive plasma levels may include depression of the myocardium, blood pressure changes (usually hypotension), and cardiac arrest. In obstetrics, cases of fetal bradycardia have occurred (see Warnings).

Allergic reactions, which may be due to hypersensitivity, idiosyncrasy, or diminished tolerance, are characterized by cutaneous lesions (e.g., urticaria), edema, and other manifestations of allergy. Detection of sensitivity by skin testing is of doubtful value.

Reactions following epidural or caudal anesthesia also may include: high or total spinal block; urinary retention; fecal incontinence; loss of perineal sensation and sexual function; persistent analgesia, paresthesia, and paralysis of the lower extremities; headache and backache; and slowing of labor and increased incidence of forceps delivery.

Treatment of Reactions. Toxic effects of local anesthetics require symptomatic treatment; there is no specific cure. The physician should be prepared to maintain an airway and to support ventilation with oxygen and assisted or controlled respiration as required. Supportive treatment of the cardiovascular system includes intravenous fluids and, when appropriate, vasopressors (preferably those that stimulate the myocardium). Convulsions may be controlled with oxygen and intravenous administration, in small increments, of a barbiturate, as follows: preferably, an ultrashort-acting barbiturate such as thiopental or thiamylal; if this is not available, a short-acting barbiturate (e.g., secobarbital or pentobarbital) or diazepam. Intravenous barbiturates or anticonvulsant agents should only be administered by those familiar with their use.

with or without epinephrine 1:200,000

air) after a 2-month hospitalization. One month later, however, she developed an osteomyelitis of several ribs on the left side and underwent rib resection. A pneumatocele followed by a bronchopleural-cutaneous fistula was treated 3 months later and again in 4 months. Organisms cultured included *Pseudomonas* and *Staphylococcus aureus*.

The patient's first admission to this hospital was in January 1975. She was a chronically ill appearing child with marked clubbing of the fingers and toes. She had 2 left chest tubes open to air, draining purulent material. A Valsalva maneuver would produce copious secretions and air bubbles from the tube. Bronchoscopy and bronchography revealed a fistula from the distal left mainstem bronchus to a large empyema cavity at the base of the left lung, and also lingular bronchiectasis. Operation consisted of decortication of the left upper lobe, removal of the empyemic left lower lobe cavity, and a subtotal lingular excision.

Anesthetic management involved induction with halothane by mask and spontaneous ventilation, with minimal gas escape from the fistula. This was followed by careful local anesthetic spray to the pharynx, larynx, and trachea. A 4-mm Storz ventilating bronchoscope was then placed in the left mainstem bronchus with the tip beyond the orifice of the left upper lobe bronchus. A 7-FG balloon-tipped arterial embolectomy catheter was then placed in the left mainstem bronchus through the bronchoscope which was then withdrawn from the trachea but left surrounding the Fogarty catheter and kept on the operating table. The trachea was then intubated with a #5 endotracheal tube, positioning the Fogarty catheter external and posterior to the tube.

Ventilation of the lungs was now attempted with the endotracheal tube in place and the Fogarty balloon uninflated. A good portion of the ventilation was seen to be emerging from the fistula. The Fogarty catheter balloon was inflated with 2.5 ml of air, a seal being demonstrated by the easy ventilation of both lungs and the absence of gas bubbles at the fistula. This seal was thus obtained without the necessity of inserting the endotracheal tube into the right mainstem bronchus, and ventilation of the left upper lobe was thus continued throughout the procedure.

Dissection of adhesions required approximately 2 hours, during which the Fogarty catheter effectively sealed the bronchus. The catheter was removed when the surgeon could clamp the bronchus directly. The patient was extubated in the operating room and has had a benign postoperative course, being discharged 12 days postoperatively with all chest tubes removed. She was followed for 10 months without recurrence of difficulty.

DISCUSSION

Positioning of the diseased lung uppermost contributed materially to the technical success of the operation. With positive-pressure ventilation, the uppermost lung is preferentially ventilated, and with an open bronchopleural-cutaneous fistula, much of the ventilation would have been wasted. Blocking the affected bronchus gave control of infective secretions, adequate control of ventilation, and optimal surgical position.

The Fogarty balloon-tipped catheter remained in place for almost 2 hours, the bronchus remaining gastight during that time. With the control thus achieved, an unhurried careful dissection probably minimized blood loss. The length of the catheter enabled the bronchoscope to be kept alongside the patient with the catheter still inside. Should the balloon have slipped out of the bronchus into the trachea, the bronchoscope could have been easily reinserted and the catheter repositioned. The Fogarty embolectomy catheter is commonly available in the operating suite and seems well suited to the occasional need for bronchial blockade.

Selective bronchial blockade in children using this balloon-tipped catheter has been described by others.[1-4] In 2 cases,[1,2] bronchi were blocked with the Fogarty catheter and patients recovered uneventfully, although this is not conclusive evidence that the blocker had indeed protected the involved lung from infective secretions. Our report is unique because of the demonstration that the bronchus was sealed to gas by the Fogarty catheter.

Difficult Extubation of an Endotracheal Tube Cuff

THIEN YEW NG, MD*
TAPAN D. DATTA, MD†
Pittsburgh, Pennsylvania‡

EXTUBATION after short-term intubation is not usually difficult. However, untoward incidents can occur, as illustrated by the following report.

REPORT OF A CASE

A 61-year-old woman, 165 cm tall and weighing 55 kg, was admitted for left Keller arthroplasty and interphalangeal fusion of the 2nd toe. Preoperative medication consisted of 75 mg of meperidine, 50 mg of hydroxyzine, and 0.4 mg of atropine IM. Anesthesia was induced with 240 mg of thiamylal IV, followed by 80 mg of succinylcholine, which provided good relaxation for a smooth orotracheal intubation with a lubricated 36 French red-rubber Murphy tube. The tube cuff was inflated until there was no leak, inflation requiring 3 ml of air. Anesthesia was maintained with N_2O-O_2 (60:40) and intermittent doses of fentanyl and d-tubocurarine.

At the end of operation, the patient's tracheobronchial tree and mouth were suctioned and the cuff was deflated. When extubation was attempted, the endotracheal tube seemed caught after withdrawal of several centimeters. The tube could be pushed down easily but came to an abrupt stop when it reached one particular level on attempted extubation. The patient was asked to hold her breath in deep inspiration and the tube was removed with some difficulty.

Examination of the endotracheal tube showed a collar-like ridge or "flange" at the lower part of the cuff (figure). The patient recovered uneventfully except for a "sore throat" lasting 2 days.

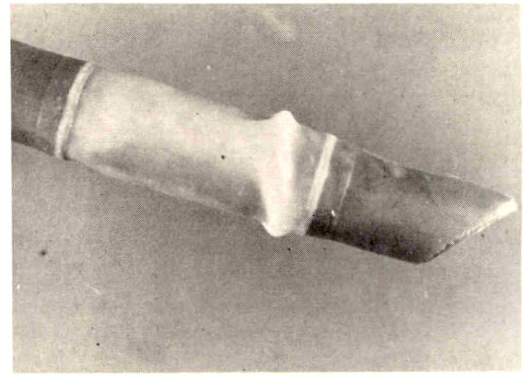

FIGURE. The collar-like ridge or "flange" formation at the distal end of the cuff of a red-rubber Murphy tube, preventing easy extubation.

DISCUSSION

Pavlin and associates[1] have described several cases of difficult removal of Portex Blue Line tracheostomy tubes, the cuffs of which have a large residual volume. Flange formation is more likely to occur in such cuffs than those with a small residual volume. Flange formation did not occur at room temperature nor with other makes of tracheostomy tubes with large residual volume cuffs incubated at 37° C for 30 minutes. The exact cause of the formation of these flanges is unclear.

Other important factors are: (1) the relation of tube and cuff size to the size of the tracheal stoma or laryngeal inlet; (2) lubrication of the tube and cuff prior to intubation, the lubricant being worn off during extubation; (3) the presence of stretching and

CLASSIFIED ADVERTISING

ANESTHESIOLOGY CHAIRMAN

The Hospital Center at Orange has an exceptional opportunity for a Board Certified or Board eligible Anesthesiologist with a minimum of 10 years experience to coordinate the activities of our Department of Anesthesiology as the Department Chairman. An affiliation with Medical School for a student and house officer training program is being pursued. The selected candidate will be considered for academic appointment to the New Jersey College of Medicine and Dentistry.

A competitive compensation package consisting of administrative fee or salary plus fee-for-service income will be available.

The Hospital Center has approximately 400 beds consisting of two units; namely The Orange Memorial Hospital and The New Jersey Orthopaedic Hospital Unit located in suburban N.J. offering convenient access to New York City and Philadelphia.

Send curriculum vitae to:
Arthur T. Dunn, President
THE HOSPITAL CENTER AT ORANGE
188 South Essex Ave.
Orange, New Jersey 07051
Equal Opportunity Employer

CHIEF OF ANESTHESIOLOGY

Major Midwestern medical center with a medical school affiliation is seeking an outstanding Anesthesiologist to head the Department of Anesthesiology. This is an immediate opportunity to restructure and/or build upon our current team. Our compensation package is exceedingly attractive and the working conditions are excellent as a result of our recently completed, multi-million-dollar expansion program. Please send curriculum vitae to: John D. Silbar, M.D., Chairman, Anesthesia Search Committee, Mount Sinai Medical Center, 950 North 12th Street, Milwaukee, Wisconsin 53233.

LOUISIANA—Tulane University, New Orleans. Immediate positions available for Academic Anesthesiologists in new Department of Anesthesiology. Positions in all anesthetic subspecialties, intensive care and respiratory therapy in new university teaching hospital. Tulane University is an Affirmative Action/Equal Opportunty employer. Curriculum vitae to: Robert R. Kirby, M.D., Department of Anesthesiology, Tulane University School of Medicine, 1430 Tulane Ave., New Orleans, Louisiana 70112.

PEDIATRIC ANESTHESIOLOGY RESIDENCY

Childrens Hospital of Los Angeles

Three-phase program: Clinical, Academic, Investigative, emphasizing practical aspects of anesthesiology related to infants and children.

AMA approval for third-year residency. Positions available from two months to one year.

Apply: George B. Lewis, Jr., M.D.
Head, Division of Anesthesiology
Childrens Hospital of Los Angeles
4650 Sunset Boulevard
Los Angeles, California 90054
Phone (213) 660-2450, Ext. 2262

DIRECTOR/SCHOOL OF NURSE ANESTHESIA. Immediate opening for CRNA with Masters Degree. We have a two-year program with university and medical school affiliation leading to a B.S. degree and CRNA certification. Ability to work independently in curriculum formation and school supervision is essential. Excellent salary and benefit package. If you are seeking a challenging position and career in a large medical teaching center, send resume with salary history and requirements to: Mrs. Anna Barker, Employment Manager, Medical Center Hospitals, Norfolk General Hospital Division, 600 Gresham Drive, Norfolk, Virginia 23507.

FACULTY POSITIONS

New University Department of Anesthesiology seeks full-time faculty (all levels) with interests in intensive care, ambulatory and obstetrical anesthesia. Also, full-time director of pediatric (not neonatal) intensive care and respiratory therapy. Challenging positions for those genuinely interested in teaching students and residents, research and development of a new Department. Pleasant university oriented community of 1,000,000. Excellent schools and living areas. Salaries negotiable. Send curriculum vitae to: R. Bryant Roberts, M.D., Professor and Chairman, Department of Anesthesiology, Wright State University School of Medicine, Dayton, Ohio 45431.

CHIEF ANESTHESIOLOGIST for 200-bed hospital—five modern OR's. All surgical services except open heart and neurosurgery. Excellent job challenge. Salary based on past experience and type of appointment. No malpractice insurance required. For information call or write to Dr. Zwemer, Chief Surgeon, Phoenix Indian Medical Center, 4212 North 16th Street, Phoenix, Arizona 85016. (602) 263-1200. The Indian Health Service is a Federal Employer and Federal Civil Service or Public Health Commissioned Corps benefits and requirements apply. Preference is given to qualified Indian or veteran applicants. IHS is an equal opportunity employer.

Classified Advertising (Continued)

ANESTHESIOLOGIST NEEDED—Board Certified desired with supervisory experience, now have three anesthesiologists and thirteen CRNAs doing all types surgery except open heart. Involved in intensive care, respiratory care, pain clinic, school for CRNAs and student and resident training cooperating with Jefferson Medical School. Lovely family community area. Call (412) 539-9711, ext. 273, or send resume to Mr. K. D. Bowman, Assistant Administrator, Latrobe Area Hospital, Latrobe, Pa. 15650. An equal opportunity employer.

CALIFORNIA—ANESTHESIOLOGISTS. Excellent opportunity to practice and participate in academically oriented program. Delightful California city. Favorable plan of remuneration and time off will be worked out. We can pay your professional liability insurance. Send curriculum vitae in first letter to: Jerome S. Harris, M.D., Director of Medical Affairs, Valley Medical Center, 445 S. Cedar, Fresno, California 93702.

ANESTHESIOLOGIST: Board certified/eligible to join newly formed group of anesthesiologists and nurse anesthetists in New Orleans. Fee for service private practice at 650-bed general hospital and newly opened Pediatric hospital. Write or call Metropolitan Anesthesia Associates, 4520 Melpomene, New Orleans, La. 70185. (504) 822-9331.

FACULTY POSITIONS

Department of Anesthesiology, Charity Hospital, New Orleans, affiliated with LSU and Tulane Medical Schools, has three faculty positions open for board certified/eligible anesthesiologists at Associate-Assistant Professor, Instructor levels. Duties involve teaching, research, clinical supervision. Salaries negotiable. Send inquiries and curriculum vitae to: M. Naraghi, M.D., Director, Department of Anesthesiology, Charity Hospital, New Orleans, Louisiana 70140.

MARYLAND: Positions on the Anesthesia Staff at Baltimore City Hospitals. Excellent fringe benefits and salary. Residency fully integrated with the Johns Hopkins Medical School program. Send CV to Peter Chodoff, M.D., Anes-in-Chief, Baltimore City Hospitals, 4940 Eastern Ave., Baltimore, Maryland 21224.

2 American anesthesiologists, eligible for oral boards in April 1977 from world-famous midwestern center, desire to relocate in Ohio or other state if center is attractive. Extensive experience in vascular, neuro and cardiovascular anesthesia. Contact Box 11-76-A in care of I.A.R.S.

ANESTHESIOLOGIST, 38, ABA certified, university trained, excellent references, seeks assoc. partner or group. No geographic preferences, prefer city or suburb. Available June 1977. Write to Box 11-76-B c/o I.A.R.S.

ANESTHESIOLOGIST—LOCUM TENEMS—1/77 - 3/77 in multispecialty center in NW lower Michigan. Excellent skiing and winter sports area. Michigan licensure necessary. Practice includes cardiac anesthesia and respiratory care. Share call with three other Board certified anesthesiologists. Contact: J. R. Rasmussen, M.D., c/o Burns Clinic Medical Center, P.C., 560 W. Mitchell, Petoskey, Michigan 49770.

ANESTHESIOLOGIST—BOARD CERTIFIED OR ELIGIBLE to assume position as director of and/or consultant to a hospital anesthesiology department in a new, rapidly growing, 171-bed Midwestern hospital; service area covers 150,000 residents and responds to a medical staff of 50-60 physicians; progressive city of 35,000 with excellent schools, cultural activities, and recreational oppotunities; salary $80,000 base and excellent compensation plan. •Send c.v. and references to Michael L. Wintory, Director of Personnel, St. Mary's Hospital, 3333 N. Seminary St., Galesburg, IL 61401.

What are you doing in airway management?

You're solving problems ...when you use the **Lanz Controlled Pressure Cuff Endotracheal Tube.**

Unique cuff system automatically compensates for increased volume/pressure caused by diffusion of N_2O or O_2 into cuff.

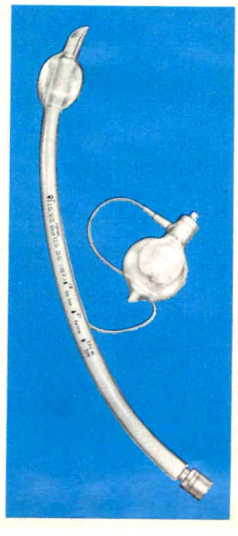
Long-term airway management is a problem. There's always the hazard of tracheal scarring and stenosis...accidental over-inflation. And so on.

Now with the Lanz Controlled-Pressure Cuff Endotracheal Tube, you can help solve your long-term intubation problems.

Dangers of Tracheal Damage Minimized.

The Lanz Endotracheal Tube is unique. It is a controlled-pressure cuff system containing an automatic, pressure regulating valve with an external, pressure-control balloon. This system is designed to eliminate excessive pressure on the tracheal wall due to over-inflation of the cuff. It's also designed to *automatically compensate* for increased volume and pressure caused by diffusion of N_2O or O_2 into the cuff.

When used in the intubation period before tracheostomy, it helps assure protection of the trachea throughout the entire period of airway management.



Patient Safety and Comfort

The Lanz Endotracheal Tube permits quick and easy intubation. The tube will flex, but not kink. It is available with either Murphy or Magill tips.

And it's available now—packaged sterile, and ready to use.

Help solve your long-term airway problems now with the Lanz Disposable Controlled-Pressure Cuff Endotracheal Tube. Write today for complete information, or call your Extracorporeal Representative.

Nesacaine®
(Chloroprocaine Hydrochloride)

1% and 2% solution in 30-ml. multiple-dose vials

For Infiltration and Regional Anesthesia

Nesacaine®-CE
(Chloroprocaine Hydrochloride)

2% and 3% solution in 30-ml. single-dose vials

For Caudal and Epidural Anesthesia

INDICATIONS

NESACAINE in multiple dose vials and NESACAINE-CE in single dose vials without preservatives are indicated for production of local anesthesia by infiltration injection and nerve block.*

*NESACAINE in multiple dose vials with preservatives is not to be used for caudal or epidural anesthesia. NESACAINE-CE contains no preservatives and the unused portion must be discarded after initial use.

CONTRAINDICATIONS

NESACAINE and NESACAINE-CE are contraindicated in patients hypersensitive to drugs of the PABA ester group. Central nervous system disease is generally considered a contraindication to caudal or epidural nerve block.

WARNINGS

RESUSCITATIVE EQUIPMENT AND DRUGS SHOULD BE IMMEDIATELY AVAILABLE WHEN ANY LOCAL ANESTHETIC IS USED. As NESACAINE-CE contains no preservative, discard unused drug remaining in vial after initial use. Equipment and drugs necessary for the treatment of inadvertent intravascular injection, intrathecal injection, or excessive dosage should be immediately available.

Usage in Pregnancy: Safe use of chloroprocaine hydrochloride has not been established with respect to adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential unless in the judgment of the physician the potential benefits outweigh the unknown hazards. In obstetrics, if vasoconstrictor drugs are used either to correct hypotension or are added to the local anesthetic solution, the obstetrician should be warned that some oxytocic drugs may cause severe persistent hypertension and even rupture of a cerebral blood vessel may occur during the post partum period.

Solutions containing vasoconstrictors, particularly epinephrine and norepinephrine, should be used with extreme caution in patients receiving certain antidepressants such as MAO inhibitors, and tricyclic compounds since a severe prolonged hypertension may occur.

PRECAUTIONS

The lowest dosage that results in effective anesthesia should be used to avoid high plasma levels and serious undesirable systemic side effects. Tolerance varies with the status of the patient. Debilitated patients, elderly patients, acutely ill patients, and children should be given reduced doses commensurate with their age and physical status.

Solutions containing vasoconstrictors should be used cautiously in the presence of disease which may adversely affect the patient's cardiovascular system.

Chloroprocaine hydrochloride should be employed cautiously in persons with known drug allergies or sensitivities.

The decision whether or not to use local anesthesia in the following conditions depends on the physician's appraisal of the advantages as opposed to the risk:

Paracervical block when fetal distress is anticipated or when predisposing factors causative of fetal distress are present (i.e., toxemia, prematurity, diabetes, etc.). Injection of solutions containing epinephrine in areas where the blood supply is limited (i.e., ears, nose, digits, etc.) or when peripheral vascular disease is present.

ADVERSE REACTIONS

Adverse reactions result from high plasma levels due to rapid absorption, inadvertent intravascular injection or excessive dosage. Hypersensitivity, idiosyncrasy, or diminished tolerance are other causes of reactions. Reactions due to overdosage (high plasma levels) are systemic and involve the central nervous system and the cardiovascular system.

Reactions involving the central nervous system are characterized by excitation and/or depression. Nervousness, dizziness, blurred vision or tremors may occur followed by drowsiness, convulsions, unconsciousness and possibly respiratory arrest. Since excitement may be transient or absent, the first manifestations may be drowsiness merging into unconsciousness and respiratory arrest.

Reactions involving the cardiovascular system include depression of the myocardium, hypotension, bradycardia and even cardiac arrest.

Treatment of a patient with toxic manifestations consists of maintaining an airway, and supporting ventilation using oxygen and assisted or controlled respiration as required. Supportive treatment of the cardiovascular system consists of using vasopressors, preferably those that stimulate the myocardium (e.g., ephedrine) and intravenous administration in small increments of an ultrashort acting barbiturate (i.e., thiopental, thiamylal) or a short acting barbiturate if these are not available (secobarbital, pentobarbital) or a short acting muscle relaxant (succinylcholine), together with oxygen. Muscle relaxants and intravenous barbiturates should be used only by those familiar with their use.

Allergic reactions are characterized by cutaneous lesions, urticaria, edema and other manifestations of allergy. The detection of sensitivity by skin testing is of doubtful value.

DOSAGE AND ADMINISTRATION

The maximum single recommended doses of chloroprocaine hydrochloride are: without epinephrine, 800 mg.; with epinephrine (1:200,000), 1000 mg. The recommended dosage is based on requirements for the average adult and should be reduced for elderly or debilitated patients and children.

The recommended doses given below serve only as a guide to the amount of anesthetic required for most routine procedures.

1. INFILTRATION AND NERVE BLOCK (NESACAINE)

Type of Block	Volume	Concentration
Occipital	3-5 ml.	1%-2%
Mandibular	2-3 ml.	2%
Maxillary	2-3 ml.	2%
Infra-orbital	0.5-1 ml.	2%
Cervical	3-4 ml. (for each segment)	1%-2%
Brachial plexus	30-40 ml.	2%
Ulnar nerve	3-5 ml.	2%
Paravertebral	3-5 ml.	2%
Intercostal	3 ml.	1%-2%
Sciatic nerve	10-15 ml.	2%
Stellate ganglion	5-10 ml.	1%-2%
Lumbar sympathetic (1 needle technic)	15-20 ml.	1%-2%
Interdigital	3-4 ml. (without epinephrine)	1%-2%

Fractional doses, up to 300 to 600 mg., may be given at 50 minute intervals.

2. CAUDAL AND EPIDURAL BLOCK (NESACAINE-CE)

For *caudal anesthesia* the initial dose is 15 to 25 ml. of a 2% or 3% solution. Repeated doses may be given at 40 to 60 minute intervals.

For *epidural anesthesia* in the lumbar and sacral regions 2.0 to 2.5 ml. per segment of a 2% or 3% solution can be used. The usual total volume of Nesacaine-CE is from 15 to 25 ml. Repeated doses 2 to 6 ml. less than the original dose may be given at 40 to 50 minute intervals.

HOW SUPPLIED

Nesacaine is supplied as follows:

1% solution (10 mg/ml.) in 30 ml. multiple-dose vials, 12 vials per carton.

2% solution (20 mg/ml.) in 30 ml. multiple-dose vials, 12 vials per carton.

Nesacaine-CE is supplied as follows:

2% solution (20 mg/ml.) in 30 ml. single-dose vials, 12 vials per carton.

3% solution (30 mg/ml.) in 30 ml. single-dose vials, 12 vials per carton.

A local anesthetic should meet your needs...

Rapid Onset of Action. Saves doctor, nurse and patient time.

Effective Anesthesia. Nesacaine (Chloroprocaine Hydrochloride) offers 80% to 90% pain-free procedures at recommended doses.

Exceptional Safety. Less potential for postoperative complications. Nesacaine is rapidly hydrolized in plasma, whereas lidocaine and other amide-type local anesthetics are metabolized in the liver. With Nesacaine, therefore, there is minimal potential risk of systemic toxicity, accumulation of metabolites, stimulation of CNS or cardiovascular effects.

Excellent Penetration. Chloroprocaine's lipid solubility and ionization characteristics impart it with excellent penetration.

Minimal Irritation at Injection Site. Few patient complaints about procedural pain, little soreness and inflammation after procedure.

Rapid and Complete Wear-Off. No residual numbness, patient back to normal faster.

See opposite page for brief prescribing information.

IS A MEMBER IN GOOD STANDING

TO

International Anesthesia Research Society

EXECUTIVE SECRETARY

The International Anesthesia Research Society is a non-profit, scientific and educational corporation of the State of Ohio founded in 1922 "To Foster Progress and Research in Anesthesia." To this end it performs two functions: (1) It publishes a bi-monthly journal, "ANESTHESIA and ANALGESIA . . . Current Researches"; and (2) It sponsors an annual scientific "Congress" meeting which meets the criteria for Category 1 credit toward the AMA Physicians Recognition Award.

Membership in the IARS is voluntary; it is also separate and distinct from membership in any other local, state or national anesthesia organization.

MEMBERSHIP - ASSOCIATE MEMBERSHIP

MEMBERSHIP is open to individuals with doctorate degrees, licensed to practice in the medical, dental, osteopathic or veterinary medicine professions (i.e., MD, MB, DDS, DMD, DO, DMV); and to individuals with doctorate degrees (Ph.D.) in any scientific discipline, engaged in academic, private or commercial research.

ASSOCIATE MEMBERSHIP is open to individuals in the allied health professions, duly certified by their professional accrediting organization as nurse anesthetists (CRNA), physician assistants-anesthesia (PA-Anesth.), inhalation therapists (ARIT) or respiratory technicians (CRTT).

DUES are $25 per year for Members and Associate Members, and include a subscription to ANESTHESIA and ANALGESIA . . . Current Researches. Members are also entitled to reduced registration fee at IARS annual scientific meetings.

EDUCATIONAL MEMBERSHIP

EDUCATIONAL MEMBERSHIP is open to interns and residents in anesthesiology training programs; registered nurses enrolled in nurse anesthesia schools; students in inhalation or respiratory therapy training programs, or in physician assistant anesthesia programs.

The official Educational Membership application blank must be completed by the individual applicant, and signed by his or her training program director.

Dues are $25 for a single, two-year period during the member's anesthesia training period, and include a two-year subscription to ANESTHESIA and ANALGESIA . . . Current Researches. Educational Members are entitled to complimentary registration at IARS annual scientific meetings.

Application forms are available from Cleveland business office. Program Directors are invited to obtain a supply of Educational Membership applications for their students in training.

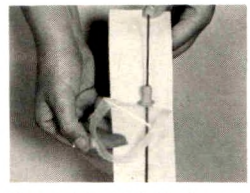
Update an old friend.

With the new universal SLICK™ STYLETTE endotracheal tube guide.

The old familiar way of intubating is not necessarily the better way. The better way to prepare for the unexpected during the critical period of induction and to increase the rate of successful first attempt intubations is to routinely use SLICK STYLETTE. Its non-friction coating eliminates the need for additional lubrication, and the stop-lock controls the extent of its advancement into the endotracheal tube. These features, plus its versatility and malleability reduce the difficulties encountered with normal anatomical variations, such as a small mouth, protruding teeth or bull neck as well as pathological obstacles.

Why not update your procedure with the addition of the SLICK STYLETTE as a standard part of your intubation pack—so it's always there when you need it?



Disposable Slick Stylette is packaged in a sterile Tyvek Mylar peel-away package. Fits all sizes and types of tubes from 3.5mm pediatric to 10.5mm adult.

Reg. U.S. Pat. Off.

When to use the word Phär′mà·sēal.

For components, features, "performance" in single-use anesthesia trays, just say the word.

The trays you've counted on from the start now offer you even more to go on.

Back in 1963 we introduced the world's first single-use, regional anesthesia trays.

Today, with a record of safe performance difficult to equal, we offer you an even wider selection of components and features—just as difficult to match—in spinal, caudal and epidural trays.

All with our all-new spinal needle. The needle that's been called the cleanest spinal needle yet. The one with a cannula with almost uncanny smoothness, a cartridge pack with an exceptional point protector, a matched-ground point, metal hub and more.

Trays that offer you a new fenestrated drape with its own adhesive tabs.

A large, moisture-resistant hospital wrap with a new "wrinkle for better procedure.

Plus, a specially designed introducer needle, a clear 5-cc. Stylex® syringe, a unique aseptic transfer carton...and a variety of other first-quality components and drugs.

But see for yourself what we're talking about. See the trays with performance you can count on. For samples, just call or write.

You know the word to use.

Aramine® (Metaraminol Bitartrate) MSD

a vasopressor with positive inotropic effect

Indications: Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
Effective: ARAMINE is indicated for prevention and treatment of the acute hypotensive state occurring with spinal anesthesia. Adjunctive treatment of hypotension due to hemorrhage; reactions to medications; surgical complications; and shock associated with brain damage due to trauma or tumor.
"Probably" effective: It may also be useful as an adjunct in the treatment of hypotension due to cardiogenic shock or septicemia.
Final classification of the less-than-effective indications requires further investigation.

Contraindications: Use should be avoided with cyclopropane or halothane anesthesia, unless clinical circumstances demand such use.

Precautions: Use with caution to avoid excessive blood pressure response. Rapidly induced hypertensive responses have been reported to cause acute pulmonary edema, arrhythmias, and cardiac arrest. Use with caution in digitalized patients, since the combination of digitalis and sympathomimetic amines is capable of causing ectopic arrhythmic activity. Treat cirrhotic patients cautiously; if diuresis ensues, restore electrolytes. Fatal ventricular arrhythmia has been reported in one patient with Laennec's cirrhosis. In several instances, ventricular extrasystoles that appeared during infusion have subsided promptly on reduction of infusion rate. Since metaraminol has prolonged duration of action, a cumulative effect is possible, leading to prolonged elevation of blood pressure even with discontinuation of therapy. Monoamine oxidase inhibitors have been reported to potentiate action of sympathomimetic amines.
When vasopressor amines are used for long periods, resulting vasoconstriction may prevent adequate expansion of circulating volume and may cause perpetuation of the shock state. Plas volume may be reduced in all types of shock, and measurement central venous pressure is the most useful means of assessing t adequacy of the circulating blood volume; blood or plasma volur expanders should be employed for hypotension or shock due main to decreased circulating volume. Because of its vasoconstricto effect, metaraminol should be used with caution in heart or thyro disease, hypertension, or diabetes. Sympathomimetic amines m provoke relapse in patients with history of malaria.

Adverse Reactions: Sinus or ventricular tachycardia, or other rhythmias, especially in patients with myocardial infarct Abscess formation, tissue necrosis, or sloughing may rarely fo use. In choosing the site of injection, it is important to avoid th areas recognized as *not* suitable for use of any pressor agent, ar discontinue infusion immediately if infiltration or thrombosis curs. The larger veins of the antecubital fossa or the thigh are ferred to veins in the dorsum of the hand or ankle veins, particu in patients with peripheral vascular disease, diabetes mellit Buerger's disease, or conditions with coexistent hypercoagulabil

Note: Response to vasopressors may be poor in patients with co istent shock and acidosis. Established methods of shock man ment, such as blood or fluid replacement when indicated, and measures directed to the specific cause of the shock should be used. *Only Sodium Chloride Injection or 5 per Dextrose Injection should be used as a diluent.*

How Supplied: Injection, in 1-ml ampuls and 10-ml vials, cont ing per ml: metaraminol bitartrate equivalent to 10.0 metaraminol; inactive ingredients: sodium chloride, 4.4 mg for injection, q.s. ad 1.0 ml; and 0.15% methylparaben, 0.02 pylparaben, and 0.2% sodium bisulfite added as preservatives.
